V. L. MINEAR,[8] ASSOC. M. AM. SOC. C. E. (by letter).—A notable contribution to the knowledge of the theory and practice of cement injection is contained in this paper. It has been read and re-read by those entrusted with pressure grouting at Boulder Dam and appurtenant works. The methods developed for this great dam correspond to a remarkable degree with the methods and practices adopted in India by the author, notwithstanding the vastly different conditions under which the two jobs were carried forward.

The author placed 64 000 bbl of cement at a maximum pressure of 80 lb per sq in. in inferior masonry structures in India, using native labor. At Boulder Dam, more than 100 000 bbl of cement have been placed at maximum pressures of 1 000 lb per sq in., and with high-grade American labor. Notwithstanding the wide variation in conditions and objectives sought, it is thought that the one job affords an independent check upon the methods of injection used and the conclusions reached upon the other. Recounting all the similarities would become tiresome, but the writer wishes to re-emphasize some of Mr. Cole's more important conclusions regarding methods, that experience at Boulder Dam tends to verify:

(1) The degree of hardness and strength (of injected grout) is proportional in general to the pressure of placement with accompanying extrusion of water.

---

[8] Care U. S. Bureau of Reclamation, Denver, Colo.

(2) For cement injection into tight ground some better efficiency is attained by the use of extra finely ground and resifted cement. Many thousands of sacks of cement, 98% of which passed the 200-mesh screen, were injected at Boulder Dam, and it was definitely established that, other conditions being the same, a tight hole will admit as much as 10% more rescreened, than ordinary, cement in a given interval of time. However, rescreening costs are relatively high, and it is thought that the apparent advantage can be more than overcome by slightly increasing the pressure applied to ordinary cement (conditions permitting).

(3) Sand is not effective for general use. It is kept in suspension within the pipe with the greatest of difficulty. It cannot be carried very far in the rock passages due to their variable cross-section and the consequent variable velocity with which the grout flows through them. In many cases sand undoubtedly clogs not only the pipe and fittings, but also the hole.

(4) Isolated grouting effects no benefits but shows a tendency to hinder the flow of grout from subsequent holes. In effect, it places obstructions in the grout passages deliberately, making it difficult or impossible to vent the air, water, and thin grout that precedes the thicker grout stream. Theory indicates, and practice seems to confirm, that a channel that has been tapped should be filled in one operation, and holes that have given a return flow should be connected in the order in which they showed grout.

(5) There is always the danger of choking the hole and sacrificing the penetration of the finer connecting passages by too much cement, too much pressure, or too much speed of delivery. The water-cement ratio, pump speed, and induced pressure must be co-ordinated in conformity with the type of grouting being done and the requirements of the individual hole. Each hole is "a law unto itself." It seems probable that more holes have been lost through inexperienced men attempting to use a thicker grout than the hole will accommodate, than from any other single cause. A sudden increase in either the speed of delivery or the pumping pressure, frequently results in the loss of a hole, especially if a water-hammer effect is present. Changes should be made gradually.

(6) Subaqueous or other inaccessible leaks can often be sealed effectively by a manipulation of the water-cement ratio and the pressure applied. The method is superior to the introduction of a sanded mixture in most cases.

(7) All joints should be left open for the free escape of water, and caulking should be resorted to only when the grout that escapes is of the same approximate density as the mixture that is being injected.

(8) The routine of grout injection developed at Boulder Dam is almost identical with that described by Mr. Cole, except for the water-cement ratio and the pressures. At Boulder Dam, the engineers strove from start to finish of a hole to maintain the maximum permissible pumping pressure, but never more than this pressure. Speed was controlled by adjustment of the mixture.

(9) There is need of a safe and reliable means of sealing the voids in otherwise completed masonry structures, in order to make them virtually

impermeable by water. This is especially true of structures founded upon pervious rock. From the study of numerous cores recovered, the writer has reached the conclusion that the benefits to be derived from the injection of Portland cement grout into rock are limited to the filling of cavities and fissures within the rock, and that results are negligible so far as securing a cut-off in water-bearing rock itself is concerned.

JAMES B. HAYS,[9] M. AM. SOC. C. E. (by letter).—This is an unusually clear and detailed exposition of the general subject of grouting. The author has given, or outlined, a routine to follow in grouting that will apply to most conditions, particularly in foundation work. Variations in the behavior of different holes develop almost immediately since no two holes are alike. The operator or engineer must "feel" his way, depending on the pressure developed and the rate of flow of the grout which can be varied by changing the mixture.

Equipment for grouting has been developed gradually from makeshift apparatus into machinery specially suited for the work. Pumping grout has generally replaced the practice of forcing it in by compressed air. Engineers and operators who have worked with both systems prefer the continuous flow and positive drive as given by the pump, rather than the intermittent method with the possible danger of getting air into the hole. Mr. Cole has given an excellent description of the equipment, but the writer would like to know more about the pistons and cylinder liners.

Although regular cements are the most generally used, the writer, after handling approximately 40 000 bags of cement screened through a No. 200 screen, is inclined to think that it has some advantages, one of which is that the cement remains in suspension for a longer time and does not clog fittings as quickly. Certainly, small cracks and seams are more likely to be grouted with the coarse particles removed than if they are left in or, to carry it a step further, if sand is added. The writer is strongly opposed to the use of sand in grouting except in extreme cases and will admit that the leakage into the reservoirs through the up-stream faces could probably be stopped by no other method. Sand has a tendency to settle particularly when used with thin mixtures. Very little cement, if any, remains with it to form a tight filler or to bond the particles together. Instead, it will be found in a porous condition. Many grouting jobs have been only partly done by the inclusion of sand. When the top of a concrete-lined tunnel is filled, with sand in the grout, it will carry a load but cannot always be considered to be water-tight. The writer would suggest that before grout is used with sand, test cylinders be made using the proposed mix. Naturally, very fine sands will remain in suspension longer than coarse grades.

In the case cited by the author the leaks were low down, and the sand could be depended upon to settle to the low point. If leaks are higher, or if water is washing grout away as fast as it is pumped in, a floating substance such as sawdust often does the work of stopping the leak. Rolled oats, bran (mill feed), and other substances can be used until the leak is stopped, after which straight cement is used to the point of refusal.

---

[9] Constr. Engr., Chickamauga Dam, T. V. A., Chattanooga, Tenn.

When leaks are on the surface and are known in advance, the writer has found it convenient to patch a considerable part of the leak before grouting is begun, leaving small outlets at frequent intervals for the escape of water, air, and thin grout. The final sealing of the patch can then be completed in short order. Various materials are used in patching, such as wedges, oakum, strips of cloth, lead wool, and quick-setting cements. The writer has had better results with a quick-setting cement mixed so as to give a flash set, and applied to the leak in a dry form. The leak furnishes sufficient moisture to cause the mix to set. Where cracks are wide, they are generally caulked with oakum, lead wool, or other material first, after which a quick-setting cement mixture is applied as soon as the leaks appear.

It is convenient, and a widespread practice, to designate the grout mixtures by the water-cement ratio (by volume). A water meter reading directly in cubic feet is useful for this purpose. Cement is generally handled and measured in bags. Grout can be mixed, using any number of full bags of cement, and the water can be metered to any fraction of a cubic foot.

Ordinarily, the writer favors isolated grouting and would prefer to drill a hole and grout it before the other holes in the vicinity were drilled. Usually, the specifications require that, when grout leaks through adjacent open holes, they be capped and also that the capped hole be grouted as soon as possible. The writer has seen grout leak from several holes, and it was absolutely impossible to start grout into any of the leaking holes before the cement had begun to set. As a consequence, the entire area was only partly grouted. Filling a group of holes simultaneously is not satisfactory since each hole takes grout at different pressures and each may require a different mixture. However, the writer wonders what the difference is between, say, four 25-ft holes and one 100-ft hole. Each of the 25-ft holes would take grout differently and, certainly, each 25-ft section of the 100-ft hole has different characteristics. This is an argument for "stage" grouting as well as for drilling single holes and grouting them before other near-by holes are drilled. Then, again, there are exceptions to this rule.

If the nature of the rock is such that there are seams carrying a material that could be washed out and replaced with grout, it would probably be advisable to drill about three holes and wash between them. The efficiency of the washing is generally doubtful. The writer has spent days trying to wash clay from a seam in the foundation of the Calderwood Dam, in Tennessee. After a few hours the water would run clear. If tested again the following day the seam would be found as dirty as ever. After several days of this experience, the holes were grouted regardless. The theory was that the clay was tight and solid in the joint and would resist leakage from the reservoir. This dam was completed in 1930 and five years later there was no increase in the originally very small leakage.

The writer has grouted more than one hole at the same time where underground connections required that it be done, by feeding small batches to each hole in turn, rotating from hole to hole until all were grouted to refusal. This method lacks the advantages of continuous flow that is one of the features of pumping grout. It can be compared with the intermittent batch system that has largely been abandoned. Considerable pains must be taken to obtain the proper mixture in each hole where variations in the mix are required.

The description of the author's experience in using the "lubrication" method and the chemical grouting is appreciated. It would seem that every effort was made to get the best possible results from these methods; hence the conclusions derived have the highest value.

D. W. Cole,[10] M. Am. Soc. C. E. (by letter).—In the several discussions of this paper there has appeared the recognition that the very special conditions and remedies exhibited in the case of the Indian dams have a rather general application to the entire field of "pressure grouting"; yet the discussions, in the main, relate to experiences in sealing by cementation the foundation rock under dams.

The experience most nearly like those treated of in the paper appears in the discussion by Mr. Reed, wherein he describes the attempt to stabilize the Ringedalsvand Dam. It is interesting to note that although some benefits were accomplished by the cementation process, the results were not entirely satisfactory and the final remedy was found in the construction of an auxiliary curtain dam strutted against the water face of the leaky dam. This must have involved unwatering the reservoir, or the construction of expensive coffer-dams, either of which expedients was to be avoided if at all possible in the Indian situation.

The discussion by Mr. Fergusson is particularly apposite to the local problem of masonry construction with surkhi mortar. Doubtless, Mr. Fergusson has become aware of the growing use of Portland cement in substitution for hydraulic lime in his territory. It has recently come to the writer's attention that the cement manufacturing industry of India is expanding, with much activity in the promotion of sales. In 1931 the writer visited the just completed largest masonry dam in Hyderabad, Deccan, which was constructed of ashler-faced rubble in surkhi mortar, and was there informed by the Chief Engineer that he proposed no more important dams of that character, but intended to use Portland cement in the next one. In this connection it may be suggested to Mr. Fergusson that useful possibilities may lie in the conversion of his kankar, or other local limestone, into natural cement rather than quick-lime, and then blending this cheaper form of cement with standard Portland cement for an economic mortar in dam construction. A lean mixture of this should prove better and but little more expensive than the surkhi.

Mr. Wright emphasizes the fundamental requirements for a safe and durable dam, a thesis which is affirmed by the experience described in the paper and which every generation of dam builders should take to heart.

The suggestion is pertinent that the "Christians" asphalt process might have been useful in staunching some of the worst runaway leaks to the lake as a preliminary to cementation. In retrospect, however, it would appear that the provision of all necessary equipment for this process in the distant and isolated locality would not have been justified for the limited requirement.

---

[10] Civ. Engr., Phœnix Eng. Corporation, New York, N. Y.

No dimension drawings are available, but the scale diagram in Fig. 1 gives all cross-sectional dimensions of Shirawta Dam as built. From this Mr. Wright will be able to analyze the stresses, using the tabulated weight of 146 lb per cu ft for masonry and such data for uplift, sliding factor, and cantilever integrity, as he will derive from the text of the paper.

The illuminating discussion by Mr. Comstock supplies a background of history, statistics, Oriental color, and technical wisdom against which the paper is most favorably displayed. Mr. Comstock's closing observation that: "A dam is made safe, or otherwise, on the job—not in the office", touches a responsive chord in the writer's constitution.

In the discussion by Mr. Minear it is gratifying to read that the Boulder Dam program of foundation grouting developed a system, independently, which is remarkably in accord with the routine in India, notwithstanding the dissimilarity of conditions and objectives. The check of one system against the other with harmonious results is indeed striking, tending to prove, for example, that both programs followed sound procedure in the situations as each was developed.

Mr. Hays raises a number of interesting points which it might be profitable to discuss if space permitted. Suffice it to say that the writer is in agreement as to the general superiority of pumps over the air gun for controlled grout delivery. Answering direct questions by Mr. Hays: The pistons of the air-driven pumps in the beginning were of cold-rolled shafting, 2 in. and 3 in. in diameter, with gland packing of a good grade of square braided hemp. Excessive wear of the piston (plunger) and the packing led to the substitution of nickel steel plungers, polished and packed in the same manner. These plungers were quite satisfactory and gave many weeks of wear, although much packing was consumed. Cylinder lining was unimportant since all wear was on the plungers with full bore packing. The distinctive feature of the pumps was the valve assembly consisting of ring-seated steel balls, as described under "Plan of Operation" in the paper.

The re-sifting of cement is an important consideration for work in tight ground, and in dams where limitation to low pressure is demanded. If again confronted with similar conditions the writer would plan to put the commercial cement through a 200-mesh, rotating or vibrating sieve which could easily be rigged in the cement shed. This fine cement would be used in borings testing less than 10 gpm water loss. By this means the input of cement would be practically of colloidal texture and would probably accomplish about all that would result from application of the "chemical treatment".

The writer agrees that sand should be used sparingly, with caution, and only in large cavities, or in runaway leaks which must be staunched as a preliminary to effective pressure grouting with thin mixtures. Sawdust, rice chaff, or other perishable materials were deemed inappropriate substitutes for sand in choking this type of leak in a structure where density was the prime essential. The writer agrees with Messrs. Hays and Minear that the best results can be secured by holding the pressure on the hole from start to finish, with the cement mixtures adjusted to give a maximum total input of solids before the hole chokes. It is not always feasible, however, and this is where experienced judgment, patience, and conscience have application.

In the writer's view a vast amount of "grouting" has been done in a perfunctory manner with ineffectual results, although reported as "holes grouted to refusal"; all for lack of intelligent and diligent supervision.

As to the multiple connection of holes for simultaneous grouting, it has been the writer's practice to require or permit this when pump delivery is demonstrably capable of holding the specified pressure on each individual hole of the series, usually not more than four holes at a time.

The discussion by Mr. Hays evidences appreciation of the requirements for effective sealing of difficult ground. There is a great variety of problems in the field, worthy of expert study.

An early example of foundation grouting is well recorded in much detail and with pertinent discussions in the paper by Harold A. Rands, M. Am. Soc. C. E., entitled: "Grouted Cut-Off for Estacada Dam".[11] A classic in tunnel grouting is the paper by James F. Sanborn and M. E. Zipser, Associate Members, Am. Soc. C. E., entitled "Grouting Operations, Catskill Water Supply".[12] Students of the general subject would do well to include these papers in their research.

LINE LOAD ACTION ON THIN CYLINDRICAL SHELLS

By Herman Schorer,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. I. K. Silverman, W. Flügge, Anton Tedesko, U. Finsterwalder, F. W. Seidensticker, and Herman Schorer.

Synopsis

The object of this paper is the derivation of influence numbers for the longitudinal edge deformations of a thin, cylindrical, shell sector, rigidly held between transverse stiffening members. This problem is of practical importance in the design of modern shell structures, such as large pipe lines, self-supporting flume structures, sector gates, and the barrel type of roof described in this paper. The monolithic action of longitudinal stiffening members, as well as the analysis of discontinuous surface loads, leads to the consideration of corrective line loads, which restore the continuity of the structure.

The proposed method is based on simplifying assumptions, and, therefore, the solution is an approximation with definite limitations. As an illustrative example the secondary stress conditions in a half-full pipe line are investigated.

Introduction

Thin shells or bent plates are three-dimensional structures, extensively used by Nature as protective housings, on account of their great resistance to impact forces. They require a minimum of construction material and are adaptable to a great variety of possible shapes. The shells may be of the open or closed type.

The excellent structural properties of closed shells are explained by the fact that external surface loads are largely transmitted by direct stresses, which act in two principal stress planes. Although concentrated loads also induce bending stresses, Geckeler[2] has shown in the analysis of spherical

[2] "Zur Theorie der Elastizität flacher rotations-symmetrischer Schalen," von J. W. Geckeler, *Ingenieur-Archiv*, Vol. 1, 1930, p. 255.

shells that a direct stress system prevails within a short distance from the load concentration. The bending zone appears distributed over an imaginary, circular plate, elastically supported by the adjacent parts of the shell. The free span of this plate is comparatively small and, therefore, the induced bending stresses are likewise small.

In case of open shells, the free rims or edges represent zones of structural weakness, because a direct stress system is possible in one direction only, namely, parallel to the free boundary. Edge loads, therefore, must be transmitted to the interior of the shell by partial plate action; that is, bending stresses in planes normal to the boundary line. For instance, a closed eggshell represents a rather stiff structure. However, if the shell is cut into two halves, it will be observed that small edge forces cause relatively large distortions of the thin walls.

As a rule, Nature protects the free edges of thin shells by thickening the weak zone, as in the case of walnut shells. The same principle is used in the glass and sheet-metal industry, where thin edges are strengthened by means of flange-shaped stiffening members. In order to be most effective such members should be placed in planes nearly normal to the surface of the shell. The advantages of true shell action will then be realized also in the case of open shells.

The practical design of shell structures in steel and reinforced concrete has opened a wide field of interesting applications in industry and architecture. A description of the more recent developments in shell-type reinforced concrete structures is given by Dischinger and Finsterwalder.[3] Most of the practical problems lead to a consideration of edge loads in connection with the design of adequate stiffening members. For this reason the analysis of shell stresses due to edge loads becomes of practical importance. The following study is limited to the stresses and deformations in a circular, cylindrical, shell sector, with a uniform wall thickness and subject to edge loads distributed along a generatrix.

Closed cylindrical shells or tubes, subject to continuous surface loads, require circumferential stiffening members at the open ends, or over the supports, as in the case of large pipe lines,[4] horizontal storage tanks, culverts, etc. The actual stress condition in such a shell is determined by the superposition of two fundamental stress systems: First, the so-called membrane stresses (which represent a statically determinate, direct stress system, being in equilibrium with the surface loads); and, second, the so-called rim stresses (which are statically indeterminate) caused by the restraining action of the circumferential stiffeners. In the case of thin shells the rim stresses are distributed only over a comparatively narrow ring zone.

The analysis of the membrane stresses in symmetrical shells of revolution, due to continuous, symmetrical, and asymmetrical surface loads, has been well established and is presented in detail by Dischinger.[5]

[5] "Handbuch für Eisenbeton," von H. J. Kraus und Franz Dischinger, Vol. 6, Fourth Edition, p. 269, Wilhelm Ernst & Sohn, Berlin, 1928.

A simplified method for the practical determination of rim stresses in symmetrical shells of revolution, subject to symmetrical rim loads, has been derived by Geckeler.[6] The rim load problem in circular, cylindrical shells, subject to asymmetrical loadings, has been fully treated by Miesel.[7]

Fig. 1 shows a cylindrical shell with a cross-section consisting of a thin, circular-ring sector, between two transverse end stiffeners, fixed in a plane normal to the axis of the shell. In the following derivations the term, "rim," always refers to the circumferential boundary of the shell and the term, "edge," refers to the longitudinal boundary, which coincides with a generatrix of the cylindrical surface.

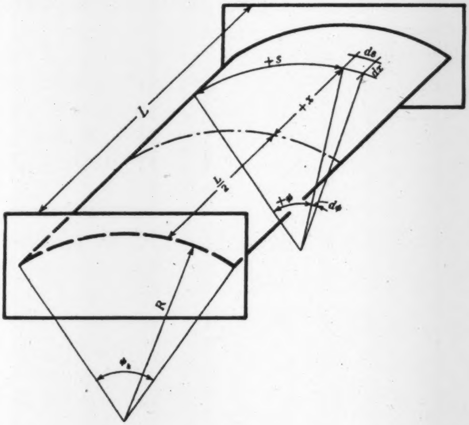

FIG. 1.

Line loads, or edge loads, are defined as loads acting on the two free edges of the shell. The present study is limited to continuous line loads only, such as those caused by the restraining action of a longitudinal edge-stiffening member. The shell stresses due to edge loads, then, represent a third stress system, designated as line load or edge stresses.

The edge load stresses in cylindrical shells, simply supported between stiff transverse members, have been investigated by Dr. Finsterwalder,[8] mainly for the purpose of analyzing a barrel, or vaulted, type of thin shell roof structure. Similar problems arise in the design of semi-circular, open flume structures, sector gates, decks of reinforced concrete dams, etc. The analysis of discontinuous surface loads, such as the partial fillings of a pipe line, partial submergence of submarines, lifting tanks, etc., also leads to the problem of line-load stresses.

Ulrich Finsterwalder, International Assoc. for Bridge and Structural Eng., Zurich, 1932; also, "Die querversteiften zylindrischen Schalengewölbe mit kreissegmentförmigen Querschnitt," von Ulrich Finsterwalder, *Ingenieur-Archiv*, Vol. 4, 1933, p. 43.

In contrast to the comparatively narrow zone of circumferential rim load stresses, the influence of edge loads may extend over the entire shell area, because such loads are largely transmitted to the stiff transverse members. At present, no exact solution of the line-load problem is available. The approximate method presented in this paper is based entirely on Dr. Finsterwalder's original investigation, which also introduces simplifying assumptions, justified by model tests and observation of full-sized structures.

The basic assumptions point out definite limitations, which the designer must keep in mind when considering structures in which plate action, rather than shell action, comes into play. For this reason the method is applicable mostly to the practical analysis of thin shells of considerable curvature and relatively large spans.

Notation.—The symbols introduced in this paper are defined where they first appear; and for the convenience of discussers, the complete notation is given in Appendix I.

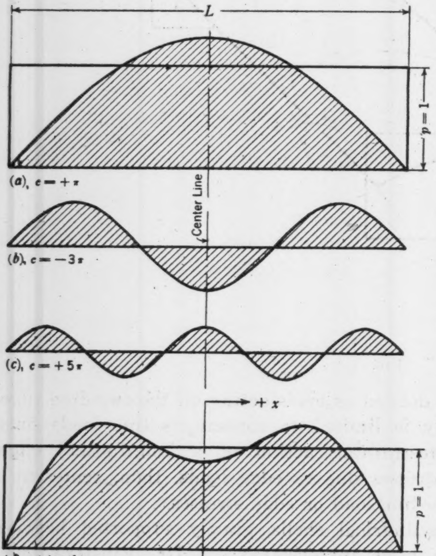

FIG. 2.—UNIFORM LOAD, $p = 1$, REPRESENTED BY FOURIER SERIES.

APPLICATION OF FOURIER SERIES

The introduction of trigonometric series in the theory of elasticity often yields decided analytical advantages because difficulties of integration are avoided and any desired degree of accuracy may be obtained by simply considering a sufficient number of terms. The solution of the flat slab problem by Lewe[9] and the derivation of the deflection curves of suspension bridges by Timoshenko,[10] are cited as well-known applications.

Consider a uniformly distributed unit load, p per unit length, acting on a simply supported beam of the span, L. This load distribution can be expressed by the sum of a trigonometric series. Assuming the origin of the co-ordinate system at the center of the span, then,

---

[9] "Pilzdecken," von Dr. Lewe, pub. by Wilhelm Ernst & Sohn, Berlin, 1926.

[10] "The Stiffness of Suspension Bridges," by S. Timoshenko, *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 377.

$$p\,(x) = \frac{4}{\pi}\left(\cos\frac{\pi x}{L} - \frac{1}{3}\cos\frac{3\,\pi\,x}{L} + \frac{1}{5}\cos\frac{5\,\pi\,x}{L} - \dots\right) = (1) \quad \text{..(1)}$$

in which, $p(x)$ = the sum of a trigonometric series expressing intensity of load; x = a horizontal distance measured longitudinally, from the center of the span; and L = the span of a simply supported beam or cylindrical shell. The general term of this series (Equation (1)) is,

$$p_c = \frac{4}{c}\cos\frac{c\,x}{L} \quad \text{..........................(2)}$$

in which, c = substitutions corresponding to the first, second, third, etc., term of a Fourier series. Fig. 2(*a*) illustrates the first term of the series, Equation (1), which is obtained by substituting $c = +\,\pi$ in Equation (2); Fig. 2(*b*), with $c = -\,3\,\pi$, represents the second term; and Fig. 2(*c*), with $c = +\,5\,\pi$, indicates the third term. The sum of the first and second terms is shown in Fig. 2(*d*); the sum of the first, second, and third terms is represented in Fig. 2(*e*); and the sum of an infinite number of terms gives the straight line, $p = 1$.

For example, at the center of the span, $x = 0$, Equation (1) results in the well-known expression,

$$p\,(0) = \frac{4}{\pi}\left(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots\right) = \frac{4}{\pi} \times \frac{\pi}{4} = 1 \quad \text{......(3)}$$

It will be noted from Fig. 2 that the sum of the first few terms in Equation (1) represents a close approximation to the uniform load distribution.

The bending moment, M, of a simply supported beam, subject to uniform loading, is obtained by double integration of Equation (1), which gives,

$$M = \frac{4\,L^2}{\pi^3}\left(\cos\frac{\pi\,x}{L} - \frac{1}{3^3}\cos\frac{3\,\pi\,x}{L} + \frac{1}{5^3}\cos\frac{5\,\pi\,x}{L} - \dots\right) \quad \text{....(4)}$$

The general term of the series, Equation (4), is,

$$M_c = \frac{4}{c}\,\frac{L^2}{c^2}\cos\frac{c\,x}{L} \quad \text{.......................(5)}$$

At the center of the span, $x = 0$, the sum of the series, Equation (5), gives the well-known moment value for a uniformly distributed unit loading, $M_0 = \dfrac{L^2}{8}$.

Likewise, the deflection, η, of a uniformly loaded and simply supported beam, is obtained by double integration of Equation (4); thus,

$$\eta = \frac{4\,L^4}{\pi\;5}\left(\cos\frac{\pi x}{L} - \frac{1}{3^5}\cos\frac{3\,\pi\,x}{L} + \frac{1}{5^5}\cos\frac{5\,\pi\,x}{L} - \dots\right) \quad \text{.....(6)}$$

in which, η = the deflection of a simply supported, uniformly loaded beam, multiplied by $E\,I$. The general term of the series, Equation (6), is,

$$\eta_c = \frac{4}{c}\,\frac{L^4}{c^4}\cos\frac{c\,x}{L} \quad \text{.......................(7)}$$

At the center of the span, $x = 0$, the sum of the series, Equation (6), gives the value, $\eta_0 = \dfrac{5\ L^4}{384}$, which is identical with that derived by the customary methods.

DEFORMATIONS OF A SMALL ELEMENT

Fig. 3(a) shows a small element of a cylindrical shell, loaded by internal forces and couples as indicated, which are defined as stress components, measured per unit width of the element. The position of the element is defined by the distance, x, from the center of the span (see Fig. 1), and the angle, ϕ, measured from the left-hand edge of the shell when the element faces in the positive direction of x. The direct stress components, T_1, acting in a longitudinal direction, and, T_2, acting in a transverse direction, are positive when they produce tension. The bending stress components, M_1, acting in a longitudinal plane, and, M_2, acting in a transverse plane, are positive when they produce tension on the inner surface of the element. The direct shearing stress component, S, acting in pairs of equal magnitude on all four sides in the plane of the element, is considered positive when it produces tension in a diagonal direction of increasing values of x and ϕ. The radial shearing stress components, N_1 and N_2, are considered positive when they act in an outward direction on the sides facing the origin of x and ϕ, respectively. The torsional moments, or twisting moments, M_t, are practically equal on all four sides, and are defined as positive when they produce tension on the outside surface in a diagonal direction of increasing values of x and ϕ. For reasons stated subsequently the influence of the longitudinal

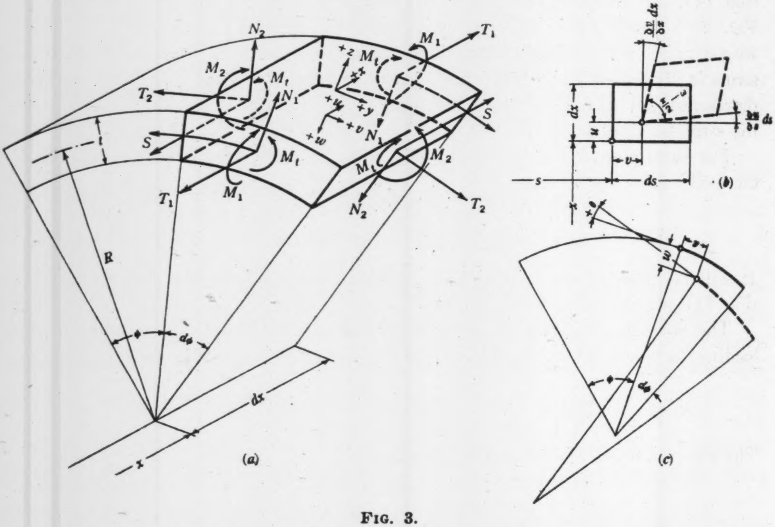

FIG. 3.

bending moment, M_1, the corresponding shearing stress component, N_1, and the influence of the torsional moments, M_t, will be neglected in the edge-load analysis.

The deflections of the small element are indicated in Figs. 3(*a*), 3(*b*), and 3(*c*). The longitudinal deflection, u, and the tangential deflection, v, are positive when the element moves in the positive direction of x and ϕ, respectively. The radial deflection, w, is positive when the element moves inward. The detrusion, ω, caused by the shearing stress component, S, is positive when S is positive. The angular deflection, θ, of the transverse tangent, is positive when the tangent is rotated in a clockwise direction.

Fig. 3 indicates the positive direction of all stress components and deflections. Love[11] has derived the following fundamental relations between the deformations, deflections, and stress components, applying to the small element of the length, dx; the width, $ds = R\, d\phi$; a constant thickness, t; and, a constant radius, R. Thus, the unit longitudinal elongation is expressed by:

$$e_1 = \frac{\partial u}{\partial x} = \frac{1}{E\, t} (T_1 - m\; T_2) \;\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

the unit transverse elongation by,

$$e_2 = \frac{1}{R} \left(\frac{\partial v}{\partial \phi} - \; w \right) = \frac{1}{E\, t} (T_2 - m\; T_1) \;\ldots\ldots\ldots\ldots (9)$$

the detrusion by,

$$\omega = \frac{\partial v}{\partial x} + \frac{\partial u}{R\, \partial \phi} = \frac{2\, S}{E\, t} (1 + m) \;\ldots\ldots\ldots\ldots\ldots (10)$$

the angular deflection of the transverse tangent by,

$$E\, t\, \theta = \frac{1}{R} \left(\frac{\partial w}{\partial \phi} + \; v \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

the change of transverse curvature by,

$$\kappa_2 = \frac{1}{R^2} \left(\frac{\partial v}{\partial \phi} + \frac{\partial^2 w}{\partial \phi^2} \right) = \frac{1}{R^2} \left(w + \frac{\partial^2 w}{\partial \phi^2} \right) = - \frac{12\, (1 - m^2)\, M_2}{E\, t^3} \ldots (12)$$

and the change of longitudinal curvature by,

$$\kappa_1 = \frac{\partial^2 w}{\partial x^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which, e = unit elongation: e_1, longitudinal, and e_2, transverse; u, v, and w are, respectively, the longitudinal, tangential, and radial deflections of a shell element; E = modulus of elasticity; t = thickness of shell; T = direct stress components on a shell element: T_1, in a longitudinal direction, and T_2, in a tangential direction; m = Poisson's ratio; ω = angular detrusion of a shell element, caused by the shearing forces, S; R = radius of curvature of a cylinder element; ϕ = angular distance of a shell element from the left-hand edge; and $\kappa =$ change of curvature of a shell element: κ_1, longitudinal, and κ_2, transverse.

---

[11] "Theory of Elasticity," by A. E. H. Love, Third Edition, Cambridge Univ. Press (1920), p. 546.

THE EDGE LOAD PROBLEM

Assume a thin cylindrical shell sector (such as that shown in Fig. 1)—of constant thickness, t; constant radius, R; a central angle, ϕ_k; and a span, L—between the two transverse end stiffeners. Assume, further, that no external loads are acting on the shell surface. Then consider a system of edge loads, such as thrusts, moments, shears, etc., continuously distributed along one or both of the free longitudinal boundaries, and resisted by the transverse stiffening members. Due to these edge loads the shell will be distorted by internal forces and couples (see Fig. 3), which transmit the loads to the end walls.

If the shell is thin, not extremely short, and has a fairly large central angle, experience and analysis both indicate that the internal work of the longitudinal bending moment, M_1, the corresponding shear, N_1, and the twisting moments, M_t, is rather small compared to the work done by the direct stress components, T_1, T_2, S, and the transverse bending moment, M_2, with the corresponding radial shearing stress component, N_2. Under these limiting conditions it will be permissible, for practical purposes, to neglect the influence of M_1, N_1, and M_t in considering the stresses and deformations of the shell due to edge loads. However, this statement does not apply to the ring zone adjacent to the end stiffeners, which is always subject to a supplementary stress system, defined by the rim stress zone, where M_1 and N_1 become relatively large, and M_2 and N_2 assume negligible values.

Based on the simplifying assumptions, $M_1 = N_1 = M_t = 0$, the five remaining stress components, M_2, N_2, T_2, T_1, and S, can then be derived from four equilibrium equations and one compatibility equation, as shown by Finsterwalder.[8] The edge load distribution is assumed to be symmetrical about the middle transverse plane, expressed by a cosine function, which can be considered as the general term of a trigonometric series. As suggested by Finsterwalder, the stress components are expressed conveniently by a stress function, $f(\phi)$, similar to Airy's presentation of the stress condition in a plane plate.

The stress function is introduced by the following definition of the bending stress component, M_2,

$$M_2 = -\cos\frac{c\,x}{L}\,f(\phi) \quad \text{.....................(14)}$$

Fig. 3(a) gives the following equilibrium conditions on a small element:

Rotation in the transverse plane,

$$N_2 = \frac{\partial M_2}{R\,\partial\phi} = -\frac{1}{R}\,\frac{df}{d\phi}\cos\frac{c\,x}{L} \quad \text{...............(15)}$$

projection on the z-axis,

$$T_2 = -\frac{\partial N_2}{\partial\phi} = +\frac{1}{R}\,\frac{d^2f}{d\phi^2}\cos\frac{c\,x}{L} \quad \text{...............(16)}$$

projection on the y-axis, and by partial integration,

$$\frac{\partial S}{\partial x} = \frac{N_2}{R} - \frac{1}{R}\,\frac{\partial T_2}{\partial \phi} = -\frac{1}{R^2}\left(\frac{df}{d\phi} + \frac{d^3 f}{d\phi^3}\right)\cos\frac{c\,x}{L} \quad \ldots. \text{(17)}$$

or,

$$S = -\frac{L}{R^2\,c}\left(\frac{df}{d\phi} + \frac{d^3 f}{d\phi^3}\right)\sin\frac{c\,x}{L} \quad \ldots\ldots\ldots\ldots \text{(18)}$$

and projection on the x-axis, and by partial integration,

$$\frac{\partial T_1}{\partial x} = -\frac{1}{R}\,\frac{\partial S}{\partial \phi} = \frac{L}{R^3\,c}\left(\frac{d^2 f}{d\phi^2} + \frac{d^4 f}{d\phi^4}\right)\sin\frac{c\,x}{L} \ldots\ldots. \text{(19)}$$

or,

$$T_1 = -\frac{L^2}{R^3\,c^2}\left(\frac{d^2 f}{d\phi^2} + \frac{d^4 f}{d\phi^4}\right)\cos\frac{c\,x}{L} \quad \ldots\ldots\ldots\ldots \text{(20)}$$

The following definition is introduced,

$$a = \frac{c^2\,R^2}{L^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(21)}$$

Substituting T_2 and T_1 from Equations (16) and (20), in Equation (8), the longitudinal deflection, u, is obtained by partial integration,

$$E\,t\,u = -\frac{1}{a\sqrt{a}}\left(\frac{d^2 f}{d\phi^2}\,(1 + m\,a) + \frac{d^4 f}{d\phi^4}\right)\sin\frac{c\,x}{L} \ldots\ldots \text{(22)}$$

From Equation (10), by partial differentiation,

$$\frac{\partial^2 v}{\partial x^2} = \frac{2\,(1 + m)}{E\,t}\,\frac{\partial S}{\partial x} - \frac{\partial^2 u}{\partial s\,\partial x} \ldots\ldots\ldots\ldots\ldots \text{(23)}$$

By partial differentiation of Equation (8), with respect to s,

$$\frac{\partial^2 u}{\partial s\,\partial x} = \frac{1}{E\,t}\left(\frac{\partial T_1}{\partial s} - m\,\frac{\partial T_2}{\partial s}\right) \ldots\ldots\ldots\ldots\ldots \text{(24)}$$

Substituting Equation (24) in Equation (23),

$$\frac{\partial^2 v}{\partial x^2} = \frac{1}{E\,t}\left(2\,(1 + m)\,\frac{\partial S}{\partial x} - \frac{\partial\,T_1}{R\,\partial\,\phi} + m\,\frac{\partial\,T_2}{R\,\partial\,\phi}\right) \ldots\ldots \text{(25)}$$

From Equations (16), (17), and (20), the expressions for the stress components are substituted in Equation (25), then, by partial integration,

$$E\,t\,v = \frac{1}{a}\left[\,2\,(1 + m)\left(\frac{df}{d\phi} + \frac{d^3 f}{d\phi^3}\right) - \frac{1}{a}\left(\frac{d^3 f}{d\phi^3} + \frac{d^5 f}{d\phi^5}\right)\right.$$

$$\left. - m\,\frac{d^3 f}{d\phi^3}\right]\cos\frac{c\,x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots \text{(26)}$$

From Equation (9), with T_2 from Equation (16), T_1 from Equation (20), and $\frac{\partial v}{\partial \phi}$ from Equation (26),

$$E\,t\,w = \left[\frac{d^2 f}{d\phi^2} \left(\frac{m}{a} - 1 \right) + \frac{2}{a} \left(\frac{d^2 f}{d\phi^2} + \frac{d^4 f}{d\phi^4} \right) \right.$$
$$\left. - \frac{1}{a^2} \left(\frac{d^4 f}{d\phi^4} + \frac{d^6 f}{d\phi^6} \right) \right] \cos \frac{c\,x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

From Equation (11), with reference to Equations (26) and (27),

$$E\,t\,R\,\theta = \left[- \frac{d^3 f}{d\phi^3} + \frac{2}{a} \left(\frac{df}{d\phi} + 2\,\frac{d^3 f}{d\phi^3} + \frac{d^5 f}{d\phi^5} \right) \right.$$
$$\left. - \frac{1}{a^2} \left(\frac{d^3 f}{d\phi^3} + 2\,\frac{d^5 f}{d\phi^5} + \frac{d^7 f}{d\phi^7} \right) + 2\,\frac{m}{a} \left(\frac{df}{d\phi} + \frac{d^3 f}{d\phi^3} \right) \right] \cos \frac{c\,x}{L} \quad \ldots. (28)$$

The constants of integration are zero, provided the following conditions are fulfilled: First, the load distribution is symmetrical about the middle transverse plane, $x = 0$; second, the shell can deform freely at the end stiffeners in a longitudial and also in a radial direction. Since the present analysis is limited to edge loads expressed by a cosine function the first condition is met. The transverse stiffening members, as a rule, are relatively flexible in a longitudinal plane, so that free movement in this direction can be assumed for practical purposes. However, the movement in a radial direction is greatly resisted by the stiffness of the transverse members, requiring the consideration of rim stresses, which can always be treated as a separate stress system. For the present purpose, therefore, the loads can be assumed as transmitted to the end members by means of tangential shearing stresses only, in accordance with the membrane theory.

The compatibility equation is obtained by substituting M_s from Equation (14), and w from Equation (27), in the expression for the transverse curvature, Equation (12), which gives the differential equation of the stress function,

$$\frac{d^8 f}{d\phi^8} + 2\,(1 - a)\,\frac{d^6 f}{d\phi^6} + [1 - (4 + m)\,a + a^2]\,\frac{d^4 f}{d\phi^4}$$
$$+ [-\,(2 + m)\,a + a^2]\,\frac{d^2 f}{d\phi^2} + 4\,a^2\,b^2\,(1 - m^2)\,f = 0 \quad \ldots\ldots (29)$$

The constant, b, is defined as follows,

$$b = \sqrt{3}\;\frac{R}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

The general solution of Equation (29) gives the following expression for the stress function,

$$f(\phi) = e^{(J1)\phi}\,(A \sin K_1\,\phi + B \cos K_1\,\phi)$$
$$+ e^{(J1)'\phi}\,(C \sin K'_1\,\phi + D \cos K'_1\,\phi) \quad \ldots\ldots\ldots\ldots\ldots (31)$$

Equation (31) indicates that the stress function consists of the sum of two damped waves, in which, $(J1)$ and $(J1)'$, represent the damping factors, and K_1 and K'_1 determine the wave length. These four values are constants, entirely governed by the dimensions of the shell (as exponents, $(J1)$ and $(J1)'$ correspond with J_1 and J'_1 in the text). The expressions, A, B, C, and D, are also constants, determined by the boundary conditions of the longitudinal edge, by which four stress components or deflections are assigned specified values, given by the edge load conditions or edge deformations.

The shell constants, J and K, are found by substituting the derivatives of Equation (31) in the differential formula, Equation (29). The first term of the stress function leads to the following relation:

$$e^{(J1)\phi} \sin K_1 \phi \left\{ J_8 + 2\,(1 - a)\,J_6 + [1 - (4 + m)\,a + a^2]\,J_4 + a\,(-2 - m + a)\,J_2 + 4\,a^2\,b^2\,(1 - m^2) \right\} + e^{(J1)\phi} \cos K_1 \phi \left\{ K_8 + 2\,(1 - a)\,K_6 + [1 - (4 + m)\,a + a^2]\,K_4 + a\,(-2 - m + a)\,K_2 \right\} = 0 \quad\ldots\ldots\ldots\ldots(32)$$

The expressions, J_2, J_4, etc., and K_2, K_4, etc., are defined by the general progressive functions,

$$J_n = J_1\,J_{n-1} - K_1\,K_{n-1} \quad\ldots\ldots\ldots\ldots\ldots\ldots(33)$$

and,

$$K_n = J_1\,K_{n-1} + K_1\,J_{n-1} \quad\ldots\ldots\ldots\ldots\ldots\ldots(34)$$

Equation (32) can be satisfied when the functions, F and G, defined by Equations (35) and (36), are zero,

$$F = J_8 + 2\,(1 - a)\,J_6 + [1 - (4 + m)\,a + a^2]\,J_4 + a\,(-2 - m + a)\,J_2 + 4\,a^2\,b^2\,(1 - m^2) = 0 \quad\ldots\ldots(35)$$

and,

$$G = K_8 + 2\,(1 - a)\,K_6 + [1 - (4 + m)\,a + a^2]\,K_4 + a\,(-2 - m + a)\,K_2 = 0 \quad\ldots\ldots\ldots\ldots(36)$$

The derivatives of the second term of Equation (31), substituted in Equation (29), give an identical pair of equations for F and G.

The progressive functions, Equations (25) and (26), furnish the following expressions,

$$J_2 = J^2_1 - K^2_1 \quad\ldots\ldots\ldots\ldots\ldots\ldots(37)$$

$$J_4 = J^2_2 - K^2_2 \quad\ldots\ldots\ldots\ldots\ldots\ldots(38)$$

$$J_6 = J^3_2 - 3\,J_2\,K^2_2 \quad\ldots\ldots\ldots\ldots\ldots\ldots(39)$$

$$J_8 = J^4_2 - 6\,J^2_2\,K^2_2 + K^4_2 \quad\ldots\ldots\ldots\ldots\ldots\ldots(40)$$

$$K_2 = 2\,J_1\,K_1 \quad\ldots\ldots\ldots\ldots\ldots\ldots(41)$$

$$K_4 = 2\,J_2\,K_2 \quad\ldots\ldots\ldots\ldots\ldots\ldots(42)$$

$$K_6 = 3\, J^2_2\, K_2 - K^3_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

and,

$$K_8 = 4\, J^3_2\, K_2 - 4\, J_2\, K^3_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

By substituting Equations (38), (39), and (40), in Equation (35), and, likewise, by substituting Equations (42), (43), and (44), in Equation (36), it will be noted that two equations are obtained for the determination of the unknowns, J_2 and K_2. These simultaneous equations cannot be solved in explicit form. However, J_2 and K_2 may be determined by successive approximations and, for instance, by Newton's method.

For this purpose it will be advantageous to consider the typical properties of a damped wave system, such as that represented by the stress function, Equation (31). In case the damping factors, J_1 and J'_1 are larger than unity, each successive derivative will be larger than the preceding one. Since the present analysis is limited to thin shells, the damping factors will be comparatively large, so that, as a first approximation, the derivatives of a lower order may be neglected compared to the derivative of the highest order. This method has been used by Geckeler,[6] in arriving at a practical solution for the rim stresses in symmetrical shells of revolution, subject to symmetrical rim loads.

The same method can be applied to Equation (29) provided the coefficients of the derivatives of lower order are not too large. These coefficients are mainly a function of a (see Equation (21)) which contains the relative span, $\frac{R}{L}$, in connection with the general term, c, of the trigonometric series. Evidently, as a first approximation, the derivatives of lower order can be neglected if,

$$a = \left(\frac{c\, R}{L}\right)^2 \leqq 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

Finsterwalder has shown,[8] that the stress conditions in the shell are largely determined by considering the first term, $c = \pi$, of the Fourier series, only, so that the accuracy will not be greatly influenced by reasonable errors of the supplementary stresses due to the additional terms, $c = -3\,\pi$, $c = +5\,\pi$, etc. At the same time, it should be stated that the multiple wave loads, represented by the higher load terms (Fig. 2(*b*) and Fig. 2(*c*)), would also induce increasingly large proportions of work done by longitudinal bending stresses and torsional moments. Since M_1 and M_t have been neglected in the basic stress system it is evident that the stresses and deformations obtained from the higher load terms are too large in any case. For practical purposes, therefore, the first load term, $c = \pi$, may be substituted in the limiting condition, Equation (45), which can now be stated in the form,

$$\frac{L}{R} \geqq \pi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

The proposed approximation, therefore, is applicable to larger spans, only, which, however, represent the most important field of practical applications.

With these simplifying assumptions the differential equation (Equation (29)) is now reduced to the following expression,

$$\frac{d^8 f}{d\phi^8} + 4\,a^2\,b^2\,(1 - m^2)\,f = 0 \dotfill (47)$$

The corresponding simultaneous equations, (Equations (35) and (36)), with J_8 and K_8 from Equations (40) and (44) respectively, become, therefore,

$$J^4_2 - 6\,J^2_2\,K^2_2 + K^4_2 + 4\,a^2\,b^2\,(1 - m^2) = 0 \dotfill (48)$$

and,

$$4\,J^3_2 - 4\,J_2\,K^2_2 = 0 \dotfill (49)$$

which gives,

$$J^2_2 = K^2_2 = a\,b\,\sqrt{1 - m^2} \dotfill (50)$$

The following definitions are introduced:

$$r = \sqrt{a\,b}\;\sqrt[4]{1 - m^2} = \frac{c\,R}{L}\sqrt{\frac{R}{t}}\;\sqrt[4]{3\,(1 - m^2)} \dotfill (51)$$

$$n_1 = \left(\sqrt{0.5} + 0.5\right)^{\frac{1}{2}} \dotfill (52)$$

and,

$$n_2 = \left(\sqrt{0.5} - 0.5\right)^{\frac{1}{2}} \dotfill (53)$$

The solution of Equation (50) gives the following roots for the unknown, J_2:

$$J_2 = +\,r \dotfill (54)$$

and,

$$J'_2 = -\,r \dotfill (55)$$

The corresponding values for the unknown, K_2, are,

$$K_2 = -\,r \dotfill (56)$$

and,

$$K'_2 = -\,r \dotfill (57)$$

The values, J_1, J'_1, K_1, K'_1, as well as J_3, J'_3, K_3, K'_3, etc., are found by means of the progressive functions, Equations (33) and (34). Since only waves of decreasing amplitude can describe the stress conditions originating from a loaded edge, it is necessary to choose the negative sign for the damping factors, J_1 and J'_1. This requirement, in turn, determines the choice of the negative sign for K_2 and K'_2, as given by Equations (56) and (57). Table 1 (Appendix II), shows the values, J, K, J', and K', respectively, corresponding to the simplified differential formula (Equation (47)).

By Newton's method it is now possible to find corrections for J_2 and K_2, designated by $\Delta\,J_2$ and $\Delta\,K_2$. For this purpose the approximate values of

J and K, as given by Table 1 (Appendix II), are substituted in Equations (35) and (36), whereby the errors, Δ_1 and Δ_2, are obtained:

$$\Delta_1 = -4\,r^3\,(1 - a) - a\,r\,(2 + m - a) \qquad (58)$$

and,

$$\Delta_2 = +4\,r^2\,(1 - a) - a\,(2 + m - a) + 2\,r\,(1 - (4 + m)\,a + a^2) \qquad (59)$$

By partial differentiation of Equations (35) and (36), with respect to J_2 and K_2, the functions, f_1, f_2, and g_1, g_2, result,

$$\frac{\partial F}{\partial J_2} = f_1\,(J_2, K_2) \qquad (60)$$

$$\frac{\partial F}{\partial K_2} = f_2\,(J_2, K_2) \qquad (61)$$

$$\frac{\partial G}{\partial J_2} = g_1\,(J_2, K_2) \qquad (62)$$

and,

$$\frac{\partial G}{\partial K_2} = g_2\,(J_2, K_2) \qquad (63)$$

The approximate values for J_2 and K_2, as given by Equations (54) and (56), are now substituted in Equations (60) to (63), whereby the following equations of differences are obtained:

$$\Delta F_1 = \Delta J_2 \times f_1(r) \qquad (64)$$

$$\Delta F_2 = \Delta K_2 \times f_2(r) \qquad (65)$$

$$\Delta G_1 = \Delta J_2 \times g_1(r) \qquad (66)$$

and,

$$\Delta G_2 = \Delta K_2 \times g_2(r) \qquad (67)$$

in which, r is a shell constant and $f(r)$ and $g(r)$ are functions of r. The desired corrections, ΔJ_2 and ΔK_2, can then be determined from the two simultaneous equations:

$$\Delta F_1 + \Delta F_2 = \Delta J_2 \times f_1\,(r) + \Delta K_2 \times f_2\,(r) = -\Delta_1 \qquad (68)$$

and,

$$\Delta G_1 + \Delta G_2 = \Delta J_2 \times g_1\,(r) + \Delta K_2 \times g_2\,(r) = -\Delta_2 \qquad (69)$$

The same method is applied in order to find corrections for the approximate values, J'_2 and K'_2, in Equations (55) and (57). Neglecting the terms of a lower order (which is justified when $a < r$) the corrected values are:

$$J_2 = +r + \Delta J_2 = +r + \frac{(a - 1)}{2} \qquad (70)$$

$$K_2 = -r + \Delta K_2 = -r \qquad (71)$$

$$J'_2 = -r + \Delta J'_2 = -r + \frac{(a-1)}{2} \qquad (72)$$

and,

$$K'_2 = -r + \Delta K'_2 = -r \qquad (73)$$

If necessary, additional corrections could be obtained by repeated applications of Newton's method. Since the general expressions for the second correction are rather complicated it is preferable to substitute the numerical values in individual cases. The final values then are substituted in Equations (37) to (44), in such a way that the entire group can be determined with any desired degree of accuracy. However, the more accurate solution of the problem, as carried through by Finsterwalder, cannot be stated in explicit form. In addition, the numerical computations must be repeated for each individual load term, *c*, so that, for a complete solution, the work is considerable.

It seems desirable, therefore, to obtain approximate solutions in simplified form, which are entirely sufficient in many cases, especially for the purpose of preliminary designs and estimates. If the shell is comparatively thin $\left(\frac{R}{t} > 100\right)$ and the relative span remains within the approximate limits, $1 < \frac{L}{R} < 10$, it can be shown that the correction, $\frac{(a-1)}{2}$ in Equations (70) and (72), does not exceed about $0.1r$. Under these limiting conditions it is then permissible to use the first approximation of the values, *J* and *K*, given in Table 1 (Appendix II), as a basis for an approximate method.

Consistent with the reasoning stated in arriving at the simplified differential equation (Equation (47)), the derivations of a lower order may also be neglected in the expressions for the stress components and deformations, Equations (14) to (28). With the limiting assumption, $a < 1$, it will be noted that the derivative of the highest order in each case also has the largest coefficient.

In order to obtain identical conditions in a longitudinal direction, only the stress components and deflections containing the factor, $\cos\frac{c\,x}{L}$, will be considered in the simultaneous elastic equations. For this reason the stress component, $\frac{\partial S}{\partial x}$ (Equation (17)), is introduced instead of *S* (Equation (18)); likewise, the stress component, T_1 (Equation (20)), is introduced instead of the deflection, *u* (Equation (22)). Assuming that continuity of stresses and deformations has been established on any point of a generatrix, the same condition then applies throughout.

The equations for the stress components and deflections are written in the general form,

$$(A\ a^* + B\ b^* + C\ c^* + D\ d^*) \cos \frac{c\,x}{L} \ldots\ldots\ldots\ldots (74)$$

in which, with reference to Equation (31), the constants, *A, B, C,* and *D,* must conform to four edge conditions, at $\phi = 0$, for example, four known values of the stress components, M_2, N_2, T_2, and $\frac{\partial S}{\partial x}$, or, the three deflections, v, w, θ, and the stress component, T_1.

The expressions, a^*, b^*, c^*, and d^*, are functions of the angle, ϕ, generally defined as follows,

$$a^* = e^{(J1)\phi}\ (\alpha \sin K_1\ \phi + \beta \cos K_1\ \phi) \ldots\ldots\ldots\ldots (75)$$

$$b^* = e^{(J1)\phi}\ (\alpha \cos K_1\ \phi - \beta \sin K_1\ \phi) \ldots\ldots\ldots\ldots (76)$$

$$c^* = e^{(J1)'\phi}\ (\gamma \sin K'_1\ \phi + \delta \cos K'_1\ \phi) \ldots\ldots\ldots\ldots (77)$$

and,

$$d^* = e^{(J1)'\phi}\ (\gamma \cos K'_1\ \phi - \delta \sin K'_1\ \phi) \ldots\ldots\ldots\ldots (78)$$

Based on the simplifying assumptions regarding the derivatives of lower order, in case, $a < 1$, the constants, α, β, γ, and δ, are derived from Equations (14), (15), (16), (17), (20), (26), (27), and (28), in connection with Table 1 (Appendix II). The value of these constants, corresponding to the various stress components and deflections, is shown in Table 2 (Appendix II), where,

$$k = \sqrt{2} - 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

INFLUENCE NUMBERS FOR EDGE DEFORMATIONS

The practical analysis of edge load stresses is greatly facilitated by the use of influence numbers for the edge deformations, corresponding to elementary, unit loads, herein defined by the general term of the trigonometric series, Equation (2). All deformations must be given for the center of the span, $x = 0$, where the intensity of the unit load assumes the value, $\frac{4}{c}$, measured per unit length.

The four fundamental edge loadings to be considered herein, consisting of $M_2 = \frac{4}{c}$; $N_2 = \frac{4}{c}$; $T_2 = \frac{4}{c}$; and $\frac{\partial S}{\partial x} = \frac{4}{c}$, are preferably divided in symmetrical and contra-symmetrical load cases, as shown in Fig. 4. ("Contra-symmetrical" denotes "equal but in opposite directions.") In both cases the same absolute load is acting at the edges, $\phi = 0$ and $\phi = \phi_k$, with the positive direction at $\phi = 0$. The contra-symmetrical loading consists in reversing the directions of the loads at $\phi = \phi_k$. In all cases the deformations are given for the left-hand edge, $\phi = 0$.

LOAD CONDITION					
M_2	N_2	T_2	$\frac{\partial s}{\partial x}$	Symmetrical	Contra-symmetrical

FIG. 4.

The stress components and deformations at any point of the shell sector, located by the angle, ϕ_1 (Fig. 5), are generally influenced by the stress waves from both the loaded edges. In Equations (75) to (78) the influence of the loads at $\phi = 0$ is found by means of the substitution, $\phi = \phi_1$. Likewise, the substitution, $\phi = \phi_2$, gives the influence of the loads acting at the edge, $\phi = \phi_k$. The algebraic sum of the two values represents the combined influence for the point, ϕ_1, and is designated by a^*_1, b^*_1, c^*_1, and d^*_1. Therefore,

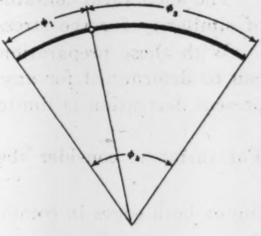

FIG. 5.

$$a^*_1 = a^*(\phi_1) \pm a^*(\phi_2) \ldots\ldots\ldots\ldots (80)$$

$$b^*_1 = b^*(\phi_1) \pm b^*(\phi_2) \ldots\ldots\ldots\ldots (81)$$

$$c^*_1 = c^*(\phi_1) \pm c^*(\phi_2) \ldots\ldots\ldots\ldots (82)$$

and,

$$d^*_1 = d^*(\phi_1) \pm d^*(\phi_2) \ldots\ldots\ldots\ldots (83)$$

With reference to Fig. 3(a), showing the positive directions of the stress components and deflections, it should be noted that, in case of symmetrical edge load conditions, the upper sign in Equations (80) to (83) applies to M_2, T_2, T_1, and w, and the lower sign to N_2, $\frac{\partial S}{\partial x}$, v, and θ. In case of anti-symmetrical loadings the corresponding signs must be reversed.

Considering the stress components and deflections on the left-hand edge, $\phi = 0$, the substitutions, $\phi_1 = 0$, $\phi_2 = \phi_k$, in Equations (80) to (83), furnish a group of values, designated by a_o, b_o, c_o, and d_o, which are shown in Table 3 (Appendix II) for the cases of symmetrical and anti-symmetrical edge loadings. The abbreviations of Table 3 are defined, as follows,

$$f = e^{(J_1)(\phi_k)} \sin K_1 \phi_k \tag{84}$$

$$g = 1 + e^{(J_1)(\phi_k)} \cos K_1 \phi_k \tag{85}$$

$$h = 1 - e^{(J_1)(\phi_k)} \cos K_1 \phi_k \tag{86}$$

$$f' = e^{(J_1)'(\phi_k)} \sin K'_1 \phi_k \tag{87}$$

$$g' = 1 + e^{(J_1)'(\phi_k)} \cos K'_1 \phi_k \tag{88}$$

and,

$$h' = 1 - e^{(J_1)'(\phi_k)} \cos K'_1 \phi_k \tag{89}$$

With reference to Table 1 (Appendix II) it will be noted that the edge values, a_o, b_o, c_o, and d_o, are mainly functions of the characteristic number, λ, defined as the shell ratio,

$$\lambda = \sqrt{r}\, \phi_k \tag{90}$$

The shell ratio contains all dimensions of the shell and expresses the law of similarity for the stress distribution in the case of edge loads.

With these preparations the values, A, B, C, and D in Equation (74), can be determined for any desired combination of four edge conditions. The present derivation is limited to the fundamental loadings, as shown in Fig. 4.

For instance, consider the case of a symmetrical unit load, $M_2 = \dfrac{4}{c}$, acting on both edges in combination with the specification, $N_2 = T_2 = \dfrac{\partial S}{\partial x} = 0$.

From Table 3(a) (Appendix II) (by using the subscripts, 1, 2, 3, etc., in reference to the edge values of M_2, N_2, T_2, etc.), the following equations can be written:

$$M_2 = A\, a_{o1} + B\, b_{o1} + C\, c_{o1} + D\, d_{o1} = \frac{4}{c} \tag{91}$$

$$N_2 = A\, a_{o2} + B\, b_{o2} + C\, c_{o2} + D\, d_{o2} = 0 \tag{92}$$

$$T_2 = A\, a_{o3} + B\, b_{o3} + C\, c_{o3} + D\, d_{o3} = 0 \tag{93}$$

and,

$$\frac{\partial S}{\partial x} = A\, a_{o4} + B\, b_{o4} + C\, c_{o4} + D\, d_{o4} = 0 \tag{94}$$

The solution of these four simultaneous equations furnishes the unknowns, A, B, C, and D, which can be stated in explicit form for any given numerical value of the shell ratio, λ.

Similar groups of equations are obtained for the unit loads, $N_3 = \frac{4}{c}$, $T_3 = \frac{4}{c}$, and $\frac{\partial S}{\partial x} = \frac{4}{c}$. In this manner Tables 4, 5, 6, and 7 (Appendix II) have been computed for symmetrical and contra-symmetrical unit loadings, using $\frac{K_1 \phi_k}{\pi}$ as argument, instead of λ.

As the argument increases, the functions, A, B, C, and D, approach constant values, which are also given. This condition is reached when the loads at the edge, $\phi = \phi_k$, do not influence the stresses and deformations of the opposite edge, $\phi = 0$ as, for instance, in the case of a very thin shell, combined with a large central angle or a short span.

The edge deflections, v, w, θ, and the edge stress component, T_1, are obtained from the general Equation (74), by substituting the values, A, B, C, and D, corresponding to a given loading, and the values, a_O, b_O, c_O, and d_O, corresponding to a desired deflection or stress component. For instance, consider again the case of a symmetrical unit loading, $M_3 = \frac{4}{c}$, for which the values, A, B, C, and D, are given by Table 4(a) (Appendix II). From Table 3(a) (Appendix II) with the subscripts previously defined, Equation (74) then furnishes the following expressions for the stress component, T_1, and the deflections at the center of the span, $x = 0$, defined as the influence numbers for M_3,

$$T_1 = A\ a_{O5} + B\ b_{O5} + C\ c_{O5} + D\ d_{O5} \ldots\ldots\ldots\ldots (95)$$

$$v = A\ a_{O6} + B\ b_{O6} + C\ c_{O6} + D\ d_{O6} \ldots\ldots\ldots\ldots (96)$$

$$w = A\ a_{O7} + B\ b_{O7} + C\ c_{O7} + D\ d_{O7} \ldots\ldots\ldots\ldots (97)$$

and,

$$\theta = A\ a_{O8} + B\ b_{O8} + C\ c_{O8} + D\ d_{O8} \ldots\ldots\ldots\ldots (98)$$

Similar expressions are obtained for the other unit loadings. The influence numbers, as shown in Table 8 (Appendix II), can be expressed in explicit form, except for a numerical coefficient, which is a function of the shell ratio only.

It is interesting to note that the influence numbers for the deflections, θ, w, and v, are symmetrical about the diagonal through the top left corner. The same symmetry applies to the coefficients, c_{21}, c_{12}, c_{31}, c_{13}, etc., throughout the diagonal, because the computations show that $c_{12} = c_{21}$, $c_{13} = c_{31}$, etc., in accordance with Maxwell's theorem of reciprocal relations between loads and deflections. Since T_1 represents a stress component, instead of a deflection, the symmetrical relations apply to the coefficients only, not to the influence numbers for T_1 as a whole.

Table 9 (Appendix II) gives the values of the influence number coefficients for symmetrical and contra-symmetrical loading, with $\frac{K_1\ \phi_k}{\pi}$ as the argument. These coefficients, plotted on logarithmic paper, are also shown in Fig. 6. It will again be noted that, for large values of the shell ratio, the coefficients approach constant values, indicating that the deflections of the edge, $\phi = 0$, become independent from the loads acting at the opposite edge, $\phi = \phi_k$. For medium values of the shell ratio the coefficients have a pronounced damped-wave shape, caused by the interference of stress waves originating from the loaded edges, which indicates typical shell action.

For smaller values of the shell ratio the coefficients plot on straight lines, indicating that plate action, rather than shell action, prevails in this region. In order to illustrate this point, consider a comparatively long shell having a small central angle, ϕ_k, and comparatively thick walls. The behavior of such a shell approaches that of a narrow, flat plate, spanning between the end stiffeners. Assume that the shell is loaded by symmetrical edge moments, M_2, which loading represents an equilibrium system in a transverse plane. Since the shell is of such a shape that the restraining action of the transverse end stiffeners becomes negligible, it is evident that the cross-section of the shell can be considered as a slightly curved beam, loaded by two equal end moments. The angular deflection, θ, can then be computed by the usual beam theory. A comparison with the values obtained from the influence number of the shell shows close agreement in this case. The agreement is also fairly good for the deflections, w and v. The longitudinal stress component, T_1, becomes negligible, which is also in accordance with plate action. Of course, the reason for the satisfactory agreement under this extreme condition is due to the fact that the transverse moment, M_2, is included in the stress components acting on the small element, Fig. 3(*a*).

On the other hand, consider the same shell loaded by a system of antisymmetrical edge moments, M_2. The behavior of the narrow shell strip then approaches that of a plate or a rod, held at both ends, and subjected to torsional moments distributed over the entire length. Evidently, the torsional deflections will govern entirely in this case. However, since the torsional moments, acting on a small shell element, have been neglected in the derivation of the differential equation (Equation (29)), it cannot be expected that the influence numbers (Table 8 (Appendix II)) would give even a rough approximation in this case of extreme conditions. The actual deflections will be much smaller than those given by the influence numbers, because the torsional work comes into play.

Similar considerations apply to other unit loadings when the central angle becomes rather small. For instance, a symmetrical load system, N_2, would then induce comparatively large bending moments, M_1, in a longitudinal direction, which have also been neglected. For these reasons the influence

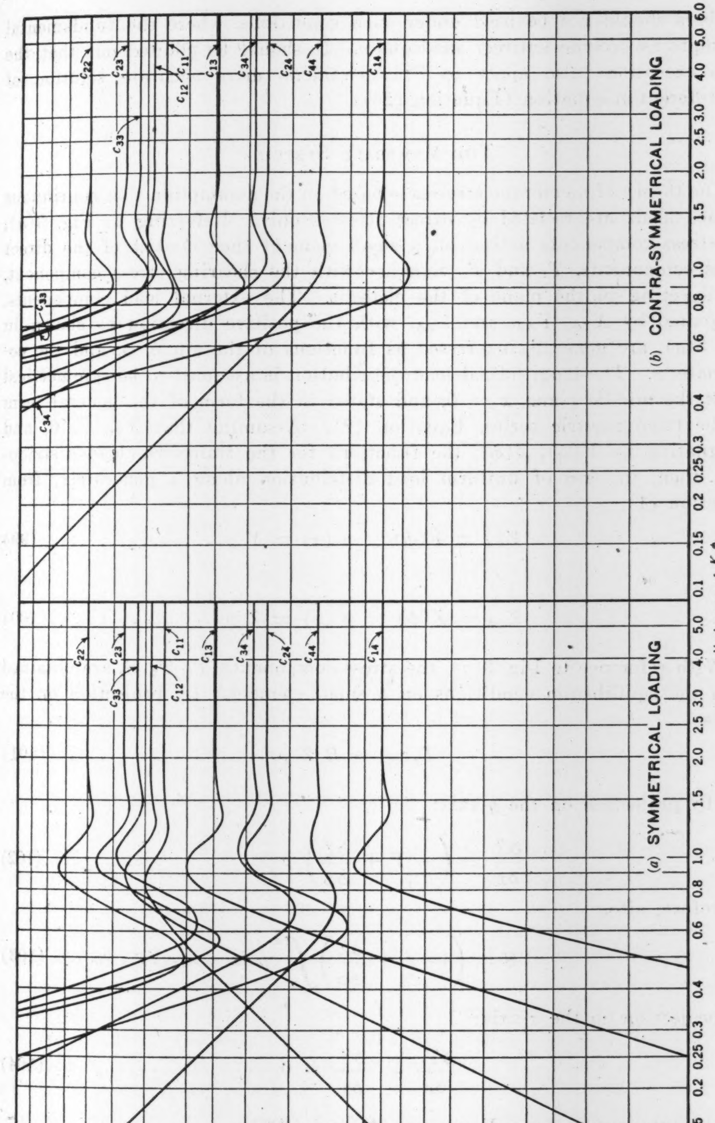

FIG. 6.—INFLUENCE NUMBER COEFFICIENTS.

numbers should not be used under such conditions, where the fundamental assumptions become entirely inadequate. It should be pointed out that the same exceptions also apply to Finsterwalder's more accurate solution of the differential equation (Equation (29)).

THE MEMBRANE SYSTEM

The theory of membrane stresses is based on the assumption that continuous surface loads are resisted by direct stresses only. Referring to Fig. 3(*a*), the stress components acting on a small element then consist of the direct stress components, T_1 and T_2, together with the shearing stress component, S, all acting in the plane of the element. The external load components, designated by $X_{x\phi}$, $Y_{x\phi}$, and $Z_{x\phi}$, with the positive direction as shown in Fig. 3(*a*), are generally expressed as functions of the angle, ϕ, and the coordinate, x. The longitudinal load distribution is assumed to be symmetrical about the middle plane, $x = 0$, and stated in the form of the general term of the trigonometric series, Equation (2). Assuming that $X_{x\phi} = 0$, and designating by $Y(\phi)$, $Z(\phi)$, the functions for the transverse load distribution, then, in case of uniform load distribution along a generatrix, from Equation (1),

$$Y_{x\phi} = Y(\phi) \times p\ (x) = Y\ p \qquad (99)$$

and,

$$Z_{x\phi} = Z(\phi) \times p\ (x) = Z\ p \qquad (100)$$

With reference to Fig. 3(*a*), the stress components, T_1, T_2, S, are obtained from the equilibrium conditions on a small element. By projection on the z-axis:

$$T_2 = -\ R\ Z\ p \qquad (101)$$

and by projection on the y-axis:

$$\frac{\partial S}{\partial x} = \left(-\ Y + \frac{\partial Z}{\partial \phi}\right) p \qquad (102)$$

Therefore, also,

$$S = \left(-\ Y + \frac{\partial Z}{\partial \phi}\right) \int_0^x p\ dx \qquad (103)$$

By projection on the x-axis:

$$\frac{\partial T_1}{\partial x} + \frac{\partial S}{\partial s} = 0 \qquad (104)$$

and by integration, from Equations (4) and (103):

$$T_1 = \frac{1}{R}\left(-\frac{\partial Y}{\partial \phi} + \frac{\partial^2 Z}{\partial \phi^2}\right) M \qquad (105)$$

The membrane stress deflections are obtained by substituting these stress components in Equations (8), (9), and (10). From Equations (8), (101), and (102), by partial integration,

$$E\,t\,u = \frac{1}{R}\left(-\frac{\partial Y}{\partial \phi} + \frac{\partial^2 Z}{\partial \phi^2}\right)\int_{-0.5\,L}^{x} M\,dx + m\,R\,Z\int_{-0.5\,L}^{x} p\,dx \ldots. (106)$$

From Equation (10), by partial differentiation:

$$\frac{\partial^2 v}{\partial x^2} = \frac{2\,(1+m)}{E\,t}\,\frac{\partial S}{\partial x} - \frac{\partial^2 u}{\partial s\,\partial x} \ldots\ldots\ldots\ldots\ldots (107)$$

Substituting, $\frac{\partial S}{\partial x}$, from Equation (102), and, with the partial derivative from Equation (8), in connection with Equations (101) and (105),

$$E\,t\,\frac{\partial^2 v}{\partial x^2} = 2\,p\left\{-(1+m)\,Y + \left(1+\frac{m}{2}\right)\frac{\partial Z}{\partial \phi}\right\} - \frac{M}{R^2}\left\{-\frac{\partial^2 Y}{\partial \phi^2} + \frac{\partial^3 Z}{\partial \phi^3}\right\} ..(108)$$

By integration, in connection with Equations (4) and (6),

$$E\,t\,v = 2\,M\left\{(1+m)\,Y - \left(1+\frac{m}{2}\right)\frac{\partial Z}{\partial \phi}\right\} + \frac{\eta}{R^2}\left\{-\frac{\partial^2 Y}{\partial \phi^2} + \frac{\partial^3 Z}{\partial \phi^3}\right\} ..(109)$$

From Equation (9,) in connection with Equations (101), (105), and (109),

$$E\,t\,w = R^2 Z\,p + 2\,M\left\{\left(1+\frac{m}{2}\right)\frac{\partial Y}{\partial \phi} - \frac{\partial^2 Z}{\partial \phi^2}\right\} + \frac{\eta}{R^2}\left\{-\frac{\partial^3 Y}{\partial \phi^3} + \frac{\partial^4 Z}{\partial \phi^4}\right\} ..(110)$$

The angular deflection of the transverse tangent is negligible in the case of membrane stresses; therefore, $\theta = 0$.

EXAMPLE

Consider the partial filling of a simply supported, horizontal pipe line or liquid storage tank, provided with adequate transverse stiffening members over both end supports. Neglecting the weight of the shell, the surface load then consists of the liquid pressure, acting continuously over the wetted perimeter of the shell.

At the liquid level the surface load becomes discontinuous, which condition can be analyzed when the shell is cut along this plane and the membrane stress equations are applied to the loaded shell sector. It will be found that a direct stress component, T_1, and a longitudinal shearing stress component, S, are acting on the free edges of the lower shell. The latter force must be applied as a reaction on the edges of the upper shell, where it induces edge load stresses and deformations. The lower shell is deformed by membrane stresses and the combined effect will be a discrepancy in the geometrical continuity of the two shell sectors.

The membrane stress component, S, representing the main disturbing force, reaches a maximum value when the pipe is exactly half full. For this reason the following derivations will be limited to this loading, which is of practical importance, although any other filling may be analyzed in a similar manner. Referring to Fig. 7, and designating the unit weight of the liquid by q, the external load components are,

$$X = Y = 0 \qquad (111)$$

and,

$$Z = -\, q\, R \sin \phi \qquad (112)$$

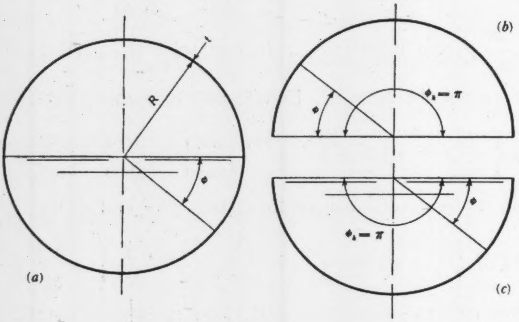

FIG. 7.

The membrane stress components and deformations at $x = 0$, $\phi = 0$, are obtained from Equations (101), (102), (105), (109), and (110):

$$T_2 = 0 \qquad (113)$$

$$\frac{\partial S}{\partial x} = -\,\frac{4}{c}\, q\, R \qquad (114)$$

$$T_1 = 0 \qquad (115)$$

$$E\, t\, v = +\,\frac{4}{c}\left\{2\left(1 + \frac{m}{2}\right) + \frac{1}{a}\right\}\frac{q\, R^3}{a} \qquad (116)$$

$$E\, t\, w = 0 \qquad (117)$$

and, since the angular deflection is negligible,

$$\theta = 0 \qquad (118)$$

Since $T_2 = 0$, the membrane stress component, $\frac{\partial S}{\partial x}$, Equation (114), represents the only reaction that must be applied as a symmetrical edge load on the upper shell. The corresponding deflections and the longitudinal edge stress of the upper shell are obtained from the influence numbers, Table 8

(Appendix II), which already contain the term, $\frac{4}{c}$, as a unit load. Therefore:

$$E\,t\,\theta = +\,c_{14}\,\frac{r^2}{c\,a^2}\,q\,R^2 \ldots\ldots\ldots\ldots\ldots\ldots (119)$$

$$E\,t\,w = -\,c_{24}\,\frac{r^{1.5}}{c\,a^2}\,q\,R^3 \ldots\ldots\ldots\ldots\ldots\ldots (120)$$

$$E\,t\,v = +\,c_{34}\,\frac{r}{c\,a^2}\,q\,R^3 \ldots\ldots\ldots\ldots\ldots\ldots (121)$$

and,

$$T_1 = -\,c_{44}\,\frac{r^{0.5}}{c\;a}\,q\,R^2 \ldots\ldots\ldots\ldots\ldots\ldots (122)$$

A comparison of the deflections, *v*, in Equations (121) and (116), indicates that the latter is relatively small in the case of thin pipes and, therefore, will be neglected.

A symmetric equilibrium system of unit edge loads, $M_2 = \frac{4}{c}$, $N_2 = \frac{4}{c}$, $T_2 = \frac{4}{c}$, and $\frac{\partial S}{\partial x} = \frac{4}{c}$, is now applied at the edges of both shells. The corresponding deformations, as given by Table 8, are shown in Table 10 (Appendix II), together with the deformations of the membrane stress system, Equations (116) to (122). Table 10 also gives the algebraic differences between the deflections of the upper and lower shell, including the differences between the longitudinal edge stresses. The continuity between the two shells is restored when the differential deformations and stresses are eliminated.

For this purpose four unknown edge force components, designated by $M_2 = X_1$, $N_2 = X_2$, $T_2 = X_3$, and $\frac{\partial S}{\partial x} = X_4$, are applied, so that the algebraic sum of the difference, Δ, becomes zero. Table 10 then gives the following elastic equations for the determination of the unknowns,

$$+\,X_1\,c_{11}\,r^{1.5} - X_3\,c_{13}\,r^{0.5}\,R + c_{14}\,\frac{q\,R^3}{2} = 0 \ldots\ldots\ldots\ldots (123)$$

$$-\,X_2\,c_{22}\,r - X_4\,c_{24}\,R - c_{24}\,\frac{q\,R^2}{2} = 0 \ldots\ldots\ldots\ldots (124)$$

$$+\,X_1\,c_{31}\,r^{1.5} - X_3\,c_{33}\,r^{0.5}\,R + c_{34}\,\frac{q\,R^3}{2} = 0 \ldots\ldots\ldots\ldots (125)$$

and,

$$-\,X_2\,c_{42}\,r - X_4\,c_{44}\,R - c_{44}\,\frac{q\,R^2}{2} = 0 \ldots\ldots\ldots\ldots (126)$$

The solution of Equations (123) to (126) gives the following values for the unknowns,

$$X_1 = C_2 \frac{q R^3}{2 r^{1.5}} \quad \text{.....................(127)}$$

$$X_2 = 0 \quad \text{.............................(128)}$$

$$X_3 = C_1 \frac{q R^2}{2 r^{0.5}} \quad \text{.....................(129)}$$

and,

$$X_4 = - \frac{q R}{2} \quad \text{.....................(130)}$$

The coefficients, C_1 and C_2 are defined by the following equations,

$$C_1 = \frac{c_{13} c_{14} - c_{11} c_{34}}{c^2_{13} - c_{11} c_{33}} \quad \text{..................(131)}$$

and,

$$C_2 = C_1 \frac{c_{33}}{c_{13}} - \frac{c_{34}}{c_{13}} \quad \text{....................(132)}$$

The unit stresses at the liquid level, in the center of the span, may be determined by considering the stress condition of the upper shell, which is subject to edge loads only.

The total longitudinal edge stress component consists of the individual components due to the edge loads, X_1 to X_4, and the component of the membrane stress system. The latter is given by Equation (122) and the components caused by X_1, X_3, and X_4, are obtained from the influence numbers, Table 8 (Appendix II). Therefore, the resulting longitudinal edge stress component, designated by T_{1r}, becomes,

$$T_{1r} = - X_1 \frac{c_{41} r^2}{R c a} + X_3 \frac{c_{43} r}{c a} - X_4 \frac{c_{44} r^{0.5} R}{c a} - c_{44} \frac{r^{0.5}}{c a} q R^2 \text{...(133)}$$

By substituting the corresponding values from Equations (127), (129), and (130), the following expression is obtained,

$$T_{1r} = - C_3 \frac{q R^2 r^{0.5}}{2 a c} \quad \text{..................(134)}$$

in which,

$$C_3 = c_{44} - C_1 c_{34} + C_2 c_{14} \quad \text{................(135)}$$

The unit stresses, corresponding to the stress components, X_1 X_3 and T_{1r}, in Equations (127), (129), and (134), are designated by σ_{M2}, σ_{T2}, and σ_{T1}, respectively, hence:

$$\sigma_{M2} = \pm \frac{6 X_1}{t^2} = \pm C_2 \frac{3 q R^3}{t^2 r^{1.5}} \quad \text{..............(136)}$$

$$\sigma_{T2} = C_1 \frac{q R^2}{2 t r^{0.5}} \quad \text{..........................(137)}$$

and,

$$\sigma_{T1} = - C_3 \frac{q R^2 r^{0.5}}{2 a c t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (138)$$

The value of σ_{T2}, being positive, is a tensile stress; σ_{T1} is a compressive stress. The tangential stress, σ_{T2}, is relatively small. However, it is interesting to compare the transverse bending stress, σ_{M2}, and the longitudinal stress σ_{T1}, with the maximum beam stress of a simply supported, full pipe, designated by σ_B, which is,

$$\sigma_B = \frac{q\ L^2}{8 t} = \frac{4}{c} \frac{q\ L^2}{c^2 t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (139)$$

Substituting r, from Equation (51), and using a value, $m^2 = 0.10$, for Poisson's ratio:

$$\frac{\sigma_{M2}}{\sigma_B} = 15.9\ C_2 \sqrt{\frac{R}{L}\left(\frac{R}{t}\right)^{\frac{1}{2}}} \frac{1}{c^{1.5}} \quad \ldots\ldots\ldots\ldots\ldots (140)$$

and,

$$\frac{\sigma_{T1}}{\sigma_B} = 4.54\ C_3 \sqrt{\frac{R}{L}\left(\frac{R}{t}\right)^{\frac{1}{2}}} \frac{1}{c^{2.5}} \quad \ldots\ldots\ldots\ldots\ldots (141)$$

Substituting C_2 and C_3, from Equations (132) and (135), respectively, it will be noted that the influence number coefficients are given as functions of $\frac{K_1 \phi_k}{\pi}$, in Table 9(*a*) (Appendix II), or Fig. 6(*a*). Since, in the present example, $\phi_k = \pi$, and K_1, from Table 1 (Appendix II), is also a function of r, it will be possible, therefore, to write Equations (140) and (141) in the following form,

$$\frac{\sigma_{M2}}{\sigma_B} = C_{M2} \sqrt{\frac{R}{L}\left(\frac{R}{t}\right)^{\frac{1}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (142)$$

and,

$$\frac{\sigma_{T1}}{\sigma_B} = C_{T1} \sqrt{\frac{R}{L}\left(\frac{R}{t}\right)^{\frac{1}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (143)$$

The values of the coefficients, C_{M2} and C_{T1}, have been computed for the first term of the Fourier series, by substituting, $c = \pi$, and are shown in Fig. 8. As already stated, the consideration of additional terms of the series does not greatly influence the final result. Due to the approximations made in the derivation of the influence numbers it is doubtful whether the accuracy would be increased thereby.

By an entirely different method, Samsioe[13] has analyzed the same problem for a pipe half full, but with fixed ends, instead of the simply supported conditions assumed in the present example. Although the results for this reason are not directly comparable, the corresponding coefficients, derived from Samsioe's analysis, are also shown in Fig. 8.

---

[13] "Die Spannungen in einem auf mehreren Stützen in gleicher gegenseitiger Entfernung aufgelegten und zur Hälfte mit Wasser gefüllten Rohr," von A. Frey Samsioe, pub. by Svenska Bokhandelscentralen, Stockholm, Sweden, 1926.

It will be noted that the maximum stresses due to the discontinuous surface load are of similar magnitude in both cases, except that the limitations of the present method are indicated in case of small values of $\sqrt{\frac{R}{L}\left(\frac{R}{t}\right)^{\frac{1}{2}}}$.

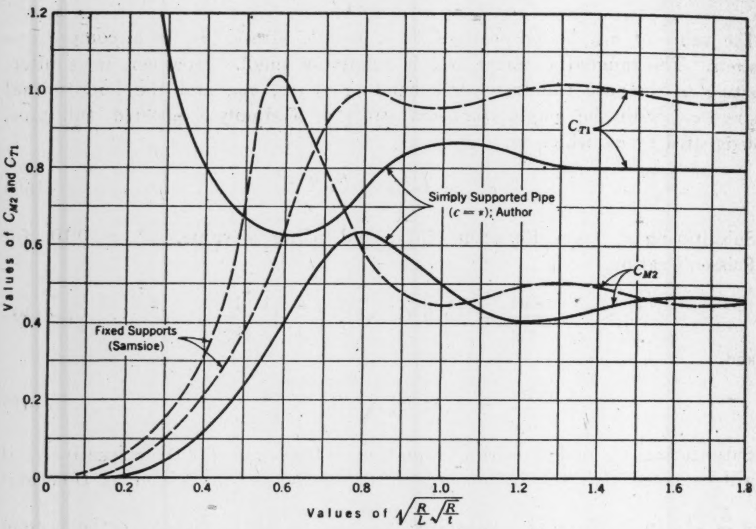

FIG. 8.—COEFFICIENT C FOR A PIPE HALF FULL OF WATER, WITH SIMPLE SUPPORTS AND FIXED SUPPORTS.

CONCLUSION

Thin shell structures will find an increasingly large field of useful application because of their economic advantages and their adaptability to architectural treatment in wide span construction. For practical purposes the analysis of such structures must be simplified so as to enable the designer to obtain a reasonably accurate stress picture in spite of the fact that exact solutions are not yet available on account of mathematical difficulties.

The proposed method is an approximation, but the comparison of the results with more accurate derivations indicates a satisfactory agreement, provided the given limitations are kept in mind.

APPENDIX I

NOTATION

The symbols introduced in this paper are defined where they first appear; and for the convenience of discussers the complete notation, in alphabetical order, is listed herein, as follows:

a = a factor, $\left(\frac{c\,R}{L}\right)^2$; also, a^*, b^*, c^*, and d^* = functions of the angle, ϕ; and, a_0, b_0, c_0, and d_0 = edge values for $\phi = 0$;
b = a shell constant $= \frac{R}{t}\sqrt{3}$; also, for b^* and b_0, refer to Symbol a;
c = substitutions corresponding to the first, second, third, etc., terms of a Fourier series; c_{11}, c_{12}, c_{13}, etc. = influence number coefficients for edge deflections; for c^* and c_0 refer to Symbol a;
d^* = function of the angle, ϕ (see Symbol a).
e = base of natural logarithms; also e = elongation: e_1, longitudinal, and e_2, transverse;
f = "function of": $f(\phi)$ = Finsterwalder's stress function for a cylindrical shell sector; f, g, and h = functions of J_1, K_1, and ϕ_k; f', g', and h' = functions of J', K', and ϕ'_k;
g = "function of": (for g and g', refer to Symbol f);
h = "function of": (for h and h', refer to Symbol f);
k = a constant $= \sqrt{2} - 1$;
m = Poisson's ratio;
n = a constant: $n_1 = (\sqrt{0.5} + 0.5)^{\frac{1}{2}}$ and $n_2 = (\sqrt{0.5} - 0.5)^{\frac{1}{2}}$;
p = load intensity per unit length of a simply supported beam; $p(x)$ = sum of a trigonometric series; p_c = general term of series;
q = unit weight of liquid;
r = a shell constant $= \sqrt{a\,b}\,\sqrt[4]{1 - m^2}$;
s = length of a circular arc corresponding to a central angle, ϕ; ds = length of a small element of arc, s;
t = thickness of shell; as a subscript, t, denotes "torsional";
u = longitudinal deflection of a shell element, positive in the direction of increasing values of x;
v = tangential deflection of a shell element, positive in the direction of increasing values of ϕ;
w = radial deflection of a shell element, positive in a direction toward the center of curvature;
x = a distance measured longitudinally along the arch barrel, from the center of the span; dx = an elementary small distance, x;
A = a constant; A, B, C, and D = constants conforming to given edge conditions of the shell;
B = a constant (see Symbol A); as a subscript, B, denotes "beam";
C = a constant (see Symbol A); C_1, C_2, and C_3 = functions of the influence number coefficients referred to in the example in this paper;
D = a constant (see Symbol A);
E = modulus of elasticity;
F = a function; F and G = functions determining J and K;
G = a function (see Symbol F);
I = moment of inertia of a beam section;

J = a shell constant; J_1 = a damping factor (as an exponent, written simply, $(J1)$); J'_1 = a damping factor of stress functions (as an exponent, written, $(J1)'$);

K = a shell constant; K_1 and K'_1 = wave length factors of stress function; K_n = a progressive function of K_1;

L = length; span of a simply supported beam or cylindrical shell;

M = moment; bending moment of a simply supported, uniformly loaded beam at the distance, x; M_0 = bending moment at the center of the span; M_1 = longitudinal bending stress component on a shell element per unit width (positive when tension is produced on the inner surface); M_2 = transverse bending moment corresponding to M_1; M_t = torsional moment acting on a shell element per unit width (positive when producing tension on the outer surface, in a diagonal direction of increasing values of x and ϕ); M_c = general term of a series;

N = radial shearing stress component per unit width (positive when acting in an outward direction on the sides facing the origin of x and ϕ);

R = radius of circular shell; radius of curvature of a cylinder element;

S = direct shearing stress component on a shell element per unit width, acting in the plane of the element (positive when producing tension in a diagonal direction of increasing values of x and ϕ);

T = direct stress component on a shell element per unit width; T_1, in a longitudinal direction, and T_2 in a tangential, or transverse, direction; T_{1r} = resulting longitudinal edge stress component in the design example of the paper;

X = force component: $X_{x\phi}$, $Y_{x\phi}$, and $Z_{x\phi}$ = external load components on a shell element per unit width; X_1, X_2, X_3, and X_4 = unknown edge force components in the design example of the paper;

Y = force component (see Symbol X);

Z = force component (see Symbol X);

α = a constant in Table 2 (Appendix II);

β = a constant in Table 2 (Appendix II);

γ = a constant in Table 2 (Appendix II);

δ = a constant in Table 2 (Appendix II);

Δ = a correction, or difference; ΔJ_2 = correction for J_2; ΔK_2 = correction for K_2; Δ_1 = errors in values of J; Δ_2 = errors in values of K;

η = deflection of a simply supported, uniformly loaded beam, multiplied by EI; $\eta_0 = \eta$ at the center of the span; η_c = general term of a series;

θ = angular deflection of the transverse tangent of a shell element (positive when the tangent rotates in a clockwise direction);

κ = change of curvature of a shell element: κ_1 = longitudinal, and κ_2 = transverse;

λ = a typical shell constant defined as a ratio $= \sqrt{\ } r \phi_k$;

σ = unit stress; σ_B = maximum beam stress in a simply supported full pipe; σ_{M2}, σ_{T2}, and σ_{T1} = unit stresses corresponding to stress components, X_1, X_2, and T_{1r}, respectively;

ϕ = angular distance of a shell element from the left-end edge; $d\,\phi$ = angular width of a small shell element; ϕ_k = total central angle of a cylindrical shell sector; $f(\phi)$ = Finsterwalder's stress function for a cylindrical shell sector;

ω = angular detrusion of a shell element, caused by the shearing forces, S (positive when S is positive).

APPENDIX II

TABLES

The ten tables in Appendix II are introduced and explained in the text of the paper.

TABLE 1.—APPROXIMATE VALUES OF J, K, J', AND K'

Values	INDICES							
	1	2	3	4	5	6	7	8
J	$-n_1 r^{0.5}$	$+r$	$-(n_1-n_2) r^{1.5}$	0	$+2 n_2 r^{2.5}$	$-2 r^3$	$2(n_1+n_2) r^{3.5}$	$-4 r^4$
K	$+n_2 r^{0.5}$	$-r$	$+(n_1+n_2) r^{1.5}$	$-2 r^2$	$+2 n_1 r^{2.5}$	$-2 r^3$	$2(n_1-n_2) r^{3.5}$	0
J'	$-n_2 r^{0.5}$	$-r$	$+(n_1+n_2) r^{1.5}$	0	$-2 n_1 r^{2.5}$	$+2 r^3$	$2(n_1-n_2) r^{3.5}$	$-4 r^4$
K'	$+n_1 r^{0.5}$	$-r$	$-(n_1-n_2) r^{1.5}$	$+2 r^2$	$-2 n_2 r^{2.5}$	$-2 r^3$	$2(n_1+n_2) r^{3.5}$	0

DISCUSSION

I. K. SILVERMAN,[13] JUN. AM. SOC. C. E. (by letter).—That thin shells, properly supported, serve as very economical structures, has been known for some time. Mr. Schorer, for the first time, has introduced into American engineering literature the theory of such shells which has been developed largely by German and Swiss engineers.

Even with the simplifications introduced in this paper, the application of the theory requires considerable computation as, for example, when the structure analyzed is not a complete surface of revolution and the loading is not symmetrical. Such a condition occurs in the analysis of the structure such as the sector gate shown in Fig. 9.

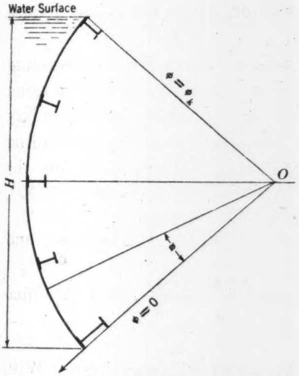

FIG. 9.

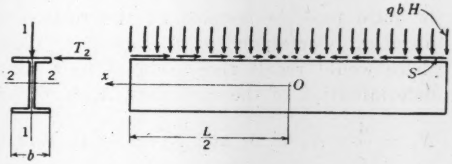

FIG. 10.

When applied to a structure of this type, the thin shell theory tends to show that large stresses may occur in the longitudinal supporting members, especially in the member at $\phi = 0$. These large stresses are due to the fact that the inevitable arch action developed in the curved skin-plate causes the member to bend about Axis 1–1, Fig. 10. Furthermore, stresses of the type, S, subject the longitudinal supporting members to loads which are axially eccentric. In combination with the direct water load, these stresses may reach large values, especially in gates of long spans.

In outline, the method of attacking such a structure as that presented in Fig. 9 is perfectly straightforward. The author has shown that the loads on a structure are carried by a primary system of stresses, the membrane system, and by a self-equilibrating system (secondary), the function of which is to preserve geometrical continuity. The stresses of the secondary system are applied along a line common to the shell part of the structure and its supporting members.

---

[13] With U. S. Reclamation Bureau, Denver, Colo.

The stresses and deflections of the membrane system are obtained as if the shell were a complete surface of revolution by means of Equations (101) to (110). The stresses at $\phi = 0$ and $\phi = \phi_k$ (it is assumed now that intermediate longitudinal members have been removed) are applied to the supporting members as reactions, and the deflections and stresses in these members are obtained in the usual manner. In general, there will be differences in these stresses and deflections, and it is the purpose of the secondary system to annul such geometrical discrepancies. It is the object of the author to derive the stresses and deflections in the shell due to this secondary system. When these stresses and deflections have been obtained in the shell for the various conditions of loading (see Fig. 4), the corresponding stresses and deflections are obtained for the supporting members.

In general, there will be eight elastic equations for the indeterminate quantities in the secondary system. In a symmetrical structure under symmetrical loading, such as that treated by the author, these equations reduce to four.

Finsterwalder[14] has reduced the number of unknowns to six by assuming that $\theta = 0$ at the connection of shell to supporting member. This condition is quite possible because of the relative rigidities of shell and boundary member. Corresponding to Equations (91) to (94) for symmetrical loading there would result three sets of four simultaneous equations each for the determination of the constants, A, B, C, and D, namely: in Equation (92), $N_2 = \frac{4}{c}$; $N_2 = 0$; and $N_2 = 0$; in Equation (93), $T_2 = 0$; $T_2 = \frac{4}{c}$; and $T_2 = 0$; in Equation (94), $\frac{\partial S}{\partial x} = 0$; $\frac{\partial S}{dx} = 0$; and $\frac{\partial S}{\partial x} = \frac{4}{c}$; and in Equation (98), $\theta = 0$; $\theta = 0$; and $\theta = 0$.

In all cases, M_2 (Equation (91)), would be different from zero. With the constants known the method of procedure follows that of the author except that for a case of symmetrical loading and symmetrical structure, the equations of continuity are, as follows: For $\phi = 0$:

$$\Delta w = (w)_s - (w)_b = 0 \ldots\ldots\ldots\ldots\ldots\ldots (144)$$

$$\Delta v = (v)_s - (v)_b = 0 \ldots\ldots\ldots\ldots\ldots\ldots (145)$$

and,

$$\Delta \sigma = \left(\frac{T_1}{t}\right)_s - \sigma_b = 0 \ldots\ldots\ldots\ldots\ldots\ldots (146)$$

in which the subscripts, s and b, refer to shell and beam, respectively, and σ = the unit stress. When the loading is unsymmetrical or the edge members are not identical, six or eight elastic equations are necessary. The equation for w will be set up in general form using the following definitions: $w_1 =$

---

[14] "Die Theorie der zylindrischen Schalengewölbe, System Zeiss-Dywidag," von Dr. Ing. Ulrich Finsterwalder, International Assoc. for Bridge and Structural Eng., Zurich, 1932.

deflection of shell due to membrane system at $\phi = 0$; w'_1 = deflection of shell due to membrane system at $\phi = \phi_k$; w_2 = deflection of beam due to membrane system at $\phi = 0$; w'_2 = deflection of beam due to membrane system at $\phi = \phi_k$; w_3 = deflection of shell due to secondary system at $\phi = 0$; w'_3 = deflection of shell due to secondary system at $\phi = \phi_k$; w_4 = deflection of beam due to secondary system at $\phi = 0$; and, w'_4 = deflection of beam due to secondary system at $\phi = \phi_k$. These deflections are broken up so that a symmetrical and contra-symmetrical system of secondary stresses may be applied.

For the symmetrical system:

$$\Delta w = \frac{(w_1 + w'_1)}{2} - \frac{(w_2 + w'_2)}{2} + \frac{(w_3 + w'_3)}{2} - \frac{(w_4 + w'_4)}{2} = 0 \quad ..(147)$$

and, for the contra-symmetrical system:

$$\Delta w = \frac{(w_1 - w'_1)}{2} - \frac{(w_2 - w'_2)}{2} + \frac{(w_3 - w'_3)}{2} - \frac{(w_4 - w'_4)}{2} = 0 \quad ..(148)$$

Corresponding equations are obtained for v and σ. Unsymmetrical loadings tend to cause large secondary stresses, and it is to be expected, in the case of the sector gate, that these high moments and stresses occur at $\phi = 0$.

Dr. W. Flügge[15] (by letter).—In general, the computations necessary for a numerical solution of shell problems have heretofore been very cumbersome. In the special case of a cylindrical shell of long span these computations may be simplified by applying the principles developed by J. W. Geckeler[6] and the author is to be congratulated on his analysis of the problem.

Following Equation (44) the author states:

> "By substituting Equations (38), (39), and (40), in Equation (35), and, likewise, by substituting Equations (42), (43), and (44), in Equation (36), it will be noted that two equations are obtained for the determination of the unknowns, J_2 and K_2. These simultaneous equations cannot be solved in explicit form."

It is possible to derive the explicit form by introducing the expression, $F(\phi) = e^{\mu\phi}$ into Equation (29) instead of Equation (31), thus[16]:

$$\mu^8 + 2\,(1 - a)\,\mu^6 + [1 - (4 + m)\,a + a^2]\,\mu^4$$
$$+ [-(2 + m)\,a + a^2]\,\mu^2 + 4\,a^2\,b^2\,(1 - m^2) = 0 \quad \ldots\ldots(149)$$

which is of the fourth order of μ^2 and may be solved by exact methods. The shell constants, J_1 and K_1, are the real numbers in the two terms of the complex number, μ; thus,

$$\mu_{1,2,3,4,} = \pm\,(J_1 \pm i\,K_1), \text{ and } \mu_{5,6,7,8,} = \pm\,(J'_1 \pm i\,K'_1)$$

The formula offered by the writer in 1934[16] is somewhat different from Equation (149):

$$\mu^8 + [-(2 + m)\,a + 2]\,\mu^6 + [(1 + 2m)\,a^2 - 2\,(2 + m)\,a + 1]\,\mu^4$$
$$+ [-m\,a^3 + (1 + m)^2\,a^2 - (2 + m)\,a]\,\mu^2 + 4\,a^2\,b^2\,(1 - m^2) = 0 \quad ..(150)$$

---

[15] Privatdozent, Univ. of Göttingen, Göttingen, Germany.

[16] "Statik und Dynamik der Schalen", von W. Flügge, Berlin, 1934, p. 139.

The disparity is of no numerical importance, however, and is to be explained by the different treatment of some second-order terms in the fundamental equations of the shell theory. It disappears entirely if Poisson's ratio, m, is made equal to zero, an assumption that may simplify the numerical computations, particularly of reinforced concrete shells. The error due to this assumption will be less than that introduced by the basic simplifications of the paper.

ANTON TEDESKO,[17] ESQ. (by letter).—In presenting a rather complex subject in a clear and useful form, Mr. Schorer has performed a splendid service to the profession. The suggested method gives good approximations of practical value over a wide range of cases. It would be interesting to investigate its degree of exactness beyond the limits given by the author.

Working for Dr. Finsterwalder, the writer has used other practical simplifications of his theory, the results of which checked well with those of the accurate method. Deformations may be calculated for statically determinate membrane stress conditions, such as are impossible in manifold statically indeterminate systems. Consequently, these deformations are eliminated in the calculations for the latter system. The unknown and resultant stress values of the indeterminate system are obtained from elastic equations conforming to the edge conditions. Where the differences of numerical values of trigonometric functions of the angle, ϕ, give inexact results, the equations for deformations are expressed in power series with the angle, ϕ, as the argument. In these, and in his trigonometric series, Dr. Finsterwalder neglected terms of higher order. He decreased the degree of statical indeterminacy by pairing a vertical and a horizontal force component with a moment, M_2, in such a manner that full restraint is obtained at the edge; or, in other words, that the direction of the tangent of the cross-sectional curve at the edge remained fixed. In the second series of calculations the tangent is assumed to rotate freely. After the degree of actual restraint is determined, the values already obtained are re-adjusted accordingly. When considering roof shell problems the value, N_2, at the edge can often be neglected because of its rather small size as compared with loads acting on the edge.

The author's corrected values, J_2, K_2, J'_2, and K'_2, as given in his Equations (70), (71), (72), and (73), should be used successfully in Finsterwalder's accurate method.

A very clear and almost popular explanation of the edge problem was given by H. Rüsch,[18] whose name second to that of Finsterwalder is connected with the development of the bending theory of cylindrical shells. Valuable bibliography on the subject has been listed by Mr. A. Floris in his discussion[19] of a paper by D. C. Coyle, M. Am. Soc. C. E. The fundamental equations and principles of the author's paper were given and discussed by H. Savage.[20]

Using his accurate theory Dr. Finsterwalder[21] has computed the stress values, T_1, S, T_2, and M_2 for the roof of the Central Market, in Budapest,[22] Hungary. The roof is constructed of cylindrical barrels of a span, $L = 136$ ft, a width of 38 ft 9 in., and a radius, $R = 32$ ft 10 in. It consists of segmental shells in combination with edge members, the cross-section of which

is shown in Fig. 11. A graphic picture of the meaning of the shell stress components, as discussed by the author, is given in Fig. 11 (*b*), 11 (*c*), 11 (*d*), and 11 (*e*), in which the solid-line curves denote values determined by the accurate theory (considering the first two terms of the Fourier series); and the broken-line curves denote values determined for the membraneous condition. The stresses are given for $x = 0$ and $x = \frac{L}{2}$, with reference to Fig. 1 of the paper.

[21] *Ingenieur Archiv*, Vol. IV, 1933, p. 57.

[22] *The Architectural Forum*, Vol. LX, May, 1934, p. 354.

The thrust, T_2, in the transverse direction of the shell, according to Equation (101) for the membrane system, is a direct function of the radius and the load of the shell. These values of T_2 are indicated by a broken line in Fig. 11 and are nearly constant over the width of the barrel. The thrust, T_2, of the statically indeterminate system is indicated by a solid line. It has its maximum value at the crown of the barrel and decreases to a small value near the edge members which are too slender to take up a considerable amount of horizontal force. The resulting maximum thrust at the crown is greater than the statically determinate thrust required to carry the given load. The excessive crown thrust results in an increased carrying capacity of the crown portion where the shell acts as a support for loads from other parts of the shell. The supporting action at the crown and at the edge members is also expressed by the moment line, M_2, of the arched plate where negative restraining moments appear at the crown and at the edge members. The bending moments are small, however, because small spans only between narrowly spaced ideal supports have to be bridged by bending action. Furthermore, only a part of the load will cause bending as the other parts are carried by the thrust directly. The thrust, T_2, toward the edge members is decreased by shearing forces, S, transferring the loads to transverse end stiffeners. The T_1-diagram (Fig. 11 (*b*)) shows compression in the shell and tension in the edge member, a distribution which could be expected for such a "T-beam with curved flange."

The limiting equation for the author's method is Equation (46), $\frac{L}{R} \geqq \pi$. In the method to which the writer has referred as "Finsterwalder's accurate theory," the longitudinal bending moment, M_1, the corresponding shearing stress component, N_1, and the torsional moment, M_t (see Fig. 3), are neglected. This simplifying assumption does not influence the results in practical cases when $\frac{L}{R} \geqq 1$, or even when $\frac{L}{R}$ is slightly less than 1. For the example to which the stress diagrams in Fig. 11 apply, the value, $\frac{L}{R}$, is equal to 4.15 and the author's method will give practically the same curves. For cases in which a shell of very great radius, R, has transverse end stiffeners quite close together, even the results of Dr. Finsterwalder's ingenious theory will become inaccurate.

DR. ING. U. FINSTERWALDER[38] (by letter).—A clear and interesting contribution to the problems of cylindrical shells, and one that will be useful for the designing engineer, is contained in this paper. Various methods are in use to simplify cumbersome numerical computations in connection with the writer's theory.[8] Accurate stress values are obtained by the use of a simplifying hypothesis; namely, that for each case of unit loading the relationship between the work of deformation of the bending stress components and the direct stress components is constant for all proportions of a shell. With the help of this hypothesis it is possible to arrive at stress values for a given shell from stress values of cases that have been computed by the use of the rather cumbersome formulas of the writer's theory.

---

[38] Chf. Engr., Dyckerhoff & Widmann, A. G., Berlin, Germany.

The writer neglected bending moments in the direction of the generatrix of the cylindrical shell. The solution as proposed by Mr. Schorer neglects, more or less, the bending resistance of the cylindrical shell in the direction of the generatrix, and also the influence of the stress components, S and T_2, on the work of deformation. For shells with widely spaced transverse stiffeners and of small widths the author's solution will be accurate. The rise of the cylindrical segment will then be comparatively small and the stress components, S and T_2, will not play an important part in the work of deformation. However, for very wide cylindrical shells, and although the distance between end stiffeners may be considerable, the influence of S and T_2 will be noticeable, and Mr. Schorer's solution may become inaccurate.

Professor F. Dischinger has worked on the problem, and has recently found the exact solution.[34] It is not more complicated than the writer's theory, although Professor Dischinger was able to eliminate the simplifying assumptions of the writer.

F. W. SEIDENSTICKER,[35] ESQ. (by letter).—Knowing from experience that many readers are reluctant to follow through a series of difficult mathematical derivations, the writer fears that, in many cases, only the "Synopsis" and "Conclusions" of this excellent paper will be read. The wording of the concluding remarks may be misleading to the average engineer unless they are read as a part of the whole subject.

The fact that the proposed method of shell design is termed an approximation does not mean that it will be unsafe to use this method for practical applications, especially if one considers that the established formulas of structural design for use in standard steel and reinforced concrete structures involve a much higher degree of inaccuracy than the method presented by Mr. Schorer. His results are within a small percentage of the elastic theory. They become less accurate in cases where the stiffening supports are narrowly spaced. However, an exact solution in that case will be less necessary; it would be interesting to mathematical physicists, but less so to engineers, since structures of small spans usually do not justify a great amount of intricate engineering computations.

Good agreement between theory and practice was recently found in the results of full-sized loading tests[36] conducted during the demolition of cylindrical barrels at the Century of Progress grounds, in Chicago, Ill.

Herman Schorer,[27] Assoc. M. Am. Soc. C. E. (by letter).—An interesting outline for the analysis of a sector gate is contained in the discussion by Mr. Silverman. In steel structures of this type, with comparatively heavy surface loads, it may become necessary to make provisions against buckling of the skin-plate in a longitudinal and radial direction, depending on the relative dimensions. As a rule, the shell is comparatively stiff in the longitudinal direction and the rim-bending stresses are limited to a narrow zone along the stiff end members. For this reason the intermediate longitudinal members, as shown in Fig. 9, could probably be eliminated. However, the danger of buckling in a radial direction would require closer investigation since the resistance of the arch is reduced by the large radial bending moments, originating from the heavy longitudinal edge member at $\phi = 0$. The necessary stiffness in a radial direction can be obtained by the provision of small radial ribs, welded to the skin-plate, perhaps combined with a few longitudinal ribs at the center zone of long spans.

Dr. Flügge's solution for J_2 and K_2 in explicit form represents a desirable improvement and will be welcomed by those who are interested in a more exact analysis of the problem. Mr. Tedesko contributes a practical illustration of the stress components in the roof of the Market Hall, in Budapest, one of the most outstanding shell structures.

The writer is greatly indebted to Dr. Finsterwalder for pointing out the exact solution of the entire problem, as recently published by Professor Dischinger[24], which enables the designer to include the stress components and simplifications neglected thus far. It also includes anisotropic shells (that is, shells with non-uniform bending resistance in different directions), such as those introduced by a series of radial or longitudinal stiffening ribs.

The discussion by Mr. Seidensticker is encouraging and his reference to the full-sized loading tests in Chicago is very timely. The excellent behavior of these structures under non-symmetrical loadings appears in striking contrast to the expectations derived from pure arch action.

UNDERGROUND CORROSION

By K. H. Logan,[1] Esq.

With Discussion by Messrs. Thomas F. Wolfe, John R. Baylis, E. P. Fetherstonhaugh, John F. Skinner, F. N. Speller, and K. H. Logan.

Synopsis

Underground corrosion is shown to be of economic importance by the fact that associations of pipe owners and pipe-owning corporations are spending considerable sums for the study of corrosion problems. The underground pipes in the United States have been estimated to have a length of 450 000 miles and a value of nearly $6 000 000 000. The annual loss due to underground corrosion of pipe lines in the oil industry alone has been estimated at $25 000 000.

Soil corrosion is characterized by the uneven distribution of the corrosion and the fact that most ferrous pipe materials corrode at nearly the same rates. The major cause of the corrosion seems to be non-uniformity in the distribution of oxygen and moisture along the surface of the pipe line.

Among the methods suggested for reducing corrosion losses are the use of copper and copper alloy pipe which corrode less rapidly than ferrous materials; increasing the thickness of the pipe walls; and the use of protective coatings.

Soil corrosivity surveys are suggested as a means for determining the need for protective coatings. Some of the weaknesses of coatings are noted and cathodic protection is suggested as a means of improving the effectiveness of coatings. In an Appendix are listed some of the more important recent articles on underground corrosion and related subjects.

Note.—Publication of this paper has been approved by the Director of the Bureau of Standards of the U. S. Dept. of Commerce. Presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 18, 1934, and published in March, 1935, *Proceedings*.

[1] Chf., Underground Corrosion Section, National Bureau of Standards, Washington D. C.

THE IMPORTANCE OF THE PROBLEM

A recent compilation gives the amount of underground trunk and distribution mains in the United States as 450 800 miles, having an estimated value of nearly $6 000 000 000. In addition, there are approximately 14 000 000 gas-service pipes and probably at least an equal number of water services. No estimate has been made of the mileage of underground pipe in use for waste disposal, but it will approximate that used for water services. The amount and value of the ferrous material exposed to the action of soil, therefore, are enormous, and even a moderate reduction in the rate of deterioration of underground pipe lines is important.

In 1931,[2] Carl R. Weidner, Assoc. M. Am. Soc. C. E., estimated the annual loss to the pipe industry on account of underground corrosion, at $50 000 000. Presumably, this value refers to oil lines, and if so, it should be multiplied by at least three to represent the losses on all underground pipe. In view of the large losses sustained by gas and oil companies on account of underground corrosion and the efforts which these organizations are making to reduce these losses, it is a little surprising that equal attention to the subject is not given by the owners of lines carrying water. Aside from the unlikely explanation that water lines do not corrode, several others might be offered. In general, the owners of water pipes are not as well organized to fight corrosion since they consist largely of independent municipalities and individuals. Water mains usually have greater wall thickness than gas mains of the same diameter and, as will be shown later, wall thickness is an important factor in pipe life. Moreover, water leaks of the same magnitude are less serious than leaks of oil or gas because of the damage which the latter cause to property and because of the fire and explosion hazard accompanying gas leaks in cities. The tendency to use thinner-walled pipe and to place expensive pavement over distribution mains makes it more important to reduce the corrosion losses to a minimum.

At first, it was customary to attribute all underground corrosion in cities to stray-current electrolysis. The improvement of operating conditions on some street railways and the abandonment of street-car lines have focused more attention on soil conditions.

CHARACTERISTICS AND CAUSES OF UNDERGROUND CORROSION

The findings of the National Bureau of Standards with respect to the action of soils have been presented in various ways and on numerous occasions. The repetition of four major conclusions herein is not for the purpose of imparting new information, but to establish a basis for the discussion of the reasons for the suggestions made in this paper.

Briefly, the Bureau has found: First, that the differences in the rates of corrosion of the commonly used ferrous pipe materials are of the same order of magnitude as those of different specimens of the same material; and, second, that the character and seriousness of soil action vary with the soil condition to which the material is exposed. This latter variation is so great that it appears to be a much more important factor than the choice of ferrous pipe material. Figs. 1, 2, and 3, are views of 6-in. lengths of 1½-in. pipe of three different materials. (If the reader will face toward a source of direct light, preferably sunlight, so that the captions of Figs. 1, 2, and 3 are on his right, the pitted condition of the pipe surface will be apparent. If the illustrations are reversed the pits will appear as projections.) The similarity of the corrosion pattern of the three materials in the same soil is shown, as is the difference between the patterns in different soils. The wide difference which may occur in the rates of corrosion of the specimens of the same material in the same soil is illustrated by Fig. 1. The third characteristic of soil corrosion which must be considered is that the rate of corrosion after a pipe has been exposed to soil for several years is considerably less than for the first period of exposure. A fourth characteristic of underground corrosion (which not only is of great economic importance, but is suggestive of the cause of corrosion) is the unevenness of the distribution of the corrosion over the surface of the buried metal. Sometimes a length or section of pipe is penetrated at only one point, whereas almost no corrosion is found elsewhere on the section. The pitting is usually confined to the bottom of the pipe, but occasionally the most severe corrosion is found on the sides or top.

---

[2] Opening Remarks to Group Session on "Corrosion of Oil Field Equipment," by C. R. Weidner, *Proceedings*, Am. Petroleum Inst., Vol. 12, Pt. 4, p. 26 (*Production Bulletin 208*).

The most interesting characteristic of underground corrosion is the irregular or spotty nature of the attack. The loss of material as such is usually too small to be of importance if it were uniformly distributed over the pipe surface. It will be helpful, in understanding these findings, to construct at least a tentative explanation of underground corrosion processes.

When the electrolytic theory of corrosion became generally accepted, the first explanation offered for the formation of pits in the pipe surface was impurities or segregations in the pipe material. This conclusion was supported by the fact that where impurities were known to exist, differences in electrical potential between the impurities and the metal could be measured. It was shown that there was a difference of potential between oxidized metal or mill scale and bright iron, and strains in metal were also shown to result in differences of potential. It was logical to assume that these potential differences resulted in corroding currents when the metal was exposed to an electrolyte. Of course, other differences of potential were observed when different metals, or two varieties of the same metal, were in metallic contact.

The mistake that has been made is not in reasoning but in evaluating the importance of the conclusion. There can be little doubt that some corrosion results as suggested, and that under some conditions one of these causes of corrosion is the controlling one. When materials are buried in soil, however, and under some other conditions as well, other causes of corrosion are more important.

The influence on corrosion of causes external to the pipe was brought forcibly to the attention of the observers at the Bureau of Standards when the first specimens of pipe were examined after approximately two years of exposure to widely different soils, and is illustrated in Figs. 1, 2, and 3. It was observed that in certain soils the corrosion took the form of isolated pits

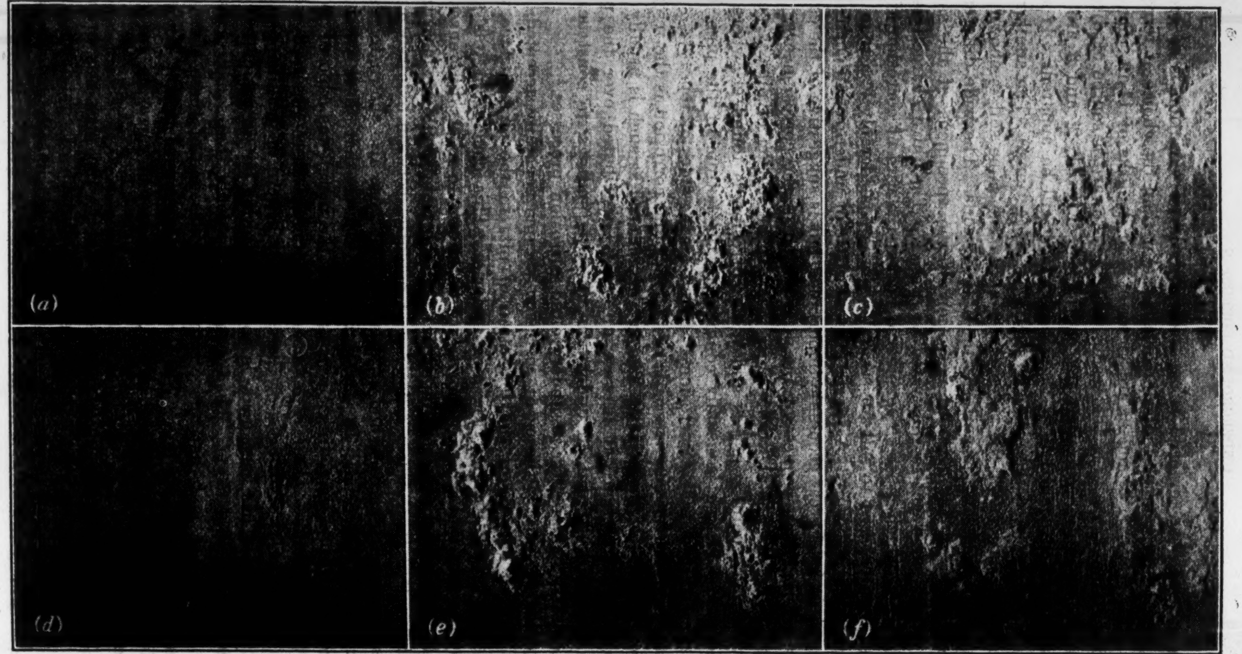

FIG. 1.—SPECIMENS OF OPEN-HEARTH IRON PIPE CORRODED BY TEN YEARS OF CONTACT WITH: (*a*) AND (*d*), WET SILT LOAM; (*b*) AND (*e*) HEMPSTEAD SILT LOAM; AND (*c*) AND (*f*) ONTARIO LOAM.

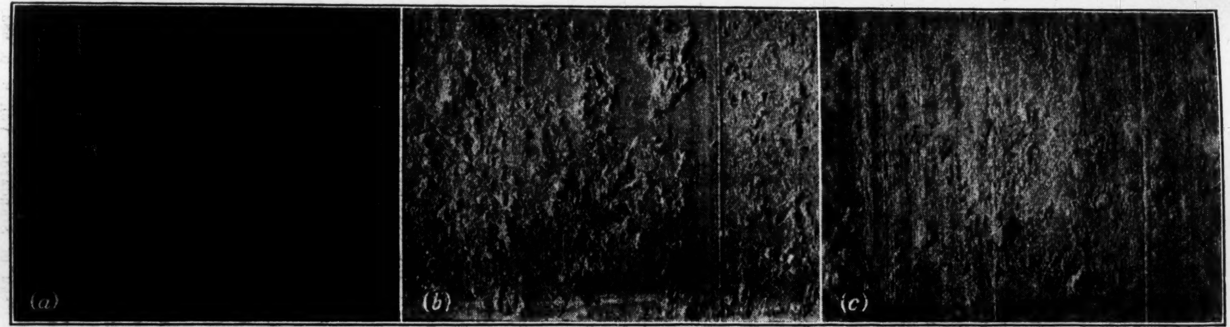

FIG. 2.—SPECIMENS OF WROUGHT-IRON PIPE, CORRODED BY TEN YEARS OF CONTACT WITH: (*a*) WET SILT LOAM; (*b*) HEMPSTEAD SILT LOAM; AND (*c*) ONTARIO LOAM.

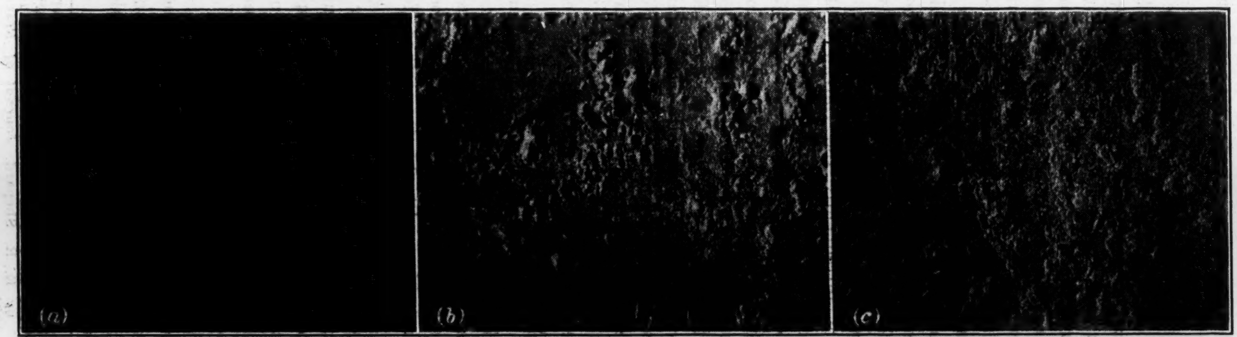

FIG. 3.—SPECIMENS OF BESSEMER STEEL PIPE, CORRODED BY TEN YEARS OF CONTACT WITH: (*a*) WET SILT LOAM; (*b*) HEMPSTEAD SILT LOAM; AND (*c*) ONTARIO LOAM.

with sharp margins. In other soils the corroded areas took the form of rather large shallow depressions with no well-defined boundaries. In one soil the removal of metal was very uniform over the entire exposed surface. Differences in the quantities and distribution of the impurities or strains might account for these differences in corrosion. That this was not the correct explanation was shown by the fact that, almost without exception, whenever Bessemer steel showed one form of corrosion, pure open-hearth iron, wrought iron, and specimens of Bessemer steel from another rolling mill showed similar corrosion patterns. Evidently, therefore, the corrosion pattern was primarily a function of the soil condition, and to a minimum extent only, a characteristic of the material. Although this observation was made public in 1927, and has been re-stated many times, its importance is still not fully appreciated.

Not infrequently the Bureau of Standards is asked what is the life of a certain type of pipe material. This will depend on the thickness of the pipe wall and the type of soil to which it is exposed. It will also depend on the area[3] exposed and on the definition of pipe life. Sometimes the inquirer has in mind the time until the first leak develops; others wish to know how long the pipe can be kept in service economically, which, of course, depends partly on the cost of repairs. In certain soils 8-in. steel oil lines have begun to develop leaks within six years after construction, although such early leaks are few. In other soils pipes have remained in service from 50 to more than 273 years. Only a small percentage of the soils of the United States are severely corrosive, but the individual corrosive areas are small in extent and widely distributed.

It is inadvisable therefore, to attempt to protect the entire length of a long line against corrosion unless the consequences of a few leaks would be very serious. Since underground corrosion is largely the result of certain soil characteristics many attempts have been made to correlate corrosion with soil properties and to develop methods for identifying corrosive soils. The location of corrosive soils along a pipe line is commonly known as a soil corrosivity survey or as a soil survey. The latter name is unsatisfactory because it has been previously used by the Department of Agriculture to indicate the identification and mapping of soils with respect to their physical appearance. Soil corrosivity surveys will be discussed in a subsequent section of this paper.

Soil Characteristics That Determine the Form and Rates of Corrosion.—In the course of an investigation of the relation of pipe-line currents to corrosion, Shepard[4] noted that the soils in which corrosion was most active were lower in electrical resistance than the adjacent soils. The lower resistance could be accounted for by higher percentages of water or of soluble salts. Of course, these differences would appear in complete soil analyses, but were obscured by other data.

---

[3] "Adjustment of Soil Corrosion Pit-Depth Measurements for Size of Sample," by G. N. Scott, *Proceedings*, Am. Petroleum Inst., Vol. 14, Pt. 4, p. 204.

[4] "Pipe Line Currents and Soil Resistance, as Indicators of Local Corrosive Soil Areas," by E. R. Shepard, *Journal of Research*, Bureau of Standards, Vol. 6, p. 683, April, 1931.

It is not to be inferred from the fact that soils of low resistance are corrosive that the corrosivity is proportional to the conductivity of the soil or that the conductivity of the soil is in itself the cause of the corrosion. It appears, however, that the conductivity of the soil either is a factor or is associated with some soil property which influences and sometimes controls the corrosivity of the soil. Although soils of low electrical resistance are usually corrosive, exceptions are known, and some soils having high resistivity are quite corrosive. Therefore, it must be concluded that while in accordance with the electrolytic theory of corrosion the conductivity of the soil is a factor, in some instances, other factors are more important.

After a study of a wide variety of soils, Denison,[5] concluded that there was a relation between the acidity and the corrosiveness of soils. However, as in the case of the resistivity-corrosion relation, cases were found in which the correlation was unsatisfactory. Investigators are thus led to the conclusion that soil acidity is a factor affecting the rate of corrosion, but that it is not in all cases the controlling factor and, perhaps, not the fundamental one.

Consideration of underground corrosion phenomena occurring under widely different conditions leads to the conclusion that there are several, perhaps numerous, factors which modify the more fundamental causes of corrosion. In an unpublished communication to the Corrosion Committee of the American Petroleum Institute Denison introduces his discussion of corrosion in acid soils, as follows:

> "Corrosion of ferrous metals in soils may be assumed generally to originate in differences in potential between parts of the metal surface accessible to the oxygen of the atmosphere and other parts from which air is completely or partially excluded. According to this explanation, corrosion occurs at the points of contact between metal and soil which are anodic to adjacent areas more accessible to air. This general statement of the 'differential aeration' theory may be used as a basis for understanding the various forms of corrosion which are encountered in pipe line operation and to explain the marked differences which have been observed in the corrosiveness of soils."

The importance of oxygen concentration was first realized in 1916 by Aston,[6] although the creation of electric currents by variations in oxygen concentration was observed at a much earlier date. The importance of the phenomenon has been pointed out by Evans,[7] in a number of papers. Evans, however, has confined his attention largely to atmospheric and underwater corrosion which does not involve so many uncontrollable factors.

It now seems probable that the electrolytic theory will account for observed corrosion underground if it is assumed that the impelling differences of potential originate largely in differences of oxygen supply at various points on the surface of the buried metal, and that the potentials, or the conductance, of the path over which the corroding current flows, or both, are modified by secondary reactions such as polarization and the deposition of corrosion products.

[7] "Corrosion of Metals," by U. R. Evans, Edward Arnold & Co., London, England.

The decrease in the rate of penetration with time manifested by the Bureau of Standards specimens and by a number of pipe systems for which records have been kept, can be explained by the protective effect of the corrosion products that are formed, or by the restriction of oxygen resulting from the settling of the soil in the trench and the increased uniformity of trench conditions. The determination of which change is the more effective is important since, as will be shown later, it is a factor in decisions as to the effectiveness of protective coatings.

THE REDUCTION OF CORROSION LOSSES

To be logical and complete, this paper should contain a section dealing with the estimation of rates of corrosion and their relation to the useful life of pipe. To be helpful, such a discussion would have to be long, since the problem is a complicated one. The writer has chosen, therefore, to avoid this subject for the present and to proceed directly to a discussion of the reduction of corrosion losses. The proposed methods follow from the ideas set forth in the preceding section. The recommendations follow the form of the ancient and well-known recipe for the cooking of a hare.

Soil Corrosivity Surveys.—As one should first catch the hare, so should the engineer first locate his corrosion. The most serious corrosion, of course, will locate itself, but as soon as the engineer is surprised by the first leak in his line, he begins to wonder how much of the line is about to fail. Experience indicates that many miles of line have been needlessly uncovered and reconditioned because the owner feared that the first few leaks would be followed by others with increasing frequency. As a result of investigations at the Bureau of Standards, based on the principles of underground corrosion which have just been enumerated, several practical methods have been developed by which the pipe-line operator can determine the point of most serious corrosion. The principles and limitations of the older and more frequently used resistivity test have been described by Shepard.[4] The method has been tested in widely separated sections of the United States under several soil conditions. In all cases it has been the means of locating some of the corrosive areas. Ewing made a study of the corrosiveness of soils along the right of way of an oil line in one of the Central States, using several methods for testing the soils and comparing the results with the replacement records for the pipe line.[8] He concluded that neither soil resistivity nor soil acidity alone is a satisfactory indicator of soil corrosivity and found that by combining the two tests with information as to soil types a useful result could be obtained. He also developed a formula for determining what part of a line should be protected against corrosion and a method for determining the economic value of soil corrosion surveys.

It is scarcely to be expected that any correlation of soil conditions at a specific time with the corrosion occurring at the selected point throughout an extended period of time can be perfect, since the action of the soil is modified by the effects of temperature, oxygen, and moisture supplies, and by local conditions which often cannot be recognized. Moreover, until methods for controlling corrosive conditions are much improved, the corrosiveness of the soil cannot be expressed by a single value. When such value is available it must be understood that it is an average and that in individual cases the observed value can be expected to be greater or less by a considerable percentage. Nevertheless, values for corrosiveness are quite useful and soil surveys which indicate even in a general way that the soil in question is not corrosive, mildly corrosive, or very corrosive, may more than justify their cost.

---

[8] "Corrosion Surveys for Transmission Lines and Distribution Systems," by S. P. Ewing, *Proceedings*, Am. Gas Assoc., 1934, p. 846.

It seems probable that if a pipe line traversing open country is to be laid or reconditioned, a systematic soil survey by a competent engineer will be justified. If the line traverses territory in which the natural soil conditions have been seriously modified by Man, as city streets containing fills of foreign material, sewer leaks, or discharges from chemical plants, or if the pipe lies beneath pavement, the economy of a survey is somewhat more doubtful, although success under these adverse conditions has been reported by Smith.[9] For the benefit of those who wish to study the subject, a list of the more important recent articles on soil corrosivity surveys is included in the Appendix.

Although probably less than 10% of the underground pipes of the country is in corrosive soil, it is likely that any extensive corrosion survey will locate one or more places where a reduction of the possible corrosive effects of the soil seems desirable. The engineer is then faced with the choice of a method for maintaining his line in one or more localities. The preferable method will depend on local conditions. Since corrosion underground has been attributed to variations in the supply of oxygen at different points along the line, an obvious method of preventing it is to secure uniform conditions with respect to oxygen. Unfortunately, the application of this principle is limited. To bury a pipe deeply is helpful unless the change in soil character and moisture with depth is unfavorable. Likewise, uniform tamping of the soil is conducive to uniform conditions. It has been suggested that the laying of a pavement over the pipe would reduce the oxygen supply and, consequently, the corrosion. This may be true only if the entire line is under pavement; otherwise, one might expect galvanic action between the pipe beneath the pavement and that in unpaved streets, with the corrosion occurring under the pavement because of the smaller quantity of oxygen there. Refilling the trench partly with less corrosive soil has been tried, but no reports as to the effectiveness of the treatment are known to the writer.

Selection of Materials.—The demand for a less corrodible pipe material is perennial, and a variety of ferrous alloys have been offered to meet this demand. The results of the investigation by the Bureau of Standards do not encourage hope in this direction if the cost of the material is considered.

It is possible that a ply-metal pipe having a corrosion-resistant metal on the outside may be developed which will not be too costly for use under conditions in which the renewal of the pipe would be expensive. Copper and high copper alloys resist nearly all soils better than ferrous materials and are being used successfully for pipes of small diameter. However, very thin copper sheet used as a shield for bituminous coatings has failed under some soil conditions.

---

[9] "A Practical Soil Corrosion Survey with Shepard Soil Corrosivity Rods," by A. V. Smith, *Proceedings*, Am. Gas Assoc., 1932, p. 790.

Those demanding more resistant pipe materials may do well to consider the significance of curves representing the change in rate of penetration with time as has been previously mentioned. Whatever the cause for the decline in the rate of pitting, there can be little doubt that in many soils this decline is so great that corrosion penetrates but slowly after the first few years. In such soils the failure of pipe lines could be minimized by providing a wall sufficient to withstand the initial attack and the subsequent slow penetration. In many instances the wall thickness required for an unusually long life before penetration, does not appear to be prohibitive. It may be better engineering to provide extra wall thickness rather than to invest in corrosion-resistant materials or protective coatings.

Experience has shown that the life of many protective coatings is rather limited. It is possible, however, that the usefulness of short-lived coatings has been under-estimated. If the decrease in the rate of corrosion previously referred to is largely the result of the settling of the back-fill of the trench (that is, the establishment of more nearly uniform conditions along the pipe with respect to its contact with the soil and to the supply of moisture and oxygen), a coating which will last until these conditions have been established will eliminate that part of the corrosion-time curve which represents the period of rapid corrosion and will greatly extend the life of the pipe.

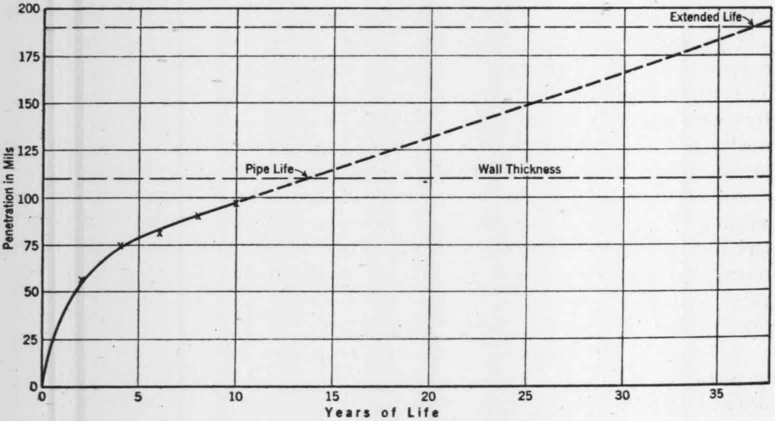

FIG. 4.—PENETRATION-TIME RELATION FOR A ¾-INCH STEEL SERVICE PIPE IN SUSQUEHANNA CLAY, AT MERIDIAN, MISS.

The effect of an increase in the thickness of the wall of a small pipe and the service performed by a temporary protective coating on such a pipe can both be seen by studying Fig. 4, the solid part of which shows the maximum penetration-time relation for wrought-iron and steel specimens in Susquehanna clay near Meridian, Miss. This curve is offered not as representative of corrosion in all soils, but only to illustrate the action of one soil with respect to ferrous metals. To be on the conservative side the curve has been extrapolated as a straight line, although it may bend downward because of the protective effects of corrosion products.

Consider the corrosion of a $\frac{3}{4}$-in. water service pipe the wall thickness of which is 0.11 in. It traverses a stratum of Susquehanna clay, a common Southern soil with stiff, plastic, red, heavy clay subsoil which becomes mottled in the lower part with gray, or bluish gray, red, and yellow. Fig. 4 indicates that the wall of this pipe will be punctured in a little less than 14 yr. If extra strong pipe, with a wall thickness of 0.154 in., or 40% greater, is used the life of the pipe should be approximately 26 yr, or nearly twice as long. If the standard pipe is galvanized or protected by a bituminous coating which will prevent corrosion for 5 yr (the period represented by the steep part of the curve), and if the corrosion decreases, only because of the settling of the trench as suggested previously, corrosion will begin at the end of the 5-yr period and progress as indicated by that part of the curve beyond the 5-yr point. Under this hypothesis, the application of the coating is equivalent (for corrosion-resisting purposes) to the addition of 80 mils (1 mil = 0.001 in.) to the thickness of the pipe wall, and the expected life of the pipe is extended from 14 to 37 yr, as is indicated by the intersection of the horizontal line representing 110 + 80 mils with the pitting-time curve. Thus, a coating lasting 5 yr may extend the life of a pipe 23 yr.

It must be remembered, however, that any conclusion is only as valid as the premises on which it is based. It is improbable that the decrease in the rate of corrosion is solely the result of the settling of the back-fill. Probably the formation of corrosion products plays an important part. If the settling of the trench has no effect, when the coating fails, corrosion begins as on a newly laid pipe and the extension of its life by the coating is equivalent only to the life of the coating. Probably the actual condition lies somewhere between the two extreme assumptions. The chief purpose of the present discussion is to call attention to the need for more complete and definite data on corrosion processes. Until such information is available the safe course is to provide as much protection for buried lines as can be justified.

Protective Coatings.—The idea is common that a moderately good coating is satisfactory for a moderately corrosive soil. There is no fundamental relation, of course, between the rates of deterioration of coating and of pipe since they are quite different materials and deteriorate for quite different reasons. The period of effectiveness necessary to justify the use of a coating is longer in a mildly corrosive soil than in a severely corrosive one. If a coating costs 10% of the cost of the line and if it prolongs the life of a line from 10 yr to a little more than 11 yr, it pays for itself; but if it lasts the same length of time on a line which would last 30 yr without the coating, it has increased the life of the line only 3% at a cost of 10% plus the interest on the additional investment. Recently, a water-works engineer in planning a new line, allowed a life extension of 5 yr for a coating to be applied to a line having an estimated life, bare, of 70 yr. A little thought will show that the interest paid on the initial investment for the coating will double that investment several times in the course of the life of the line, and that the cost per year of the protected line will be considerably higher than it would have been without the coating.

In 1924, the Bureau of Standards buried a considerable number of specimens of galvanized and lead-coated pipe in a variety of soils. These coatings have deteriorated slowly and until recently it has not been possible to make statements of practical value regarding their usefulness. The Bureau's data as to the corrosion of galvanized steel indicate that the protection afforded by the zinc coating is to be ascribed to the low corrodibility of that metal rather than to the fact that the zinc is anodic to steel. Tests of 2-oz coatings of zinc applied to pipe and sheet steel indicate that rust spots may be expected in a few soils within 4 yr, whereas in other soils more corrosive with respect to steel, rust will not appear for 6 or 8 yr.

At this time a definite relation between any soil characteristic and the rate of corrosion of zinc has not been recognized. Some acid soils appear to attack the coating, whereas other soils having higher acidity do not seriously affect it. In one severely corrosive alkali soil a 2-oz zinc coating failed within 2 yr. In less corrosive alkali soils, however, the same coating has shown much more satisfactory resistance.'

A comparison of the rates of penetration of lead-coated steel and plain steel does not show, definitely, an increased rate of corrosion of the steel after puncture of the lead because of electrolytic action between the two metals. Sometimes, the punctured lead coating appears to corrode more rapidly than bare steel and sometimes less rapidly. Whether the differences in the rates of corrosion are accidental or whether they are the results of different electrolytes is not known.

Research on bituminous pipe coatings has been handicapped by the inability of the Bureau to keep the same man on the problem continuously. Most of the bituminous coating work at the Bureau has been done by research associates supported by the American Gas Association and the American Petroleum Institute. The results of their work will be much more valuable after later examinations of coatings which they have had exposed to soils since 1929 and 1930. These results are most directly applicable to steel pipe lines of moderate diameters. The recommended treatment for these lines may require some modification before they are suitable for service pipes, cast-iron pipe, or pipes of large diameter.

The work indicates that the failure of properly applied bituminous coatings is usually caused by stones or earth clods. The remedy indicated is to shield or reinforce the coating by a layer of rather stiff material, such as roofing felt. For soils that are destructive to organic fabrics, a metallic or asbestos reinforcing material is preferable. As yet, the lives of the better types of bituminous coatings have not been determined. However, a sufficient number of specimens have been buried to yield satisfactory data on coating life if the project can be continued over the period of time necessary for an adequate exposure of the coatings.

Several satisfactory methods for determining the condition of a pipe coating have been developed, but no entirely satisfactory accelerated test for coatings has been proposed. While the desirability of buying coatings on the basis of performance specifications has been recognized, no such specifications are in general use and the lack of convincing data makes the writing of such specifications, at this time, difficult and unsatisfactory.

In 1933 an electrical test[10] was developed whereby the application of a continuous coating could be insured. The writer had an opportunity to test a coating which had been applied so as to meet this continuity test. After the coated pipe had been laid in the ditch and covered, the test indicated that one or more bare spots had developed. In other words, the benefits of the careful application of the coating had been lost to a large extent because of careless treatment of the coated pipe.

The purchaser of a pipe coating should consider not only whether its fundamental properties are satisfactory but also the probability of getting it in the ground in a satisfactory condition. If the size or weight of the pipe section is so great that it cannot be handled commercially without injury to the coating, the advisability of the coating is at least debatable.

Cathodic Protection.—Fortunately, a method of treating coated pipes has been developed within the last few years which, under favorable conditions, protects the abraded parts. This is known as cathodic protection and has been well described by Kuhn[11] and by Thayer.[12] Essentially, the method consists in maintaining a negative charge in the pipe line with respect to the adjacent earth by means of a superimposed current supplied by a rectifier. The economic success of the method depends on the insulating properties of the protective coating. If the coating is impervious to moisture and has not been broken in too many places, an inexpensive amount of current may prevent corrosion. Cathodic protection of bare lines, or of coated lines in metallic contact with bare lines, is not feasible because of the amount of current required.

NEED FOR CORROSION RESEARCH

The purpose of this paper is primarily to show the status of the fight against corrosion. If the statements that have been made herein regarding rates of corrosion have been indefinite, and if the suggestions as to methods of reducing corrosion have been vague, it is because the collection of satisfactory corrosion data is necessarily slow and expensive. A definite plan of study has been outlined by students of corrosion, and definite progress has been made. The continuation of the work for a few more years should yield definite results.

DISCUSSION

THOMAS F. WOLFE,[13] M. AM. SOC. C. E. (by letter).—A concise description of the corrosion study being conducted at the National Bureau of Standards, is presented in this paper. In spite of the fact that metal pipes have been used underground in the United States for considerably more than a century, the investigation of the corrosive effects of soil had not been given the attention it deserved until investigators at the Bureau began their studies, which were based on a long-time plan and covered a number of different types of soil. In some of the tests conducted prior to this development, changes in management or in the personnel resulted either in discontinuing the test or in the loss of some of the data that would have been useful in interpreting the results. The tests at the Bureau of Standards have been based on a definite plan and from the very beginning have been under the direction of one man continuously thereafter.

The impetus responsible for the intensive study of soil corrosion was probably furnished by the fact that oil and gas lines installed in the early days of cross-country transmission were beginning to show signs of deterioration. Many of these lines were laid in soils that were more corrosive than soils in other sections of the country where pipes of considerably greater age were still giving service. These older pipes as a rule were cast-iron water mains and gas mains and had wall thicknesses in excess of that in the pipe used for gas and oil transmission lines.

The original idea behind the tests at the Bureau was not to develop information concerning relative merits of pipe materials when exposed to soil corrosion, but rather to determine the corrosive qualities of soils. However, the use of a number of types of ferrous pipe specimens in the work has led some engineers to use the data for the comparison of materials. Although the continuation of the tests described by Mr. Logan, at some future time, may warrant drawing conclusions as to relative lives of materials under similar soil conditions, it would seem wise at this time to reserve judgment on this phase of the problem until more data are available. It cannot be stressed too strongly that this work is really pioneer work and, although of considerable value, great care should be taken in using data that are necessarily based on short-time testing.

One of the dangers to be avoided in the use of these soil corrosion data is to attempt at this time to develop any hard and fast rule regarding pipeline depreciation. The best guide as to what depreciation actually occurs is to examine specimens removed from the property under consideration. The attempt to correlate any given soil with one of the soils presented in the paper, without having an intimate knowledge of soils, may lead one far astray. Even more serious error would result from attempting to predict depreciation according to the geographic location of pipe; for instance, one of the most corrosive soils under test is peat. The only test specimens buried in this particular soil in the original tests happens to be in Milwaukee, Wis. However, very few of the pipe lines in service in Milwaukee are actually laid in peat soil consequently, any one examining the data and predicting a life for Milwaukee pipe based on the specimens in Milwaukee would be very much in error.

---

[13] Research Engr., Cast Iron Pipe Research Assoc., Chicago, Ill.

In addition to valuing pipe lines the data may finally come into use in the selection of materials for underground pipe construction. Under some conditions longevity is of much more importance than under other conditions. For instance, a gathering line in an oil field that has a limited life need last no longer than the field. On the other hand, a water line in a city street would properly be considered a permanent necessity. The economical angle varies also with location. Maintenance, reconditioning, or re-laying of cross-country lines at comparatively short intervals may be satisfactory from the standpoint of the operator of the lines, because of the fact that such lines are in open country and the excavation costs are relatively small. In the case of lines in city streets, conditions are reversed. The cost of the work is high because of the existence of pavements. As a rule the lines can only be shut down at great inconvenience to the consumers. In addition to the cost feature, the effect on public relations of repeatedly opening streets is very bad. The net result is that a greater expenditure to provide additional life is warranted for water and gas main construction within cities.

When further experience becomes available, the use of soil surveys to determine the amount and type of protective coating necessary may develop a regular procedure from which tangible results may be expected. It is doubtful if soil surveys within cities will be particularly useful. In many cities street grades have been changed by filling with cinders, ashes, slag, and various types of waste material of a more or less corrosive nature. In other cities, the construction of pavements and the installation of sewers, conduits, and other underground utilities may have disturbed the soil so that it no longer resembles the natural soil of that particular region.

The tests of coatings discussed in the paper have not been in process long enough to make it possible to draw any conclusions as to which type of coating would be suitable for all conditions. The general conclusion can be drawn, however, that it is difficult to predict what additional life may be expected when any of the ordinary coatings are used. Coatings which, in themselves, might appear satisfactory are often disturbed during installation, and although the coating that remains on the pipe may be effective, much of it may be removed, with the net result that corrosion may still continue its destructive work. The fact that the tests have shown that the rate of corrosion decreases with time would indicate that one of the best means of prolonging the life of a pipe is to provide additional wall thickness. The advantage of additional wall thickness over a coating is that the thicker pipe needs no special handling to avoid loss of its added protective qualities.

When one considers that hundreds of millions of dollars of pipe lines are now in service underground, one cannot help but be impressed by the necessity for developing information on soil corrosion. It is to be hoped that the

Bureau of Standards will be able to continue its investigations and that from time to time new specimens and new soils may be brought under the test to the end that, at some future time, soil corrosion data will be so extensive that they can be used by the Engineering Profession both in valuation and design work to the same extent as other scientific data.

JOHN R. BAYLIS,[14] ASSOC. M. AM. SOC. C. E. (by letter).—A brief but important factual summary of the principal findings in the field of underground storage, is contained in this paper. The writer is in full accord with Mr. Logan's interpretation of the facts as revealed by the soil corrosion study on practically all phases of the work. Certainly, this problem is now much better understood than before the work at the National Bureau of Standards was started.

The main comments that can be made by the writer, except to praise the work, is to urge that it be continued and that it be extended to include varying the conditions for the chief types of soils in which pipe are now being used. Mr. Logan has shown that there is marked similarity in the corrosion of the various ferrous metals buried in the same locality. In the localities where the samples of pipe are now buried, it is likely that such factors as moisture, temperature, penetration of oxygen into the soil, and acidity of the soil, are the same for samples buried at a certain point, although they vary for different localities. No one knows definitely the effect of varying the moisture and other factors that influence the rate of corrosion.

Another series of tests might well be undertaken with provisions for varying most if not all of the factors influencing the corrosion. Part of the soil should be covered to represent a pavement. Other parts should be subjected to artificial rainfall. An impervious stratum should be constructed under another section of the soil so that some samples may be permanently under water in the soil, others under water part of the time and out of water part of the time, and other samples out of the water all the time, except for the moisture received from rains or from capillary attraction. These are a few of the variables that should be studied.

It is likely that soils have been selected already which vary widely in moisture content, temperature, acidity, etc., but there are so many factors influencing the results that the effect of each factor for each type of soil should be studied. This implies costly experimentation, but the enormous value of pipe now buried in the ground and gradually depreciating in value, due to corrosion, justifies the expenditure of a very substantial sum to obtain full information on the subject.

E. P. FETHERSTONHAUGH,[15] ESQ. (by letter).—The gradual accumulation of information on soil corrosion and the growth of knowledge of the subject as a result of studying the data are well described in this paper. The theory of differential aeration as a probable major cause of soil corrosion is apparently supported by many of the observed and recorded facts and, if fully substantiated, may prove of great usefulness in forecasting what is likely to occur under a given set of conditions. It also suggests some important possibilities with regard to the value of protective coatings in prolonging the life of pipe buried in corrosive soils.

[14] Physical Chemist, Bureau of Eng., City of Chicago, Chicago, Ill.

[15] Prof. of Elec. Eng., Univ. of Manitoba, Winnipeg, Man., Canada.

In the references in the paper to the observed reduction in the rates of corrosion and the causes of this phenomenon, there seems to be an assumption that special abnormal conditions should be sought to account for the shape of the curves that show decreasing rates of penetration with increasing life. A consideration of an assumed set of ideal conditions would seem to indicate that the decreasing rate of penetration might be regarded as a normal, rather than as an abnormal, phenomenon.

The ideal conditions suggested are that: (*a*) The source of the electromotive force causing the pitting remains constant; (*b*) the resistance of the path of the current through the earth, the pipe, and the pit, remains constant; and (*c*) throughout its growth, the shape of the pit remains constant.

Conditions (*a*) and (*b*) would result in a constant current flowing from the pit to the earth and, therefore, equal weights of metal removed in equal intervals of time. With equal weights or volumes of metal removed in equal intervals of time, the volume of the pit will increase at a constant rate, but since its shape is assumed to remain unchanged, its depth will increase as the cube root of the time. These assumptions suggest a fundamental law governing the relation between penetration and time which may be expressed by the equation:

$$D = A \sqrt[3]{T} \qquad (1)$$

in which A is a constant, or the depth of the penetration at the end of the first year; T is the time of exposure, in years; and, D is the depth of the pit at the end of T yr.

It could not be expected that observed data from tests in which there are so many possible variables would follow any mathematical curve exactly, but the similarity between the curve plotted from Equation (1) and the graphs plotted from observed data is striking, and even in other graphs of observed data, in which there is a greater departure, their general form seems to be at least characterized by a fundamental law such as that expressed by the formula.

It seems, therefore, that it is not necessary to attribute the decreasing rates of penetration to any varying condition, such as the gradual settlement of back-fill, as a rapid decrease is to be expected when all the aforementioned conditions are constant. The decreasing rates of loss of weight may perhaps require such explanations, but it is interesting to note that this decrease is in many cases comparatively small, which might suggest that the conditions assumed herein do not differ greatly from those which, in some cases, obtain in and around a buried pipe.

The value of this method of approaching this intricate problem lies in the fact that it suggests a normal law for the rate of penetration with which observed results may be compared, in order that the importance of various abnormal or fluctuating influences, such as those suggested by the author, may be more closely evaluated. Equation (1) may also prove of some value in an attempt to calculate from a single set of observations the time in which a pipe might be penetrated if the conditions of exposure remain constant.

JOHN F. SKINNER,[16] M. AM. SOC. C. E. (by letter).—The information presented by Mr. Logan is interesting in the light of experience with a pipe line (designated Conduits I, II, and III) in Rochester, N. Y. Conduit I, about 28.3 miles long, is still in service although constructed in 1874. The first 10 miles of it, 36 in. in diameter, is made of wrought iron, $\frac{3}{16}$ in. thick. Then follows 3 miles of 24-in. wrought-iron pipe. The remainder of the conduit is cast iron, with a diameter of 24 in. Conduit II was completed in 1894, twenty years later. It consisted of 12 000 ft of 6-ft brick tunnel and a pipe line of which the greater part (nearly 26 miles) was made of riveted steel plate, $\frac{1}{4}$ in., $\frac{5}{16}$ in., and $\frac{3}{8}$ in., in thickness.

At the end of 1913, when the writer prepared a report[17] on the subject, there were 727 holes in Conduit II through approximately 450 of the steel sheets. In the 36-in. section of Conduit I (which was 20 yr older and made of thinner material), there were only 34 holes in 14 sheets. The next leak through the wrought-iron plate occurred on May 29, 1916, after a hiatus of 10 yr; and, to January 1, 1934, there had been a total of 81 holes in 29 sheets of Conduit I, which was then more than 58 yr old.

For several miles these conduits are parallel and only 20 ft apart, so that the soil conditions are practically identical. The first leak due to pitting the wrought-iron plate of the 36-in. Conduit I was discovered on July 12, 1894, after the pipe had been in the ground nearly 19 yr. The first leak through the steel plate of Conduit II was discovered on May 21, 1900, after the pipe had been in the ground nearly 6.5 yr, and the second on October 15, 1900; and 13 holes occurred in 1901 through 10 sheets scattered over 9.7 miles of conduit. All these leaks were through the $\frac{1}{4}$-in. plate. The first leak through the $\frac{5}{16}$-in. plate was in 1904; and the first through the $\frac{3}{8}$-in. plate was in 1908. By the end of 1913, when the aforementioned report was published, 31 978.7 ft of Conduit II had been excavated, scraped clean, and re-coated on the outside. This painting covered 23.5% of the conduit and included 77.5% of the holes discovered.

During the fall of 1933, a section of the conduit was uncovered upon which many leaks had been repaired since the last re-coating operations. To the time this work was begun, 2 260 holes in the steel pipe had been repaired. Including the foregoing work, a total of 2 532 holes had occurred prior to January 1, 1934.

When re-coating is in progress, a great many incipient leaks are scratched through in the process of scraping, thus anticipating holes which, if undisturbed, would occur in the following year or two. The first 200 ft of pipe re-coated in the fall of 1933 was laid through boulders which had injured the original coating. Along this section the plates showed an unusual amount of pitting, and the holes were more numerous than they were farther along the line where the trench was free from boulders. The coating of California asphalt had apparently given protection, where it was not abraded, for about ten years.

---

[16] Cons. Engr., Los Angeles, Calif.

[17] Report on the Steel Plate Pipe Conduit II of the Rochester, (N. Y.), Water-Works, by John F. Skinner, M. Am. Soc. C. E.

Conduit III was constructed during the World War (1914–1918). About 17.6 miles of this line was a lock-bar steel pipe made of plates $\frac{1}{4}$ in and $\frac{5}{16}$ in. thick with riveted circular seams. A few leaks have occurred, generally where the painting was found to be defective. It has been suggested that the subsequent laying of the steel pipe parallel to the wrought-iron pipe may have had an inhibiting effect upon the corrosion of the wrought iron. The answer to this is that 58% of the holes in the wrought-iron pipe (and 52% of the sheets affected) occurred after the steel pipe was installed. The difference in the pitting of steel and wrought iron, in practically the same location, over a long period, is worthy of serious consideration.

In 1901, Professor F. L. Kortright investigated the causes of pitting in Conduit II. He examined samples of earth from twenty-five test pits along Conduit II, as well as rock from the vicinity, ground-water from the trench excavations, and the contents of pits in the steel, both outside and inside the pipe.

From his analysis, he concluded that the earth surrounding the conduit did not affect it except that, being more porous in some places than in others, it admitted the ground-water more freely to the pipe in the places where it was porous and in this way allowed carbon dioxide and oxygen freer access. He reported that the rock in the vicinity of the pipe had no effect on it; but that the injurious constituents in the water were dissolved oxygen and the carbon dioxide that was brought to the pipe in large quantities by the calcium carbonate, which is loosely combined with it.

Electrical measurements were made between Conduits I and II, and between the conduits and the surrounding earth, but neither current nor difference of potential could be detected.

From the foregoing remarks it will be noted that in nearly identical locations and exposure, the wrought-iron Conduit I resisted the first pitting through a $\frac{3}{16}$-in, plate nearly three times as long as the steel Conduit II and that, in later years, although it is twenty years older and of thinner material, it has developed far less pitting through the plate. Although the comparisons shown in the paper exhibit a marked uniformity of action for different pipe materials under the same exposure, it must be evident that a much longer period, commensurable with the life of such structures, may show very different results, such as have been observed in the different behaviors of different materials in places where one has replaced another and is subject to the same environment.

Mr. Logan is to be commended for the energy, imagination, and enthusiasm he has put into this work. It is hoped that he and his successors will be able to continue their observations over a period sufficiently long to insure reliable conclusions of lasting value.

F. N. SPELLER,[18] ESQ. (by letter).—The principal work on soil corrosion of metals and the study of protective coatings has been centered at the National Bureau of Standards. Considerable progress has been made in correlation of soil factors with corrosion, but much remains to be done before the practice of pipe-coating underground can be said to be on a sound engineering basis.

It is now probable that an economical and durable coating can be found for use in most of the corrosive soils. In many cases, as Mr. Logan points out, no coating is required. This is particularly true in the eastern part of the United States. In Philadelphia, Pa., the records of the local gas company over the thirty-six years, 1899 to 1935, indicate that small steel service pipes having a thickness of about $\frac{1}{8}$ in. have an average life of forty-seven years with no more than a thin coat of coal-tar paint which probably gave little advantage except to prevent more general distribution of pit-holes.

It seems very unlikely that a low-cost, rust-resisting metal will be found that is sufficiently durable in all corrosive soils, and (as Mr. Logan points out), there is no material difference between the corrosion resistance of the common ferrous metals; therefore, for the present, the work should be concentrated on improvements in protective coatings. Such coatings should be chemically resistant to soil water, mechanically strong or sufficiently reinforced to resist soil stresses, and thick enough to be durable and prevent contact between the soil and the metal. Reinforced bituminous coatings usually should not be less than $\frac{3}{32}$ in. in thickness.

Portland cement concrete coatings ($\frac{5}{8}$ in. to 1 in. thick) cost from 6 to 10 cents per sq ft, and are highly durable in many soils. They have given 35 to 40 yr of satisfactory protection on oil pipe lines; for instance, on lines crossing low salty marshes, and acid streams in coal-mining districts.

Research work on soil corrosion is of such general interest to tax-payers at large that it seems a portion of the expense of this work should be paid by the Government. Thus far, it has been carried out on this basis by the National Bureau of Standards with the co-operation of the American Petroleum Institute, American Gas Association, and pipe manufacturers, but has been seriously retarded by curtailment of appropriations due to the economy program. The general opinion of those who have followed this investigation is that it should by all means be continued in order to realize on the $300 000 already invested through the Bureau toward the solution of this problem.

K. H. LOGAN,[19] ESQ. (by letter).—As one who has been in close touch with the soil-corrosion investigation since its beginning in 1922, Mr. Wolfe is quite right in cautioning against the unrestricted use of the data for the comparison of materials or the prediction of pipe life. In many of the soils under consideration the corrosion is not sufficiently serious to permit a reliable estimate of pipe life. In a few soils, however, all or nearly all the thinner walled specimens have been punctured. It is expected that the data on the

---

[18] Director, Dept. of Metallurgy and Research, National Tube Co., Pittsburgh, Pa.

[19] Chf., Underground Corrosion Section, National Bureau of Standards, Washington, D. C.

12-yr old specimens, which will be available in the spring of 1936, will show the standard deviation for each material[20]. This will indicate whether or not there are significant differences between the rates of corrosion of the materials. As Mr. Baylis indicates, the causes and mechanism of underground corrosion need further investigation. To be of value any field investigation must involve a rather large number of specimens and, consequently, a very considerable expense for materials and labor. The outlook for the extension of the soil-corrosion investigation in the near future is not bright.

The relation between rate of penetration and time to which Professor Fetherstonhaugh calls attention, has been studied by several investigators. Dr. G. N. Scott[21] reached the conclusion that the relation for any soil could be represented by the equation, $P = \frac{U\,T}{B + T}$, in which P is the depth of the deepest pit at any time, T; B is a constant which is the same for all soils; and U is another constant different for each soil and equal to the ultimate pit depth.

Additional data recently obtained seem to indicate that some such an equation as that of Dr. Scott or Professor Fetherstonhaugh will represent the progress of corrosion in well-drained soils, but that in poorly drained soils the depth of penetration is nearly proportional to the duration of the exposure.

The interesting experience of the City of Rochester cited by Mr. Skinner deserves further investigation. Although the superior service rendered by Conduit I may be due to the superiority of the material used, two other explanations are possible. The map showing the locations of the conduits which the writer obtained from the City Engineer's Office indicates that, although the two older conduits lie quite near each other, the older line lies at a slightly higher elevation and, consequently, is somewhat better drained. It is possible also that the protective coating applied to the older line was superior either as to material or application. This is suggested by the fact that at least some of the failures of the older line occurred at points where the coating had been injured. It is probable that the troubles on the newer line have been accentuated by its rather frequent exposure for repairs. A thorough investigation of the causes of the differences between the performances of the two conduits might be of great value to those who have to construct similar lines.

THE ADJUSTMENT OF A LEVEL NET

BY GEORGE H. DELL,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. EARL F. CHURCH, W. H. RAYNER, AND GEORGE H. DELL.

SYNOPSIS

Two closely related methods of obtaining a "least squares" adjustment of the closing errors in a level net are described in this paper. The first method involves the writing, by inspection, of the appropriate normal equations and their subsequent solution by a process of converging increments; the second utilizes the principle of successive distributions, and is suggested by the Cross method of moment distribution.[2]

Both methods are well adapted to the use of the slide-rule and possess the advantages of simplicity and brevity, as compared with the conventional least squares solutions. They are intended to apply primarily to surveys of ordinary extent and accuracy, such as those executed by municipal and highway engineering organizations.

Beyond the consideration that, in practice, one method may appeal more than the other to a given individual, the reasons for presenting a dual treatment of the subject include the following: (*a*) The first method derives immediately from the principal hypothesis of the theory of least squares, and thus serves to substantiate the correctness of the second method; (*b*) the process utilized (in the first method) for solving the normal equations may be successfully applied to various other types of engineering problems (for example, to indeterminate structures); and (*c*) the parallel solutions show the inter-relations of the two methods and suggest a procedure that may be used to advantage in devising extensions of the distribution method to new types of problems.

INTRODUCTION

The precision that characterizes the planning and execution of present-day structures demands, in general, that reliable bench-marks be established and maintained throughout, at least, the period of construction. In towns and cities, bench-marks should be created with a view to permanence.

The value of a bench-mark depends as much upon the reliability of the elevation assigned to it as upon its ability to maintain itself at a fixed height. Much difficulty is encountered in attempting to arrive at the correct elevation of bench-marks by field work alone, due to unavoidable discrepancies which are found when closing in from various lines. It appears, at times, that the more one levels in a given locality the greater is the uncertainty in the bench-marks.

Much of this difficulty in the field can be avoided by adopting, in part, the methods that have been used by the United States Coast and Geodetic Survey in the execution of many thousands of miles of precise levels. Particularly commendable in this connection are the establishment of a definite standard of precision and the practice of running all level lines twice for the purpose of putting them to test; in case of satisfactory agreement, the mean of the observed differences in elevation is then used.

In spite of all precautions, however, discrepancies still persist, and some form of adjustment is necessary. Generally speaking, there are three methods of adjusting elevations, namely, (1) by "guessing"; (2) by using a "rule of thumb" (which may be worse than guessing); and (3) by calculating the most probable values in accordance with the laws of probability.

The latter method, under the title of "least squares," has been in use for more than a century, but its application has been restricted rather closely to problems in astronomy and geodesy. For such purposes, a high degree of precision is generally required, and, consequently, the treatises dealing with that method are likely to appeal to the layman as being too elaborate for his requirements, and the calculations overly precise and laborious.

The aim of this paper is to present methods whereby the closing errors in a level net can be adjusted with approximately the same time and effort as are required to solve the somewhat analogous problem of finding the bending moments in a framed structure. These methods are proposed for use principally in connection with work done with the ordinary engineer's level, in which instance it is doubtful whether the precision obtainable in the field warrants an attempt to deal with elevations or readings in units of less than 0.01 ft, or 0.005 ft. Nevertheless, with a little added effort, the precision of the calculations is capable of further extension.

The use of a "polyphase" type of slide-rule is of great assistance in performing the necessary calculations, as in both methods an entire series of values can then be read off with a single setting of the slide.

DEFINITIONS AND PRELIMINARY EXPLANATIONS

To facilitate description, the following terms will be used:

Control Bench-Mark: A bench-mark with an elevation which is to remain fixed, and to which the elevations of other bench-marks are to be adjusted.

Junction Point: A bench-mark at which three or more level lines meet.

Section: The length of level line connecting consecutive junction points or control bench-marks.

Intermediate Bench-Mark: A bench-mark located at some intermediate point of a section.

Sub-Section: A part of a section terminating at an intermediate bench-mark.

Circuit: A polygon or closed figure bounded by sections (but containing none within its interior).

Exterior Section: A section situated along the boundary of the net, and hence belonging to only one circuit.

Interior Section: A section situated within the interior of the net, and hence common to two circuits.

Positive Direction of a Section: The direction in which the correction is to be computed (regardless of whether the difference in elevation is positive or negative).

Direction Arrows.—"Main direction arrows" are those used to designate the positive directions of the sections. In general, these direction arrows serve also to indicate the direction in which the closing error of a circuit is calculated. In certain interior sections, however, the latter direction may be contrary to the former, and is then distinguished by means of an "auxiliary direction arrow," which is written beside the section and within the circuit in question, as shown in Fig. 1.

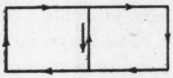

FIG. 1.

Weights.—The weight, p, of an observed difference in elevation in a given section depends upon the length of the section, the number of set-ups it contains, the number of independent measurements entering into the data, and the quality of instruments and survey methods used. On ordinary slopes, the number of set-ups is approximately proportional to the length of the line, and, therefore, it is customary to weight the observations in inverse proportion to the distance (which may be determined by stadia measurements, by pacing, or by scaling from a map). Moreover, the weight is directly proportional to the number of times the levels were run; that is, a difference in elevation which is determined from the mean of two separate runnings of a section is given twice as much weight as a difference in elevation obtained from a single running.

Effective Lengths.—It is convenient, in the problem of the level net, to deal with weights in terms of the "effective lengths" of sections. The effective length of a section is defined as the reciprocal of the weight; that is, $\frac{1}{p}$; consequently, it is directly proportional to the length of the section and inversely proportional to the number of measurements.

Closure Conditions.—Two types of closure will be considered, namely, the circuit closure and the route closure. By a "circuit-closure condition" is meant the requirement that the sum of the section corrections in a given circuit must be equal, and opposite in sign, to the closing error of that circuit.

If the level net contains two or more control bench-marks, conditions of route closure arise. By a "route-closure condition" is meant the requirement that the section corrections along an arbitrary route connecting two given control bench-marks must have a predetermined sum, equal (and opposite in sign) to the closing error along that route; this situation gives rise to the following term:

Conditioned Route: An arbitrary route, selected for purposes of adjustment, connecting two control bench-marks.

Condition Multipliers.—"Condition multipliers" are undetermined coefficients which are used to represent the closure conditions to which a section is subject. For example, Closure Conditions Nos. I, II, etc., are represented by the condition multipliers, C_{I}, C_{II}, etc., respectively. By this means, the correction for any section may be expressed as a linear function of the closure conditions.

Section Corrections.—The corrections to be determined for the observed differences in elevation along the various sections are called "section corrections." They are denoted by v_1, v_2, etc., the subscripts of which refer to Sections Nos. 1, 2, etc., respectively. By means of the theory of least squares it is found (see Appendix I) that the section correction for a given section is equal to the product of the effective length of the section by the sum of its condition multipliers. Expressed algebraically, the section correction, v_m, of Section No. m, with an effective length of L'_m, which is subject to Closure Conditions Nos. I, II, etc., is given by the equation,

$$v_m = L'_m \, (C_{\text{I}} + C_{\text{II}} + \ . \ . \ .) \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The number of closure conditions governing a given section is equal to the number of circuits or conditioned routes to which the section belongs.

Normal Equations.—Equations of the type obtained when the section corrections as expressed in Equation (1) are summed up around a circuit or along a conditioned route and placed equal, and opposite in sign, to the closing error, are known as "normal equations." The number of normal equations in any net is equal to the number of circuits, plus the number of conditioned routes.

DESCRIPTION OF METHOD 1; EXAMPLE NO. 1

For purposes of description, the solution will be divided into the following steps: (*a*) Preparation of plan for the adjustment, and calculation of closing errors; (*b*) formation and solution of normal equations; (*c*) calculation of section corrections and verification of circuit closures; and, (*d*) calculation of adjusted elevations of bench-marks.

To illustrate the detailed procedure, two examples will be given, the first involving only circuit-closure conditions, and the second entailing a route-closure condition.

The net chosen to exemplify Example No. 1 is illustrated in Fig. 2. It contains four circuits and nine bench-marks, five of which are junction points, and the remaining four, intermediate bench-marks. Point *A* will be assumed to be a control bench-mark, with an elevation of 416.15 ft. The approximate distances between bench-marks are shown in Fig. 2.

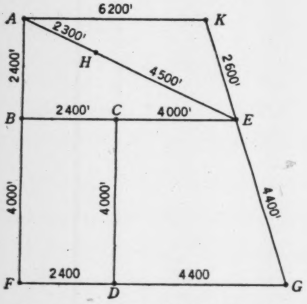

FIG. 2.—SKETCH OF LEVEL NET.

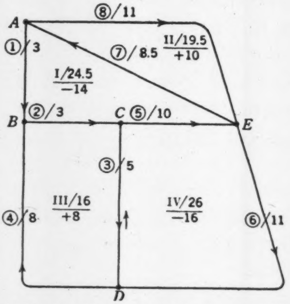

FIG. 3.—PLAN FOR ADJUSTMENT.

The observational data are given in Table 1, Appendix II, and consist of field notes covering levels which were run over six routes, as follows: Route No. 1: *A* to *B* to *C* and return; Route No. 2: *C* to *D* to *G* to *E* and return; Route No. 3: *D* to *F* to *B* and return; Route No. 4: *C* to *E* (one way); Route No. 5: *A* to *H* to *E* and return; and, Route No. 6: *A* to *K* to *E* and return.

(a) Preparation of Plan for the Adjustment, and Calculation of Closing Errors.—The preliminary details necessary to put the data in readiness for performing the adjustment include the preparation of a plan and the determination of the closing errors, and may be performed in the following order:

(1) Prepare a plan showing the junction points and control bench-marks, and the connecting routes over which the leveling was executed;

(2) Assign a system of direction arrows;

(3) Number the sections, determine their effective lengths, and record these values on the plan;

(4) From the field data, calculate the observed difference in elevation over each section in the positive direction (that is, as shown by the main direction arrow); also, determine the observed differences in elevation over the sub-sections, which will be required in computing the adjusted elevations of the intermediate bench-marks; and,

(5) Number the circuits, calculate their total effective lengths and their closing errors, and record these values on the plan.

The plan for the adjustment for Example No. 1 is shown in Fig. 3, intermediate bench-marks being omitted. Direction arrows are assigned in such a way as to secure continuous routing through all the circuits with a minimum number of auxiliary direction arrows. This system of marking the sections possesses the following advantages: (1) It fixes the route to be taken in calculating the closing error of each circuit; (2) it determines the direction in which each section correction is to be calculated; and (3), it enables the normal equations to be formed by inspection.

In Fig. 3, the number of the section is shown by the figure enclosed within a circle, and the effective length is written to the right of the diagonal bar. Fig. 3 also contains, near the center of each circuit, a notation showing the number of the circuit, its total effective length, and its closing error (for example, $\frac{\text{I}/24.5}{-14}$ indicates Circuit No. I, with a total effective length of 24.5, and a closing error of − 0.14 ft).

The calculation of the effective lengths of sections and of the corresponding observed differences in elevation is contained in Table 2(*a*), Appendix II. It will be noted that the actual lengths are reduced to terms of relative lengths by dividing by 800. The use of the smaller units is a matter of convenience. The effective lengths are taken equal to the relative lengths of the corresponding sections, except for Section No. 5. Since this section was leveled only once (all other sections having been leveled twice), its effective length is twice its relative length.

In explanation of the calculation of the observed differences in elevation, consider Section No. 1, which extends from Point *A* to Point *B* in Fig. 2. The field notes, given in Table 1, Appendix II, show that this section is a part of Route No. 1 and was run both forward and back. In the forward running the observed difference in elevation was $422.59 - 416.15 = +6.44$; in the back running the result was $416.17 - 422.65 = -6.48$. In this instance the positive direction of the section (as shown by the direction arrow in Fig. 3) coincides with the forward running, and, consequently, the observed (mean) difference in elevation is + 6.46 ft (Column (8), Table 2(*a*), Appendix II). (In taking the arithmetic mean of an even number and an odd number, the even value is chosen for convenience; for example, in Section No. 7, Table 2(*a*), the mean of 9.20 and 9.07 is taken as 9.14). Table 2(*b*) contains the calculation of the observed differences in elevation over the sub-sections.

The calculation of the closing errors is contained in Table 3, Appendix II. The closing error of a given circuit is simply the sum of the observed differences in elevation of its component sections, taken in a continuous direction around the circuit in accordance with the direction arrows. The closure conditions corresponding to the various circuits are numbered in the same way as the circuits themselves, and, hence, the condition multipliers for Circuits Nos. I, II, III, etc. (Fig. 3), are C_{I}, C_{II}, C_{III}, etc., respectively.

(*b*) *Formation of Normal Equations.*—In accordance with Equation (1), the section corrections, taken in a continuous direction around the various circuits, are as shown in Table 4, Appendix II. When the sums of these corrections are placed equal, and opposite in sign, to the closing errors of the respective circuits (0.01 ft being taken, for convenience, as a unit), the following normal equations are obtained:

$$24.5\ C_{\text{I}} + 8.5\ C_{\text{II}} + 3\ C_{\text{III}} + 10\ C_{\text{IV}} = +\ 14 \dots\dots\dots\dots (\text{I})$$

$$8.5\ C_{\text{I}} + 19.5\ C_{\text{II}} = -\ 10 \dots\dots\dots\dots (\text{II})$$

$$3\ C_{\text{I}} + 16\ C_{\text{III}} - 5\ C_{\text{IV}} = -\ 8 \dots\dots\dots\dots (\text{III})$$

and,

$$10\ C_{\text{I}} - 5\ C_{\text{III}} + 26\ C_{\text{IV}} = +\ 16 \dots\dots\dots\dots (\text{IV})$$

In Equation (I) the greatest numerical coefficient is that of C_{I}, and is equal to the total effective length of Circuit No. I; likewise, in Equation (II) the greatest numerical coefficient is that of C_{II}, and it is equal to the total effective length of Circuit No. II; and, similarly, for Equations (III) and (IV). These quantities (namely, 24.5 C_{I} in Equation (I), 19.5 C_{II} in Equation (II), etc.) will be referred to as the "major" terms of their respective equations. The remainder of the quantities on the left-hand side of the equations will be called "minor" terms.

As a matter of fact, it is simpler to write the normal equations at once as in Table 5(*a*), Appendix II. They are written in columns which are numbered to correspond to the various closure conditions, the individual terms being entered in the lines with numbers that agree with the subscripts of the condition multipliers. The major terms (which are underscored) thus appear in diagonal formation. As already stated, their coefficients are merely the total effective lengths of the respective circuits (or conditioned routes).

Minor terms arise from sections which are subject to two (or more) closure conditions, and their coefficients are equal to the effective lengths of the sections involved. For example, in writing the minor terms of Equation (I), it is seen from Fig. 3 that Circuit No. I is tied to Circuit No. II by Section No. 7, with effective length, 8.5; to Circuit No. III by Section No. 2, with effective length, 3; and to Circuit No. IV by Section No. 5, with effective length, 10. Consequently, in Column (I), Table 5, Appendix II, 8.5 is entered in Line II, 3 in Line III, and 10 in Line IV.

In the case of sections marked with an auxiliary direction arrow the minor term is always prefixed with the negative sign. The constant, or right-hand, term of the equation is entered at the bottom of the appropriate column.

Checking the Normal Equations.—As the coefficients of the minor terms always appear in two of the normal equations, it is desirable to utilize this fact as a check. The coefficients should read the same vertically and horizontally.

Solution of Normal Equations.—From the following typical system of equations, in three unknowns, namely,

$$A C_{\text{I}} + b C_{\text{II}} + c C_{\text{III}} = k_1 \dots\dots\dots\dots (\text{I}a)$$

$$b C_{\text{I}} + B C_{\text{II}} + d C_{\text{III}} = k_2 \dots\dots\dots\dots (\text{II}a)$$

and,

$$cC_{I} + dC_{II} + CC_{III} = k_3 \ldots\ldots\ldots\ldots\ldots\ldots (\text{III}a)$$

Equations (I*b*), (II*b*), and (III*b*) may be written, thus:

$$AC_{I} = k_1 - (bC_{II} + cC_{III}) \ldots\ldots\ldots\ldots\ldots\ldots (\text{I}b)$$

$$BC_{II} = k_2 - (dC_{III} + bC_{I}) \ldots\ldots\ldots\ldots\ldots\ldots (\text{II}b)$$

and,

$$CC_{III} = k_3 - (cC_{I} + dC_{II}) \ldots\ldots\ldots\ldots\ldots\ldots (\text{III}b)$$

respectively. Let, $C_{I} = C_{I\text{-}1} + C_{I\text{-}2} + C_{I\text{-}3} +$ etc.; $C_{II} = C_{II\text{-}1} + C_{II\text{-}2} + C_{II\text{-}3} +$ etc.; and, $C_{III} = C_{III\text{-}1} + C_{III\text{-}2} + C_{III\text{-}3} +$ etc.

Upon substituting these values of C_{I}, C_{II}, and C_{III} into Equations (I*b*), (II*b*), and (III*b*), the following expressions, respectively, are obtained:

$$AC_{I\text{-}1} + AC_{I\text{-}2} + AC_{I\text{-}3} + \ldots = k_1 - (bC_{II\text{-}1} + cC_{III\text{-}1}) - (bC_{II\text{-}2} + cC_{III\text{-}2}) - \ldots\ldots\ldots\ldots\ldots\ldots (\text{I}c)$$

$$BC_{II\text{-}1} + BC_{II\text{-}2} + BC_{II\text{-}3} + \ldots = (k_2 - bC_{I\text{-}1}) - (dC_{III\text{-}1} + bC_{I\text{-}2}) - (dC_{III\text{-}2} + bC_{I\text{-}3}) - \ldots\ldots\ldots\ldots\ldots\ldots (\text{II}c)$$

and,

$$CC_{III\text{-}1} + CC_{III\text{-}2} + CC_{III\text{-}3} + \ldots = (k_3 - cC_{I\text{-}1} - dC_{II\text{-}1}) - (cC_{I\text{-}2} + dC_{II\text{-}2}) - (cC_{I\text{-}3} + dC_{II\text{-}3}) - \ldots\ldots\ldots\ldots (\text{III}c)$$

A solution by parts (if convergent) may now be made, one term at a time being computed from each of the foregoing equations. Its value is then used in the succeeding equations to find the next term, in the following manner: $AC_{I\text{-}1} = k_1$; $BC_{II\text{-}1} = k_2 - bC_{I\text{-}1}$; $CC_{III\text{-}1} = k_3 - (cC_{I\text{-}1} + dC_{II\text{-}1})$; $AC_{I\text{-}2} = -(bC_{II\text{-}1} + cC_{III\text{-}1})$; $BC_{II\text{-}2} = -(dC_{III\text{-}1} + bC_{I\text{-}2})$; $CC_{III\text{-}2} = -(cC_{I\text{-}2} + dC_{II\text{-}2})$; $AC_{I\text{-}3} = -(bC_{II\text{-}2} + cC_{III\text{-}2})$; $BC_{II\text{-}3} = -(dC_{III\text{-}2} + bC_{I\text{-}3})$; $CC_{III\text{-}3} = -(cC_{I\text{-}3} + dC_{II\text{-}3})$; etc. Quantities of this type will be referred to as "principal terms;" they comprise both "preliminary values" (or terms found in the first set of computations, as, for example, $AC_{I\text{-}1}$, $BC_{II\text{-}1}$, $CC_{III\text{-}1}$) and "increments" (or terms similar to $AC_{I\text{-}2}$, $BC_{II\text{-}2}$, $CC_{III\text{-}2}$, etc.), which result from succeeding sets of computations.

This method appears to be applicable to the vast majority of normal equations encountered in practical engineering problems, and possesses the important advantage that, in dealing with equations containing four or more unknowns, the solution is usually obtained in appreciably less time than that required by a precise method. Although, generally, a small degree of approximation is involved, the results are practically exact in many cases.

The number of sets of computations required to obtain an accurate solution is usually from four to six; occasional examples may require one or two additional sets. If the convergence is rapid, the computations may be continued until the increments become negligible. The principal terms in each equation are then totaled, and the value of the unknown is found by dividing the resulting sum by the coefficient of the major term of the equation.

If the convergence is relatively slow, it generally happens that, after a few sets of computations are completed, the increments in the separate equations begin to converge with ratios that tend to be nearly equal. When this stage is reached, the solution can be expedited greatly, without appreciable sacrifice of precision, by summing up the remaining increments as geometrical series. This expedient may also be utilized in connection with the more rapidly converging equations, provided the ratios of convergence in the separate equations are approximately equal.

Before effecting the summation, in any case, it is desirable that the ratios of convergence in the separate equations be brought to agreement within fairly definite limits, depending upon the desired degree of precision. The writer's experience indicates that if the range of variation in these ratios does not materially exceed 0.05 (as will presently be illustrated by numerical examples), the remaining increments can be summed up as geometrical series with results sufficiently accurate to reduce the closing errors of the individual circuits to considerably less than 0.01 ft.

The process of summing up the remaining terms of the various series of increments consists of multiplying the last set of calculated increments by the summation factor. These summations are then added to the principal terms previously calculated, and, finally, the unknowns are found by dividing the resulting totals by the coefficients of the major terms of the respective equations. The summation factor of a geometrical series is equal to $\frac{r}{1 - r}$, in which r is the ratio of convergence of successive terms. For present requirements, the summation factor will be computed by means of an "average ratio of convergence."

If the increments in the separate equations attain the desired degree of uniformity of convergence in five or less sets of computations, the average ratio of convergence is given, with satisfactory precision, by:

$$r = \frac{s_n}{s_{n-1}} \quad \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

in which s_n is the absolute sum of the increments in the final set of computations, and s_{n-1} is the absolute sum of the increments in the preceding set.

If more than five sets of computations are required before the ratios attain the desired degree of uniformity, a better approximation of the average ratio of convergence is generally obtained by using the last three sets of results, as follows:

$$r' = \frac{r^2}{r_{n-1}} \quad \dots\dots\dots\dots\dots\dots\dots\dots (3)$$

in which r is as defined in Equation (2), and $r_{n-1} = \frac{s_{n-1}}{s_{n-2}}$. The corresponding summation factor is then taken as $\frac{r'}{1 - r'}$.

Referring to Table 5(*a*), Appendix II, the calculations incident to the solution of the equations of Example No. 1 are as follows: In Line 1, the constant term of Equation (I) (namely, 14.00), is taken as the preliminary value of 24.5 C_{I}. It is entered as a "principal term," is underscored, and is extended horizontally in proportion to the coefficients in Line 1, Table 5(*a*), as follows:

$$\frac{8.5}{24.5}(14.00) = 4.85 \text{ (Column (II))}$$

$$\frac{3}{24.5}(14.00) = 1.71 \text{ (Column (III))}$$

and,

$$\frac{10}{24.5}(14.00) = 5.71 \text{ (Column (IV))}$$

For the preliminary value of 19.5 C_{II} in Line 2 the value found for Line 1, Column (II), is subtracted from the constant term of Equation (II), giving $-10.00 - 4.85 = -14.85$. This quantity likewise constitutes a principal term, and is underscored and extended horizontally in proportion to the coefficients in Line II, giving:

$$\frac{8.5}{19.5}(-14.85) = -6.48 \text{ (Column (I))}$$

The preliminary value of 16 C_{III} in Line 3 is determined by subtracting from the constant term of Equation (III) the value calculated for Line 1, Column (III) of Table 5(*a*), which gives the following result: $-8.00 - 1.71 = -9.71$. This quantity, in turn, is extended horizontally in proportion to the coefficients in Line III.

In a similar manner, the preliminary value of 26 C_{IV} in Line 4, Table 5(*a*), is calculated by subtracting the values in Line 1, Column (IV), and Line 3, Column (IV), from the constant term of Equation (IV), giving: $16.00 - (5.71 + 3.04) = 7.25$, which is then extended in the same fashion. This completes the first set of computations.

In succeeding sets (Lines 5 to 16), the principal terms are obtained by taking the negative sum of all the values which occur below the principal term in the preceding set; for example, in Line 5, the principal term, or increment of 24.5 C_{I}, is: $-(-6.48 - 1.82 + 2.79) = 5.51$.

At the end of the fourth set of computations, the ratios of convergence in the separate columns of Table 5(*a*) (obtained by dividing the increments of the fourth set by those of the third set) are as follows: $\frac{\text{I}}{0.429}$, $\frac{\text{II}}{0.431}$, $\frac{\text{III}}{0.404}$, and $\frac{\text{IV}}{0.423}$. From the foregoing quantities, the maximum range of variation is found to be $0.431 - 0.404 = 0.027$. Although these ratios are quite uniform, it is obvious that several additional sets of computations would be required in order to reduce the increments to negligible quantities; the remaining increments, therefore, are summed up as geometrical series.

The average ratio of convergence, as given by Equation (2), is $\frac{1.41}{3.33} = 0.423$, and the corresponding summation factor is 0.734. The resulting summations (obtained by multiplying the fourth set of increments by the summation factor) appear in Line 17, Table 5(*a*). Line 18 contains the sums of the principal terms (including the quantities in Line 17), and the values of the unknowns (the condition multipliers), are given in Line 19.

The calculations of Table 5(*a*) were performed with the aid of a 10-in. slide-rule. The results of this solution, when compared with values obtained from a precise solution,[8] are all found to be correct to three decimal places, as shown.

(c) Calculation of Section Corrections and Verification of Circuit Closures.—Table 6(*a*), Appendix II, contains the computation of the section corrections, which is developed in accordance with Equation (1). This step is facilitated by tabulating the condition multipliers in groups, according to the sections composing the successive circuits. For example (see Fig. 3), C_{I} is applied to Sections Nos. 1, 2, 5, and 7; C_{II}, to Sections Nos. 7 and 8; C_{III}, to Sections Nos. 2, 3, and 4; and C_{IV}, to Sections Nos. 3 (with sign reversed), 5, and 6. The sum of the condition multipliers for each section appears in Column (5), Table 6(*a*), and the section corrections (the products of Column (2) and Column (5) to the nearest tenth of a unit, corresponding to the thousandth of a foot), are given next. In Column (7) the adopted section corrections are recorded to the nearest 0.01 ft.

The verification of the circuit closures is given in Table 7(*a*), Appendix II, which indicates that the section corrections as calculated will reduce the closing errors to zero.

(d) Calculation of Adjusted Elevations of Bench-Marks.—The calculation of the adjusted elevations of the bench-marks is given in Table 8(*a*), Appendix II. In dealing with intermediate bench-marks, the adjusted difference in elevation over each sub-section is calculated by prorating the section correction in the ratio of the length of the sub-section to that of the section (see Table 2(*b*), Appendix II).

DESCRIPTION OF METHOD 1; EXAMPLE NO. 2

The data contained in Table 1, Appendix II, will also be used in connection with Example No. 2, with the added requirements that both Points *A* and *C* shall be treated as control bench-marks, with elevations of 416.15 and 424.01, respectively. For purposes of adjustment, it is theoretically immaterial which path connecting these points is taken as the conditioned route. The selected route is that consisting of Sections Nos. 1 and 2.

The closing errors of the four circuits are as given in Table 3, Appendix II; that of the conditioned route is found by subtracting the required difference in elevation from the observed difference in elevation, and is equal to $7.90 - 7.86 = + 0.04$.

---

[8] For a general method of obtaining a precise solution of normal equations, see "Application of the Theory of Least Squares to the Adjustment of Triangulation," by Oscar S. Adams, *Special Publication No. 28*, U. S. Coast and Geodetic Survey.

The new system of normal equations, together with their solution, is given in Table 5(*b*), Appendix II. Equation (V) expresses the closure requirements of the conditioned route. It will be noted that the inclusion of the added closure condition requires that the term, 6 C_v, be included in Equation (I), and the term, 3 C_v, in Equation (III).

At the end of the fifth set of computations, the increments in each column have begun to converge, with the exception of Column (III). By carrying the calculations through one additional line, it will be found that the next increment in that column is − 0.06, from which it may be concluded that the first five sets of computations are sufficient, provided the ratios of convergence are sufficiently uniform. These ratios are, as follows: $\frac{\text{I}}{0.557}, \frac{\text{II}}{0.554}, \frac{\text{III}}{0.600}\left(\text{using } \frac{0.06}{0.10}\right), \frac{\text{IV}}{0.564}$, and $\frac{\text{V}}{0.540}$, from which it is seen that the maximum difference is approximately 0.06.

The final results given in Table 5(*b*), when compared with a precise solution, are found to be correct to three decimal places, except for C_v, which is in error by 0.003.

Table 6(*b*), Appendix II, contains the calculation of the section corrections, and Table 7(*b*), Appendix II, the verification of the closures. The calculation of the adjusted elevations of the bench-marks is given in Table 8(*b*), Appendix II.

DESCRIPTION OF METHOD 2

The second method of adjusting a level net differs from the first in the following respects: (1) Instead of the writing and solution of the normal equations, the errors in the various circuits are successively distributed, carried across, and re-distributed; (2) the section corrections are found by direct addition of the distributed quantities; and (3) all these calculations are entered directly on the plan for the adjustment.

In order to illustrate this method, the closing errors of the previous examples will be adjusted. The explanations will be confined to the determination of the section corrections, as the preliminary and final details are the same in both solutions. Moreover, the results are theoretically identical in the two methods.

Example No. 1.—The calculation of the section corrections is given in Fig. 4, and the errors requiring distribution in the different cycles are listed in Table 9(*a*), Appendix II.

Table 10, Appendix II, which has been especially prepared for the purpose of assisting in the explanation of the method, contains complete details of all the calculations involved in the first two cycles of the adjustment. The closing error of each circuit is distributed (with change in sign) among the several sections of the circuit in proportion to their effective lengths. Corrections thus applied to sections subject to two or more closure conditions constitute new errors in the adjoining circuits (or conditioned routes), and, therefore, are carried across at the first opportunity; in the first cycle of adjustments, they are added to the original closing error of the adjoining circuit, the combined closing error being then distributed.

FIG. 4.—ADJUSTMENT OF LEVEL NET BY SUCCESSIVE DISTRIBUTION OF THE CLOSING ERRORS, EXAMPLE NO. 1.

Referring to Table 10(a), the closing error of Circuit No. I (namely, −14.00), is distributed as follows: Section No. 1; $\frac{3}{24.5}$ (+14.00) = + 1.71; Section No. 2: $\frac{3}{24.5}$ (+ 14.00) = + 1.71; Section No. 5: $\frac{10}{24.5}$ (+ 14.00) = + 5.71; and, Section No. 7: $\frac{8.5}{24.5}$ (+ 14.00) = + 4.85.

In Circuit No. II, the foregoing correction to Section No. 7, is carried across and added to the original closing error, giving: +4.85 + 10.00 = +14.85; this quantity is then distributed as follows: Section No. 7: $\frac{8.5}{19.5}$ (− 14.85) = − 6.48; and, Section No. 8: $\frac{11}{19.5}$ (− 14.85) = − 8.37.

In Circuit No. III, the correction already applied to Section No. 2 is taken up, and the combined error (namely, +1.71 + 8.00 = +9.71) is distributed in the following proportions: Section No. 2: $\frac{3}{16}$ (−9.71) = −1.82; Section No. 3: $\frac{5}{16}$ (−9.71) = −3.04; and, Section No. 4: $\frac{8}{16}$ (−9.71) = −4.85.

In Circuit No. IV, the corrections previously assigned to Sections Nos. 3 and 5 are carried across, and the error requiring distribution is, therefore, +3.04 +5.71 −16.00 = −7.25, which, in turn, is distributed (with change in sign) in proportion to the effective lengths of the sections which compose this circuit.

The circuits are adjusted in a fixed sequence, and the same process of distribution is continued in succeeding cycles, the closing errors being found by bringing over and combining the corrections not previously transferred from adjacent circuits.

A record is kept of the errors requiring distribution in the successive steps (see Table 9(*a*)). These values are numerically identical with the "principal terms" found in the first method, and are used to determine: (1) The stage in the solution at which satisfactory convergence is established; (2) the average ratio of convergence; and (3) the summation factor, previously mentioned in connection with Equations (2) and (3).

When the errors in the separate circuits have attained the desired uniformity of convergence, the remainder of each series of corrections is computed by multiplying the last cycle of distributed corrections by the summation factor. These summations constitute the fifth set of values in Fig. 4.

It should be noted that in dealing with sections marked by the auxiliary direction arrow (Section No. 3, for example), the sign of the correction is always changed upon being carried over into the adjoining circuit; furthermore, the signs of all quantities on that side of the section which bears the auxiliary direction arrow are reversed when the individual corrections of a section are totaled.

FIG. 5.—ADJUSTMENT OF LEVEL NET BY SUCCESSIVE DISTRIBUTIONS OF THE CLOSING ERRORS, EXAMPLE NO. 2.

Example No. 2.—The calculation of the section corrections for Example No. 2 is given in Fig. 5. The errors requiring distribution in the successive steps are shown in Table 9(*b*), Appendix II. Table 10(*b*), Appendix II, contains an explanation of the manner of determining the errors to be distributed in the first two cycles, together with their distributions (the first cycle in this case being the same for Examples Nos. 1 and 2).

In adjusting the conditioned route, the closing error is found by bringing across and combining the errors arising from the preceding distributions in the contiguous circuits (including, in the first cycle, the original closing error of the conditioned route), and is then distributed in proportion to the effective lengths of the sections composing the conditioned route. For exterior sections (Section No. 1 for example), such corrections are entered on the outer side of the section (see Fig. 5) whereas, for interior sections (Section No. 2), they are written astride the section.

In turn, these corrections are taken up into the adjacent circuits when the closing errors of the latter are next calculated. Since interior sections of a conditioned route are subject to three closure conditions, all corrections applied to such sections are carried across in two places. In Fig. 5, the sixth set of values are those found by summation of series.

CONCLUSIONS

As the result of the foregoing examples, the following conclusions appear to be justified: (1) The methods presented are sufficiently precise to meet the requirements of the majority of level nets, except those of large geodetic surveys; and (2), in view of the comparative ease with which a correct adjustment can be effected, and of the obvious advantages of thus eliminating the uncertainty and confusion which otherwise prevail, no carefully executed system of bench-marks should be considered complete until the elevations have been properly adjusted.

APPENDIX I

THEORY

According to the theory of least squares, the sum, $\Sigma p v^2$, is to be made a minimum, subject to the given closure conditions. Using the data of Example No. 1 (Tables 1 to 3, inclusive, Appendix II), the function which is to be made a minimum may be expressed as follows:[4]

$$F = \frac{v^2_1}{3} + \frac{v^2_2}{3} + \frac{v^2_3}{5} + \frac{v^2_4}{8} + \frac{v^2_5}{10} + \frac{v^2_6}{11} + \frac{v^2_7}{8.5} + \frac{v^2_8}{11}$$
$$- 2\,C_{\mathrm{I}}\,(v_1 + v_2 + v_5 + v_7 - 14) - 2\,C_{\mathrm{II}}\,(v_7 + v_8 + 10)$$
$$- 2\,C_{\mathrm{III}}\,(v_2 + v_3 + v_4 + 8) - 2\,C_{\mathrm{IV}}\,(- v_3 + v_5 + v_6 - 16) \ldots . (4)$$

When the partial derivatives of this function with respect to v_1, v_2, etc., are equated to zero, the following expressions for the section corrections are obtained: $v_1 = 3\,C_{\mathrm{I}}$; $v_2 = 3\,(C_{\mathrm{I}} + C_{\mathrm{III}})$; $v_3 = 5\,(C_{\mathrm{III}} - C_{\mathrm{IV}})$; $v_4 = 8\,C_{\mathrm{III}}$; $v_5 = 10\,(C_{\mathrm{I}} + C_{\mathrm{IV}})$; $v_6 = 11\,C_{\mathrm{IV}}$; $v_7 = 8.5\,(C_{\mathrm{I}} + C_{\mathrm{II}})$; and, $v_8 = 11\,C_{\mathrm{II}}$.

The foregoing results may be summarized in the statement that the section correction for a given section is equal to the product of the effective length of the section by the sum of its condition multipliers.

DISCUSSION

EARL F. CHURCH,[5] ASSOC. M. AM. SOC. C. E. (by letter).—This interesting paper well deserves the attention of all engineers interested in the practical computations of surveys. It contains a description of two methods for adjusting engineering level nets and one of the most interesting features is that the two methods presented are identical. (The term, "engineering leveling," is used to denote ordinary leveling as distinguished from "geodetic leveling.") The first is the least squares method, the "condition multipliers" being the usual "correlatives." This part of the paper refers to a "converging increment" method of approximation for solving the normal equations to be used instead of the precise Gauss method. The lack of rigidity in the theory is implied by the author in his statement that the method "appears to be applicable to the vast majority of normal equations encountered in practical engineering problems." After all, the real test of any method of solving normal equations lies in obtaining values of the correlatives which satisfy the equations; and this method of approximation will undoubtedly give the desired results in most cases of engineering level nets, as it does in the specific examples shown. Regardless of whether the method possesses any marked advantages over the usual Gauss method, the author is entirely justified in presenting it on account of the fact that, by the identity of the results by the two methods and even of the steps in obtaining the results, it establishes the correctness of the second method.

The second method, called "successive distributions," shows a process of adjusting engineering level nets which is certainly a useful one. Requiring no knowledge of least squares and eliminating the necessity of setting up the normal equations themselves, it is easy to comprehend and easy to apply; and for both these reasons it should appeal to the average surveyor. The method appears at first glance to have no relation to least squares and to give results which, although they might render the level net consistent, would bear no relation to the "most probable values" and might even vary with the order arbitrarily chosen for closing the various circuits. This is not the case, however. The identity of the results of the two methods shows the elevations from the second method to be virtually the "most probable values." Furthermore, the identity of the steps in obtaining the results in the two methods establishes the correctness of the second method as virtually a least squares adjustment for cases in which the "converging increments" would solve the normal equations, regardless of the order chosen for closing the circuits in the second method.

The following notes may be of assistance in observing the identity in the successive steps in the two processes. Compare the values shown in Fig. 4 for the method of "successive distribution" with those shown in Table 5 for the solution of the normal equations by "converging increments": On Line 1 of Table 5, 4.85, 1.71, and 5.71 are the values "carried over" in Fig. 4 from Circuit No. I into Circuits Nos. II, III, and IV, respectively; on Line 2 of Table 5, -6.48 is the value in Fig. 4 "carried over" from Circuit No. II to Circuit No. I, and the two blank spaces on Line 2 show that in Fig. 4 there were no values "carried over" from Circuit No. II to either Circuit No. III or Circuit No. IV; on Line 3 of Table 5, -1.82 and 3.04, are the values in Fig. 4 "carried over" from Circuit No. III to Circuits Nos. I and IV, respectively; on Line 4 of Table 5, 2.79 and -1.39 are the values in Fig. 4 "carried over" from Circuit No. IV to Circuits Nos. I and III, respectively; on Line 5 of Table 5, 5.51 is the closure distributed in Circuit No. I, in Fig. 4 the second time; and 1.91, 0.67, and 2.24, on Line 5 of Table 5, are the values in Fig. 4 "carried over" the second time into Circuits Nos. II, III, and IV, respectively. This identity of the steps can be followed throughout.

---

[5] Associate Prof. of Photogrammetry, Coll. of Applied Science, Syracuse Univ., Syracuse, N. Y.

Undoubtedly, the use of series summations to obtain section corrections in the method of "successive distribution," will generally prove to be a useless refinement. In fact, in the specimen adjustment shown in Fig. 4, the correct values of the section corrections would have been obtained if the additions had been made after the third distribution, and both the fourth distribution and the series summations were actually unnecessary.

This discussion may be summarized somewhat as follows: The second method (that of "successive distribution"), gives a simple and useful means of adjusting engineering level nets. This method is particularly simple in the frequent cases in which one can dispense with the series summations. The desirability of the method depends entirely upon whether the resulting elevations are the "most probable values" regardless of the order of closing the circuits, and that they are approximately the most probable values is proved by the identity with the results from the least squares method. The only remaining question is whether the first method (with which the comparison is made) actually gives "most probable values" when the converging increment approximation is used to solve the normal equations; but it will be observed that it must do so provided the correlatives obtained actually satisfy the normal equations. Therefore, for any cases in which "converging increments" would solve the normal equations, the second method of "successive distribution" without the normal equations will give correct results.

In presenting to the average surveyor an excellent process for adjusting ordinary engineering level nets, this paper serves a useful purpose and is to be highly commended.

W. H. RAYNER,[6] ASSOC. M. AM. SOC. C. E. (by letter).—This presentation is an excellent example of that type of study which consists in the application of existing theory to new problems; and an especial reason for commendation is the fact that, for good measure, the author has given two equally good solutions of a complex and important problem.

The simplicity and clarity of treatment are excellent but a statement under "Solution of Normal Equations," needs a brief additional explanation, it seems, to make clear the computation of the "condition multipliers," $C_{\rm I}$, $C_{\rm II}$, etc. Referring to Table 5(a), Mr. Dell states that "Line 18 contains the sums of the principal terms (including the quantities in Line 17), and the values of the unknowns (the condition multipliers), are given in Line 19." The value of $C_{\rm I}$, for Method 1, Example No. 1, is given by the relation, $C_{\rm I} = \dfrac{\text{Major terms of Circuit No. I}}{\text{Total effective length of Circuit No. I}}$. Hence, $C_{\rm I} = \dfrac{22.07 \text{ (Line 18)}}{24.5}$ $= 0.901$. Likewise $C_{\rm II} = \dfrac{-17.65}{19.5} = -0.905$.

---

[6] Asst. Prof. of Civ. Eng., Univ. of Illinois, Urbana, Ill.

Two approximate methods are sometimes used to adjust level nets, and may be designated: (1) The "successive-circuit" method; and (2) the Geological Survey method. The writer was interested to compare both the results and the labor involved in each of these approximate methods with those of Mr. Dell's methods.

Briefly stated, the successive-circuit method consists in adjusting the sides of connected circuits in proportion to the lengths of the sides, beginning with that circuit having the largest error of closure. The second circuit to be adjusted is the one having the second largest error of closure, etc. The method is described in detail, in the more complete surveying textbooks.[7]

The Geological Survey method consists in beginning with a fixed benchmark, from which the nearest junction points of connected circuits are given a preliminary adjustment. The weights assigned to the different elevations of such junction points, as found by the different connecting lines, are inversely proportional to the lengths of the lines. Using the preliminary adjusted values thus found, other junction points are similarly adjusted to include all points within the level net. From such tentative values, a second computation establishes the final elevations of the successive junction points.[8]

For purposes of comparison, a net including five circuits comprising nine lines from 5 miles to 30 miles in length, was adjusted by each of the approximate methods and by each of Mr. Dell's methods, with the results shown in Table 11.

TABLE 11.—COMPARISONS OF ADJUSTMENTS OF A LEVEL NET

Point	DELL	GEOLOGICAL SURVEY		SUCCESSIVE-CIRCUIT	
	Elevation	Elevation	Discrepancy with Dell	Elevation	Discrepancy with Dell
E	650.00	650.00	0.00	649.85	—0.15
B	810.21	810.25	+0.04	810.26	+0.05
A	601.39	601.35	—0.04	601.39	0.00
F	682.65	682.64	—0.01	682.56	—0.09
D	748.17	748.18	+0.01	748.14	—0.03
C	715.29	715.28	—0.01	715.36	+0.07

It is evident that, for this example, the discrepancies between the Geological Survey method and the Dell method are, in the average, about one-third as large as those of the successive-circuit method. Of course, the two Dell methods yielded identical results.

---

[7] "Surveying," by Davis, Foote, and Rayner, Second Edition, p. 174.

[8] The method is described in detail in "Instructions to Topographers of the U. S. Geological Survey."

Each of the Dell methods and the Geological Survey method required about an equal amount of labor. However, the writer believes that the layman will find Method 2 the easier to apply. The successive-circuit method is much easier of application than the others; but it is also the least accurate.

It is evident, therefore, that for engineers who meet this problem, Mr. Dell has provided two methods that are mathematically correct and convenient, thus making unnecessary and inexcusable the use of approximate methods.

GEORGE H. DELL,[9] ASSOC. M. AM. SOC. C. E. (by letter).—The discussions submitted on this subject by Professors Church and Rayner contain interesting and helpful comments. Both writers find the distribution method superior from the standpoints of simplicity and applicability.

The example analyzed by Professor Rayner is a typical indication of the errors inherent in "compromise" methods of adjustment. Professor Church has clarified an important item in pointing out that the corrections are substantially independent of the order of adjusting the separate circuits. He has also made noteworthy observations in regard to the elimination of undue refinements of precision.

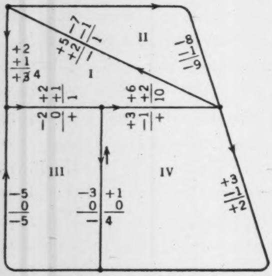

FIG. 6.—SIMPLIFIED ADJUSTMENT OF LEVEL NET, EXAMPLE NO. 1.

The original solutions were prepared with a view to presenting methods capable of yielding results correct to approximately 0.001 ft, and therefore, applicable to precise surveys. For ordinary level nets, in which an inaccuracy of 0.01 ft in any section is permissible, two cycles will generally be sufficient if supplemented by occasional arbitrary corrections of 0.01 ft. Fig. 6 illustrates the solution of Example No. 1 under such conditions. It will be noted that at the end of the second cycle the only remaining error was in Circuit No. I; this was eliminated by changing the correction of Section No. 1 to + 0.04 ft.

STRUCTURAL BEAMS IN TORSION

By Inge Lyse,[1] M. Am. Soc. C. E.,
and Bruce G. Johnston,[2] Jun. Am. Soc. C. E.

With Discussion by Messrs. H. M. Westergaard and R. D. Mindlin, Joseph B. Reynolds, Harold E. Wessman, F. B. Seely and W. J. Putnam, P. Wilhelm Werner, F. L. Ehasz, W. P. Roop and John B. Letherbury, Alfred T. Waidelich, and Inge Lyse and Bruce G. Johnston.

Synopsis

Results of a study of the torsional properties of standard structural steel beams are offered for discussion in this paper. The purpose of the investigation was to furnish a reliable basis for the design of structural members subjected to torsional loads. The relation between torque and stress on the one hand, and between torque and twist on the other, for any piece subjected to torsion involves a constant the value of which is a function of the material and the shape of the cross-section. An accurate method is given for the evaluation of this torsion constant, K, for standard **H**-sections and I-sections, taking full account of all factors involved. This has been made possible by applying the "membrane analogy" to about sixty sections of widely varying flange, web, and fillet proportions.

The investigation included a study of the effect of end fixity in torsional design, and shows how it may be obtained effectively. The proposed formulas are applied to practical design problems, and are checked by torsional tests on structural steel sections ranging in size from a 3-in. I-beam weighing 7.5 lb per ft, to a 12 by 12-in. beam weighing 190 lb per ft.

Note.—Published in April, 1935, *Proceedings*.

HISTORICAL FOREWORD

The problem of pure torsion as applied to non-circular sections was first treated correctly by Saint Venant (1)[a] in 1855, and his general solution is applicable to any cross-section. In 1903, Prandtl (2) showed that if a thin membrane were stretched across a hole having the shape of the cross-section in question and distorted slightly, the equation of its surface had the same form as the general differential equation involved in the torsion problem. Prandtl showed that by measuring the volume and slopes of the displaced membrane a direct measurement of the torsional rigidity and stress was obtainable. Prandtl's analogy, with a thin soap film as a membrane, was used in several torsion investigations, first in England by Griffith and Taylor (3) who studied the torsional strength of aeroplane sections in 1917, and, later, in the United States by Trayer and March (4), who, in 1930, made similar studies for the same purpose.

Important contributions to the torsion problem have been made by Timoshenko (5). He has shortened the pure torsional theory by slight modifications of Saint Venant's equations and by mathematical application of the principles of the membrane analogy. He was also among the first to consider the effect produced by preventing the warping of a cross-section. This problem has had the attention of numerous investigators in connection with problems of elastic stability and buckling during bending. Sonntag (7) treated the theoretical aspects of this problem in an article published in 1929.

INTRODUCTION

The investigation reported herein was undertaken as a study of all available information on the subject, both theoretical and experimental, supplemented by a considerable number of actual torsion tests of structural steel beams and soap film experiments on various cross-sectional shapes. The writers first considered testing beam sections 3 ft in length, welded to thick plates at the ends. A study of the problem, however, showed that such beams would be several times stronger than if they were tested free-ended, and that, unless the exact percentage of end fixity was known, it would not be possible to draw definite conclusions from such tests.

In order to study the effect of end fixity directly, tests were first made on eight sections of a 3-in. I-beam (7.5 lb per ft), varying from 3 in. to 4 ft 6 in. in length and cut from the same rolled section. The ends of each piece were welded to plates 1 in. thick, and the specimens were tested in a standard 26 000 in-lb torsion machine.

The results of these tests pointed the way to a revised general program, and a torsion testing rig capable of applying torsional load up to 750 000 in-lb was designed. Provision was made for testing beams either fixed or free at the ends, and with lengths of 1 ft 6 in., 3 ft, or 6 ft. Nineteen different tests were made, twelve on beams with the ends fixed by welding the side and end plates to form a box section at the ends, and seven with ends free. The beams ranged in sizes from the 3-in. I-beam, weighing 7.5 lb per ft, to a

---

[a] The numbers in parentheses refer to references given in Appendix I.

12 by 12-in. beam weighing 190 lb per ft. Tensile and shearing properties of the material in each type of beam were obtained by standard tensile tests, round bar torsion tests, and slotted plate shear tests. Soap film experiments on fifty-seven differently proportioned sections were made for the determination of the torsional rigidity.

This paper contains the final summary of all phases of the investigation. Use has been freely made of the findings of previous investigators, for which acknowledgment is made at appropriate points.

Notation.—The symbols in this paper are introduced in the text as they occur, and are summarized for reference in Appendix II.

THE TORSION THEORY

General Problem.—The solution of the torsional properties of a section of any shape consists primarily in determining the distribution of lateral shearing stresses over the cross-section. The shear components will be of uneven distribution, except in the case of the circular section, and as a result plane sections will be warped during twisting as shown in Fig. 1 (Note that, in Fig. 1(*c*), the web and each flange are warped as individual rectangles, in addition to the warping of the section as a whole.)

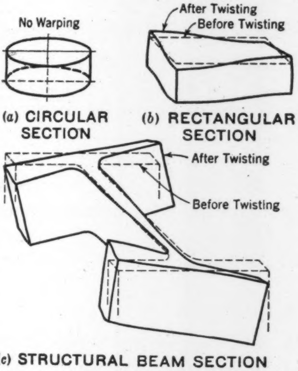

FIG. 1.—TWISTING OF BARS OF VARIOUS CROSS-SECTIONS

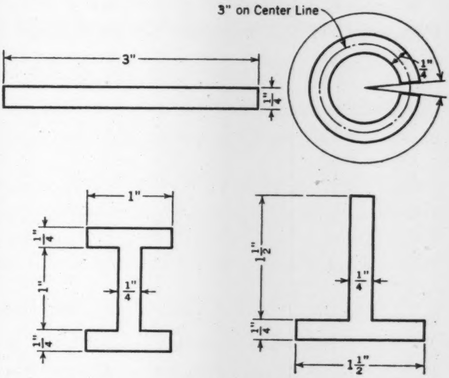

FIG. 2.—SECTIONS HAVING APPROXIMATELY EQUAL TORSIONAL RIGIDITY

It is assumed that the lateral displacements are proportional to the angular twist and to the distance from the twisting axis (as is the case in a circular section). The longitudinal displacements cause the warping, and the resulting distribution of shearing stress is taken care of by introducing a "stress-function," F, of x and y. This function must satisfy the differential equation:

$$\frac{\partial^2 F}{\partial x^2} + \frac{\partial^2 F}{\partial y^2} = -2G\theta \quad \text{.....................(1)}$$

in which, G = the shearing modulus of elasticity, and θ = angle of twist, in radians per inch. It may be shown that the function, F, must be a constant along the boundary of the section for solid bars, and, therefore, may be chosen arbitrarily as equal to zero.

If the boundary conditions are such that Equation (1) may be solved and the value of F determined, it is possible to evaluate the torsion constant of the section and find the stress at any point in the cross-section. Formulas for the torsion constant and critical shearing stresses have been derived in this manner for such sections as the square, rectangle, ellipse, equilateral triangle, and sector of a circle (1).

In the case of the circular shaft the shearing stress components have a uniform distribution along each radius, and since the longitudinal shear is likewise evenly distributed, there is no longitudinal warping of first-order importance. The well-known simple theory using the polar moment of inertia is thus applicable to the case of the circular section.

If, in some way, warping which takes place in non-circular sections is restrained or prevented, longitudinal fiber stresses will be introduced and the beam stiffened and strengthened.

The Membrane Analogy.[4]—Equation (1) may be solved mechanically for any cross-section by means of Prandtl's membrane analogy, thereby overcoming the mathematical limitations of the theoretical derivation.

In the application of this analogy, a soap film is stretched across an opening having the same shape as the structural section under consideration. The bubble is distended slightly by a variation in pressure. Prandtl showed that the following relations obtain for this bubble: (1) The torsion constant, K, is proportional to the total volume of the displaced bubble; (2) the shearing stress at any point is proportional to the maximum slope of the film at that point; and (3) the contour lines on the bubble give the direction of maximum shearing stress.

The analogy is also useful as an aid in visualizing the rigidity and stress distribution in various sections, and makes evident why the four sections shown in Fig. 2 have approximately equal rigidities in pure torsion, since the volumes of the various soap bubbles are approximately the same in each case. This would not be the case if the ends of the beams were restrained.

EVALUATION OF THE TORSION CONSTANT

Definition.—The torsion constant, K, is the measure of the torsional rigidity and twisting deflections. It is also a part of any formula for torsional shearing stresses, and may be determined from test results by observing the ratio of torsional moment to unit twist, in radians per inch, at any place below the yield point of the beam, and dividing this ratio by the shearing modulus of elasticity.

The Relation Between K and J.—When a torsional couple, T, is applied to a circular shaft of radius, r, the maximum shearing stress, τ, at the surface, is given by:

$$\tau = \frac{T\,r}{J} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, J = polar moment of inertia. In terms of T Equation (2) may be re-arranged to read:

---

[4] A detailed description of the soap film studies is given in a thesis by Bruce G. Johnston, Jun. Am. Soc. C. E., presented to Lehigh University in partial fulfillment of the requirements for the degree of Master of Science.

$$T = \frac{\tau J}{r} \qquad \text{(3)}$$

The torque, T, may also be expressed in terms of θ and G, thus:

$$T = J G \theta \qquad \text{(4)}$$

For non-circular sections the torsional resisting moment may again be expressed in terms of θ and G, with the substitution of K, the torsion constant, in place of J, thus:

$$T = K G \theta \qquad \text{(5)}$$

The torsion constant, K, is equal to the polar moment of inertia for circular sections. Although for non-circular sections it is always less than the polar moment of inertia, there is no direct relation between the two factors.

The Rectangle.—In dealing with structural shapes, two principal types of section require consideration, the rectangle, and the rectangle modified by sloping sides, as in the flange of a standard I-beam. In the case of the rectangle an accurate formula was derived originally by Saint Venant (1):

$$K = \frac{n^3 b}{3} - 2 V n^4 \qquad \text{(6)}$$

in which n = the breadth of a rectangular section; b = the length of a rectangular section; and V = a factor depending upon the ratio, $\frac{b}{n}$, but practically constant for $\frac{b}{n} > 3$. Fig. 3 shows the values of V for $\frac{b}{n}$ from 1 to 3. For $\frac{b}{n}$ -ratios greater than 3, $V = 0.105$, and for $\frac{b}{n}$ greater than 4, $V = 0.10504$. Equation (6) finds a direct, qualitative interpretation in the

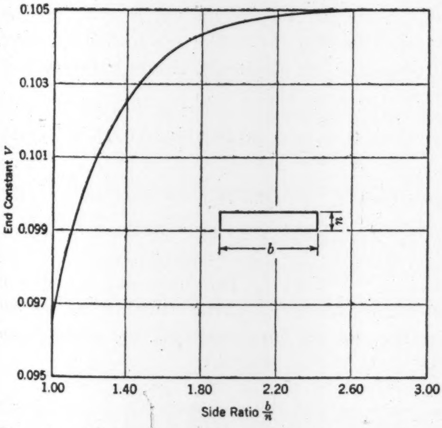

FIG. 3. — END CONSTANTS FOR RECTANGULAR SECTIONS, WITH $\frac{b}{n} < 3$. (SEE EQUATION (6)).

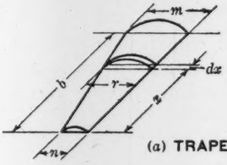
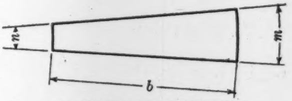
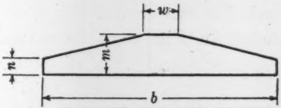


(a) TRAPEZOID



(b) PART OF A SECTOR



(c) SLOPING FLANGE SECTION

FIG. 4.

soap film analogy. It is evident that for long rectangular sections the bubble will be of constant cross-section along the central part, but at the two ends it will be contracted and brought down to meet the small side. The quantity, $-2\ V\ n^4$, then represents the "end loss," which for long sections is evidently a function of n only.

It also follows that if the ends were made discontinuous, as if they were parts of infinitely long rectangles, one might state without error:

$$K = \frac{1}{3}\, n^3\, b \qquad \text{(7)}$$

and for any differential length, dx, along the section:

$$K = \frac{1}{3}\, n^3\, dx \qquad \text{(8)}$$

The Section with Sloping Sides.—Equation (8) provides a basis for evaluating K for the sloping flange section. Considering the section shown in Fig. 4(a), let the thickness at any point be taken as r. Then, if the ends are assumed discontinuous:

$$K = \frac{1}{3} \int_0^b r^3\, dx \qquad \text{(9)}$$

Evaluating r in terms of m and n, and integrating:

$$K = \frac{b}{12}\,(m + n)\,(m^2 + n^2) \qquad \text{(10)}$$

in which m = major flange thickness and n = minor flange thickness. A deduction must be made for end effects, as in the case of the simple rectangle, thus:

$$K = \frac{b}{12}\,(m + n)\,(m^2 + n^2) - V_L\, m^4 - V_S\, n^4 \qquad \text{(11)}$$

in which V_L and V_S are the end constants, V, for the large end and the small end, respectively, of the flange (see Fig. 5). The evaluation of these two constants was the work of Professor J. B. Reynolds, through an analysis of a section having the shape shown in Fig. 4(b)[5]:

$$V_L = 0.10504 - 0.10000\, S + 0.08480\, S^2 - 0.06746\, S^3 + 0.05153\, S^4 \qquad \text{(12)}$$

and,

$$V_S = 0.10504 + 0.10000\, S + 0.08480\, S^2 + 0.06746\, S^3 + 0.05153\, S^4 \qquad \text{(13)}$$

in which S = the total slope of the section; that is, $\dfrac{m - n}{b}$.

Torsion Constant for **H**-*Beams and* **I**-*Beams.*—The foregoing supplies a basis for evaluating the K-values of the component parts. Taking the section shown in Fig. 4(c) as a basis for the sloping flange section, the sum of two trapezoids and a small rectangular part is expressed by:

$$K_f = \frac{b - w}{12}\,(m + n)\,(m^2 + n^2) + \frac{1}{3}\, w\, m^3 - 2\, V_S\, n^4 \qquad \text{(14)}$$

---

[5] "Theory of Elasticity," by A. E. H. Love, Fourth Edition, p. 319.

in which K_f = the K-value for the flange. The web is considered as a discontinuous section between the flanges, giving:

$$K_w = \frac{1}{3}\ (d - 2\ m)\ w^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which K_w = the K-value for the web; d = total depth of beam; and, w = thickness of web (see Fig. 6). There still remains the evaluation of the added rigidity due to the connection of the flange and web and also due to the fillet at this point. It is evident that these will cause a considerable "hump" in the soap bubble.

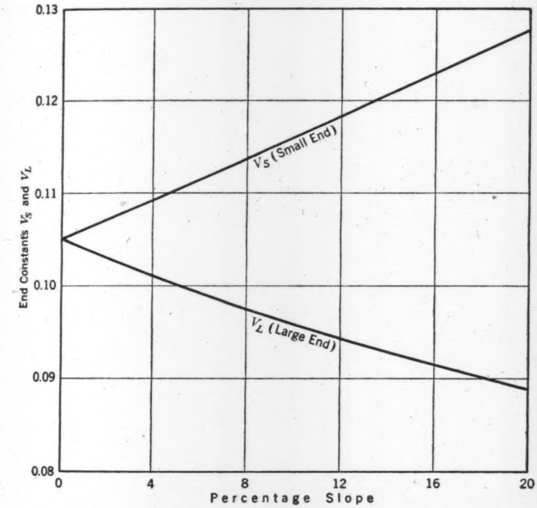


FIG. 5.—END CONSTANTS FOR K-VALUES OF FLANGES WITH SLOPING SIDES.

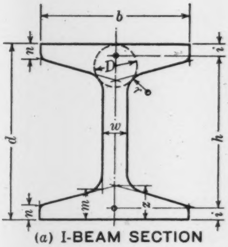
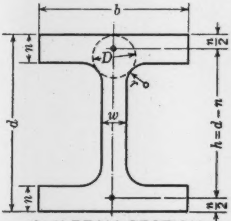


(a) I-BEAM SECTION



(b) H-BEAM SECTION

FIG. 6.

Trayer and March (4) in an investigation of aircraft strut sections assumed this addition to the torsion constant to be proportional to the fourth power of the diameter of the largest circle that can be inscribed at the juncture of the web and flange (see Fig. 6), giving, as an additional K-value:

$$K = \alpha\ D^4 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which D = the diameter of an inscribed circle; and α = a factor that depends on two ratios, $\frac{w}{m}$ and $\frac{r}{m}$.

Values of α for sections with parallel-sided flanges, and for sections with flange slopes of 1 on 6, are given in Fig. 7. These curves were determined experimentally as the result of soap film tests which will be described subsequently. It will be noted in Fig. 7(a) that for parts of the curves to the right of *a-a,* the lines are parallel and uniformly spaced. All standard rolled beams are in this area, in which case, for parallel flange sides:

$$\alpha = 0.094 + 0.070 \frac{r}{m} \qquad \text{(17)}$$

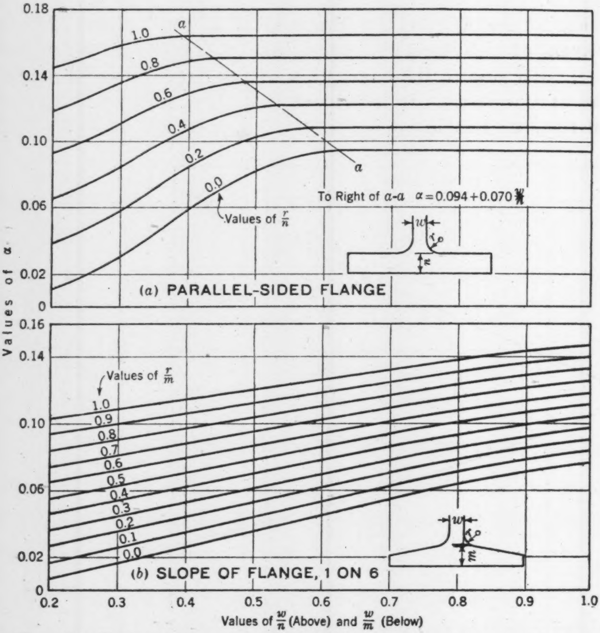


FIG. 7.—VALUES OF α FOR RIGHT-ANGLE JUNCTION OF FLANGE AND WEB.

For flange sections with side slopes of 1 on 20 and 1 on 50 the following formulas represent an interpolation between the curves in Fig. 7:

For a slope of 1 on 20:

$$\alpha = 0.066 + 0.021 \frac{w}{m} + 0.072 \frac{r}{m} \qquad \text{(18)}$$

and, for a slope of 1 on 50:

$$\alpha = 0.084 + 0.007 \frac{w}{m} + 0.071 \frac{r}{m} \qquad \text{(19)}$$

The various elements entering into the total K-values, can now be summarized as follows (refer to Fig. 6):

For sloping flange sections,

$$K = \frac{b - w}{6} (m + n)(m^2 + n^2) + \frac{2}{3} w m^3 + \frac{1}{3} (d - 2m) w^3 + 2 \alpha D^4 - 4 V_S n^4 \qquad \text{(20)}$$

Values of V_L and V_s for standard slopes are, as follows:

S	V_L	V_s
$\frac{1}{6}$	0.09045	0.12441
$\frac{1}{20}$	0.10026	0.11026
$\frac{1}{50}$	0.10307	0.10707
$\frac{1}{\infty}$	0.10504	0.10504

and, for sections with parallel-sided flanges,

$$K = \frac{2}{3}\, b n^3 + \frac{1}{3}\,(d - 2\,n)\, w^3 + 2\,\alpha\, D^4 - 0.42016\, n^4 \quad \ldots\ldots(21)$$

SECTIONS	RIGIDITY	STRENGTH
(a)	100.0	100.0
(b)	637.0	332.0
(c) 	5.5	18.0
(d)	70.0	62.0
(e)	88.0	74.0
(f)	341.0 (Approx.)	280.0 (Approx.)
(g)	9.9 (Nearly Exact)	22.2 (Approx.)
(h)  $r=w=\frac{2}{3}\,n$	11.6 (Nearly Exact)	22.8 (Approx.)
(i) $6\frac{1}{2}''$  Fixed Ends 1'6"	78.1 (Approx.)	38.3 (Approx.)

FIG. 8.—TORSIONAL RIGIDITY AND STRENGTH OF DIFFERENT SECTIONS OF EQUAL CROSS-SECTION AREAS.

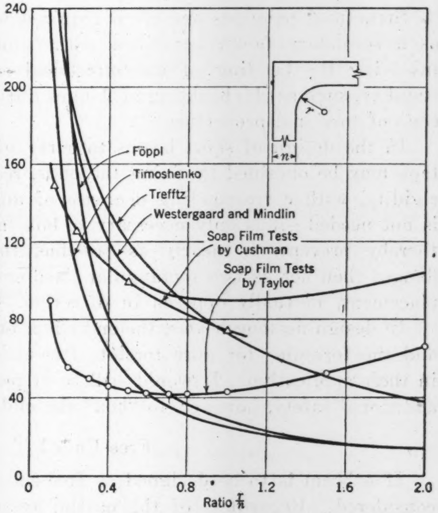

FIG. 9.—FORMULAS FOR STRESS CONCENTRATION IN FILLETS DUE TO TORSION.

Diameter D may be determined by a large scale layout, or by the following formulas:

For parallel-sided flange sections,

$$D = \frac{(n + r)^2 + w\left(r + \frac{w}{4}\right)}{2\,r + n} \quad \ldots\ldots\ldots\ldots\ldots\ldots(22)$$

for sloping-sided flange sections,

$$D = \frac{(B + z)^2 + w\left(r + \frac{w}{4}\right)}{B + r + z} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which z = the maximum flange depth shown in Fig. 6, and,

$$B = r\,S\left[\sqrt{\frac{1}{S^2} + 1} - 1 - \frac{w}{2\,r}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Comparative Efficiencies of Different Sections.—Fig. 8 shows the comparative torsional efficiencies of certain different shapes, illustrating the striking advantages of the hollow box, or tubular, construction. These advantages would not obtain entirely if the section were built up by use of bolts or rivets.

Examples of Design

General Statement

Structural members are often required to carry torsional loads, generally as a secondary factor combined with bending or direct stress. Problems involving the bending of unsymmetrical sections, and problems of elastic stability, such as the buckling of flanges during bending, also require a knowledge of torsional properties.

In the design of short beams to carry torsional loads considerable advantage may be obtained by fixing the ends, resulting in increased strength and rigidity, with corresponding decrease of angular deflection. External fixity is not needed—it is only necessary to box in the two flanges at each end and thereby prevent, as nearly as possible, their relative warping. The two flanges then act as two rectangular fixed-ended beams carrying a lateral displacement, mutually opposed in direction.

In designing long beams, the end effect tapers out rapidly toward the center, and the formulas for pure torsion, free-ended, will be adequate and simpler in their application. It would still be of practical advantage and a means of additional safety, however, to "box" the ends of the beam.

Free-Ended Torsion

If a beam is to be designed as free-ended, only shearing stresses need be considered. Regardless of the partial restraint that does exist as an incidental feature of the details, such a design will be on the safe side. The critical shearing stresses will occur along the outer surface of the beam where the material is thickest, generally along the outside center line of the flange and along the inside re-entry fillets.

The shearing stress is a function of the thickness of the material and the following formula is proposed for the maximum shearing stress in the flange of an **H**-beam or an **I**-beam in free-ended torsion:

For parallel-sided flange sections,

$$\tau_f = \frac{T\,(D + n)}{2\,K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

for sloping flange sections,

$$\tau_f = \frac{T\,(D + m)}{2\,K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25b)$$

and for shear stress in the web,

$$\tau_w = \frac{T\,w}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which T = torsional moment. Although Equation (26) is in accord with torsional theory it gave results which proved low by comparison with actual tests. The following tentative formula was found to give better agreement:

$$\tau_w = \frac{T\,(w + 0.3\,r)}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

Equation (27) was adopted for use in the reported investigation. More accurate stress formulas might be developed by further use of soap film tests, taking slope measurements at critical points, and testing sections with various ratios of web, fillet, and flange as was done in determining the torsion constant. An equation similar to Equation (27) will give practically the same values for flange stress as Equation (25), thus:

$$\tau_f = \frac{T\,(n + 0.3\,r)}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Equation (25) was used in the reported investigation.

Concentration of Shearing Stress at Re-Entry Fillet

At the re-entry fillet of an **I**-beam torsional shearing stress concentrations occur due to the sharp curvature of the fillet. These stresses are mostly of a local nature and do not greatly influence the yielding of the beam as a whole. Although they do not necessarily govern the design of the beam they are important in the study of adequate fillet sizes and in the determination of loads producing strain lines in the fillets. In a beam subjected to flexural as well as torsional stresses the total stress concentration at the fillet is the sum of the stresses due to these two causes.

The concentration of torsional stress at the fillet between flange and web is illustrated in Fig. 9 for the formulas developed by Föppl(9), Trefftz(8), Timoshenko(5), and Westergaard and Mindlin, and for soap film experiments conducted by Griffith and Taylor(3), and by Cushman(13). The analysis resulting in the Westergaard-Mindlin curve was communicated to the writers by its originators. It is noted that all curves indicate a rapid increase in stress concentration with the decrease of the ratio, $\frac{r}{n}$, between the radius of the fillet and the thickness of the section next to it, particularly for ratios of less than 1.0. Strain lines, therefore, will appear at relatively small torsional moment for sections having small fillets.

As the fillets become increasingly large another factor is introduced since the increased stress due to the greater thickness of material becomes of more importance. The rigidity of the beam is increased in proportion to the third power of the thickness, whereas the stress varies directly with the thickness. Hence, for any given moment the stress would actually decrease. The curve of soap film tests by Griffith and Taylor indicate this reverse effect, but further experiments along this line should be conducted to establish these relations more definitely.

Fixed-Ended Torsion

Assumptions.—If the ends of a non-circular section are fixed in some manner so as to prevent free warping of the end section, pure torsion no longer exists.

Various investigators have studied this problem—Föppl(9), Timoshenko(5), Sonntag(7), and others. In 1930 an investigation on channel sections was reported by Seely, Putnam, and Schwalbe (10). These investigators have generally been concerned with the problem of elastic equilibrium involved in the side buckling and twisting of a beam in bending without lateral support. Hence the torsion problem has been a secondary issue.

In the present tests both ends of structural beams have been fixed by welding on heavy end plates and additional side stiffening plates between the flanges at each end of the beam. The major stiffening effect produced is that of fixing the flanges relative to each other. (Refer to Fig. 10.) The prevention of the individual warping of the component rectangular parts would taper out so rapidly that it would be of negligible importance; but, by fixing the flanges with respect to each other, the effect of two opposed fixed-ended beams is produced, as illustrated in Fig. 10.

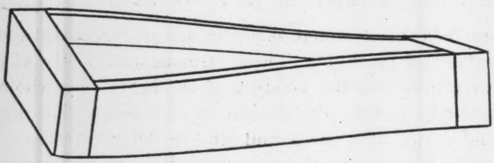

FIG. 10.—BEAM WITH FIXED ENDS.

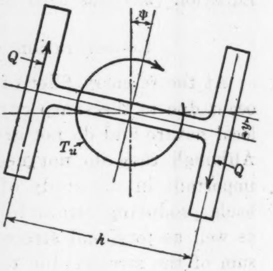

FIG. 11.—TWISTING OF A STRUCTURAL SHAPE.

The following assumptions have been made: (1) The flanges remain at right angles to the web; (2) the angular deflection is small compared with the length of the beam; (3) the bending of each flange about its weaker axis is a negligible factor; (4) a point on the neutral axis of one flange can be located with sufficient accuracy by co-ordinates (x, y) measured along the perpendicular to the original position of the axes; (5) the two ends of the beam are held between mutually parallel planes as twisting takes place; (6) the displacement of the flanges due to beam action is due to bending only (that is, lateral shearing deflection is neglected; a correction is made afterward for shearing deflection in very short beams); and (7) $\frac{I_y}{2}$ = moment of inertia of one flange about the web axis.

Assumption (7) is quite accurate and of great convenience in the case of standard **I**-beams and **H**-beams for which I_y is given in all handbooks. The following symbols in addition to those previously given will be used:

$$a = \frac{h}{2}\sqrt{\frac{EI_y}{KG}}$$

or, for steel,

$$a = 0.806\ h\ \sqrt{\frac{I_y}{K}}$$

and for sloping flange sections,

$$h = d - \frac{2}{3}\left(n + \frac{z^2}{z + n}\right)$$

in which h = distance between flange centroids; or, approximately,

$$h = d - \frac{m + n}{2}$$

which is sufficiently accurate for practical purposes.

Derivation of General Equations.—Consider the equilibrium of any cut section as shown in Fig. 11. The outer torsional moment must be resisted by the internal moment of the resisting forces, thus:

$$T = T_u + Qh \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

in which T_u = torque required to twist a beam in a free-ended condition; and Q = total lateral shearing force developed by one flange. In terms of the chosen co-ordinates, $\frac{h}{2}\ d\psi = dy$, approximately, and the twist, ψ, per unit length = $\frac{d\psi}{dx}$. Hence,

$$T_u = K\,G\,\frac{d\psi}{dx} = \frac{2\,K\,G}{h}\,\frac{dy}{dx} \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

Furthermore, assuming that the larger moment of inertia of one flange is equal to $\frac{I_y}{2}$,

$$\frac{E\,I_y}{2}\,\frac{d^3y}{dx^3} = -\,Q \ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Considering Equations (29), (30), and (31):

$$\frac{E\,I_y}{2}\,\frac{d^3y}{dx^3} - \frac{2\,K\,G}{h^2}\,\frac{dy}{dx} = \frac{-\,T}{h} \ldots\ldots\ldots\ldots\ldots (32)$$

Differentiating with respect to x, and substituting $a = \frac{h}{2}\sqrt{\frac{EI_y}{KG}}$:

$$a^2 \frac{d^4y}{dx^4} - \frac{d^2y}{dx^2} = 0 \quad \text{.....................(33)}$$

As a general solution of this differential equation:

$$y = A \sinh \frac{x}{a} + B \cosh \frac{x}{a} + C + Dx \quad \text{............(34)}$$

Torsion with Both Ends Restrained.—By proper evalution of the constants for the conditions obtaining in a beam fixed at both ends:

$$y = \frac{T\,h\,a}{2\,K\,G}\left(\cosh \frac{x}{a} \tanh \frac{l}{2\,a} - \sinh \frac{x}{a} + \frac{x}{a} - \tanh \frac{l}{2\,a}\right) \text{...(35)}$$

in which l = length of the beam. For $x = l$, the total deflection equals,

$$y = \frac{T\,h\,a}{2\,K\,G}\left(\frac{l}{a} - 2 \tanh \frac{l}{2\,a}\right) \quad \text{...............(36)}$$

The moment in each flange equals,

$$M = \frac{E\,I_y}{2}\,\frac{d^2\,y}{dx^2} = \frac{T\,a}{h}\,\frac{\sinh u}{\cosh \dfrac{l}{2\,a}} \quad \text{..............(37)}$$

in which $u = \frac{l}{2\,a} - \frac{x}{a}$; and, furthermore, the shear in each flange equals,

$$Q = \frac{E\,I_y}{2}\,\frac{d^3\,y}{dx^3} = \frac{-\,T}{h}\,\frac{\cosh u}{\cosh \dfrac{l}{2\,a}} \text{...............(38)}$$

The longitudinal stresses along the outer fibers of the flanges will be given by:

$$\sigma = \frac{M\,c}{I} = \frac{M\,b}{I_y} = \frac{T\,a\,b}{h\,I_y}\,\frac{\sinh u}{\cosh \dfrac{l}{2\,a}} \quad \text{............(39)}$$

Critical stress will be either longitudinal stresses at the end of the beam, or the sum of the lateral and torsional shearing stresses at the center of the beam.

At the end of the beam, $u = \frac{l}{2\,a}$, and, consequently,

$$\sigma = \frac{T\,a\,b}{h\,I_y} \tanh \frac{l}{2\,a} \quad \text{....................(40)}$$

and at the center of the beam, $u = 0$, giving,

$$Q_c = \frac{T}{h} \operatorname{sech} \frac{l}{2\,a} = \frac{T}{h \cosh \dfrac{l}{2\,a}} \quad \text{..............(41)}$$

At the center of the beam both the lateral and torsional shearing stresses will be maximum in the middle of the flange.

By the simple beam theory, the lateral shearing stress will be: For parallel flange sections,

$$\tau = \left(\frac{3}{2}\,\frac{Q}{A_f}\right) = \frac{Q\,b^2}{4\,I_y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

in which $A_f = A$ for one flange. For sloping flange sections,

$$\tau = \frac{Q\,b^2\,(2\,n + m)}{12\,m\,I_y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (43)$$

For torsional shearing stress at the center of the beam, the approximate formulas proposed in Equations (25) and (27) are applied. Instead of K, the torsion constant, an equivalent constant must be introduced, which is measured by the rate of angular twist at the center of the beam.

To obtain this, differentiate Equation (35) with respect to x, giving the slope of the flange, $\frac{dy}{dx}$, at any point. The unit angular twist, $\frac{d\psi}{dx} = \frac{2}{h}\frac{dy}{dx}$, and from this relation and the substitution of $x = \frac{l}{2}$, an expression is derived for $\theta_c = \frac{d\psi}{dx}$ at the center; thus,

$$\theta_c = \frac{T}{K\,G}\left[\frac{\cosh\left(\frac{l}{2\,a}\right) - 1}{\cosh\left(\frac{l}{2\,a}\right)}\right] \quad \ldots\ldots\ldots\ldots\ldots (44)$$

This derivation (Equation (44)) has been based on the assumption (6) that deflection is due to bending only. As the beam is shortened, however, shearing deflection becomes of increasing importance and should be considered.

Timoshenko(6) has indicated a strain energy method for calculating the deflection due to shear when cross-sections are constrained from warping. By combining his result for the simple cantilever beam the correction, $1 + 2.95\,\frac{b^2}{l^2}$, is obtained for a fixed-ended beam with point of inflection at the center; that is,

$$\theta_c = \frac{T}{K\,G}\left[\frac{\cosh\left(\frac{l}{2\,a}\right) - 1}{\cosh\left(\frac{l}{2\,a}\right)}\right]\left(1 + 2.95\,\frac{b^2}{l^2}\right) \quad \ldots\ldots\ldots (45)$$

and, denoting the "equivalent" torsion constant at the center by C_c:

$$C_e = \frac{T}{\theta_c\,G} = K\left[\frac{\cosh\left(\frac{l}{2\,a}\right)}{\cosh\left(\frac{l}{2\,a}\right) - 1}\right]\left[\frac{1}{1 + 2.95\,\frac{b^2}{l^2}}\right] \quad \ldots\ldots (46)$$

Using C_c as the measure of torsional shear developed at the center of the beam instead of K and combining Equations (25) with Equations (42) and (41), Equations (47) to (53) are derived for combined torsional and lateral shearing stresses, as follows:

Total Maximum Shearing Stress at Center of Beam (Along Center Line of Flange).—For parallel flange sections:

$$\tau = T\left[\frac{b^2}{4\,h\,I_y \cosh\left(\dfrac{l}{2\,a}\right)} + \frac{(D+n)}{2\,C_c}\right] \quad\text{..........(47a)}$$

for sloping flange sections:

$$\tau = T\left[\frac{b^2\,(2\,n+m)}{12\,h\,m\,I_y \cosh\left(\dfrac{l}{2\,a}\right)} + \frac{D+m}{2\,C_c}\right] \quad\text{........(47b)}$$

and the stress in the web may be computed by:

$$\tau_w = \frac{T\,(w + 0.3\,r)}{C_c} \quad\text{.....................(48)}$$

Total Twisting Deflections of Fixed-Ended Beams.—Equation (46) provides an equivalent torsion constant based on the unit angular twist at the center of the beam. A measure of the total twisting deflection of the beam over the entire length is desired and can be obtained effectively by evaluating an average equivalent torsion constant, which will be denoted as C_A.

The expression for total angular twist is, then:

$$\psi = \frac{T\,l}{C_A\,G} \quad\text{........................(49)}$$

For very short beams most of the deflection is that producing shear and C_c approaches C_A in value. Equation (36) is an expression for the total deflection of the flanges due to bending only. Constant C_A may be evaluated from Equation (36) in so far as bending deflections are concerned.

The ratio of $\dfrac{C_A}{C_c}$ reduces to the following expression:

$$\frac{C_A}{C_c} = \frac{\left(\cosh\dfrac{l}{2\,a} - 1\right)}{\left(\cosh\dfrac{l}{2\,a}\right) - \left(\dfrac{2\,a}{l}\sinh\dfrac{l}{2\,a}\right)} \quad\text{..............(50)}$$

The graph of $\dfrac{C_A}{C_c}$ is given on Fig. 12, permitting the quick calculation of C_A after C_c is known. As the length approaches zero, C_A should approach C_c in value and the curve on Fig. 13 gives the reduction to be made in C_A for various $\dfrac{l}{b}$ -ratios in terms of a factor to be multiplied by $(C_A - C_c)$. As an example, let: $C_c = 6.00$ by Equation (46); $\dfrac{l}{2\,a} = 2.00$; and, $\dfrac{l}{b} = 5.00$.

From Fig. 12, $\frac{C_A}{C_c} = 1.42$; and, from Fig. 13, the reduction = (0.42) (0.105) = 0.44; or, $C_A = 6.00\ (1.42 - 0.044) = 8.28$.

Torsion with One End Fixed and One End Free.—Often, in cases of combined bending and torsion, one end of the beam will be relatively unrestrained while the other end is fixed. At the free end there will be no lateral shearing stresses in the flanges and the shearing stress formulas (Equations (25)) for free end torsion will apply. The evaluation of Equation (34) for these end conditions gives the following: For maximum bending moment in the flange at the unrestrained end:

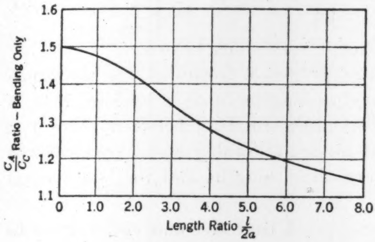

FIG. 12.—POSITIVE FACTOR TO OBTAIN C_c. TO BE USED IN CONJUNCTION WITH NEGATIVE FACTOR FROM FIG. 13.

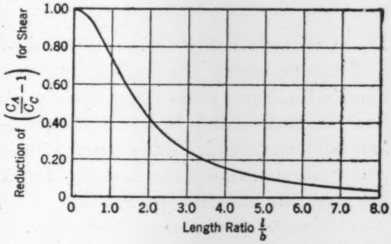

FIG. 13.—REDUCTION FACTOR FOR SHEAR (FOR USE WITH FIG. 12 TO OBTAIN C_A FROM C_C).

$$M_{\max} = \frac{T\,a}{h} \tanh \frac{l}{a} \quad \dots\dots\dots\dots\dots\dots\dots\dots (51)$$

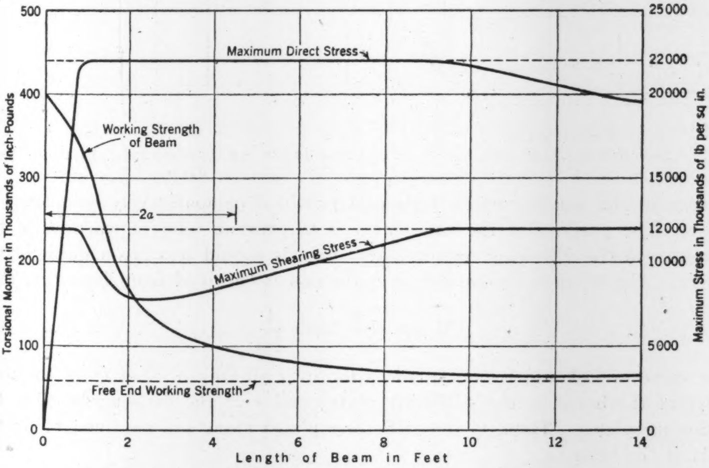

FIG. 14.—WORKING STRENGTH OF AN 8 BY 8-INCH BEAM WITH FIXED ENDS (SHOWING LIMITING STRESSES FOR DIFFERENT LENGTHS).

and for maximum direct fiber stress in the outer edges of the flanges at the restrained end:

$$\sigma = \frac{T\,a\,b}{h\,I_y}\tanh\frac{l}{a} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(52)$$

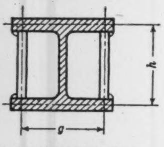
The total angle of twist is given by:

$$\psi = \frac{T\,a}{K\,G}\left[\frac{l}{a} - \tanh\frac{l}{a}\right]\left[1 + 0.74\,\frac{b^2}{l^2}\right]\ldots\ldots\ldots\ldots(53)$$

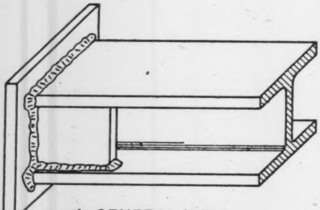
Equation (53) will be accurate for all except very short beams.

Fig. 14 shows the application of the proposed formulas for maximum longitudinal and shearing stresses to varying lengths of an 8 by 8-in. **H**-beam fixed at both ends. It is noted that for lengths ranging between about 1 ft and 9 ft the longitudinal stresses based on an allowable stress of 22 000 lb per sq in. determine the design. For very short lengths and for long lengths the shearing stresses are critical.

Design of End Connection.—It is suggested that the end connections be built as illustrated in Fig. 15. Connections of this type proved very satisfactory in the actual torsion tests and provided comparatively complete end fixity. The purpose of the end plates is to prevent relative warping of the flanges, and the following approximate analysis should serve as a guide in the design. The moment in one flange at the end is obtained from Equation (37)



(a) END SECTION



(b) GENERAL VIEW

FIG. 15.—FIXED-ENDED BEAM.

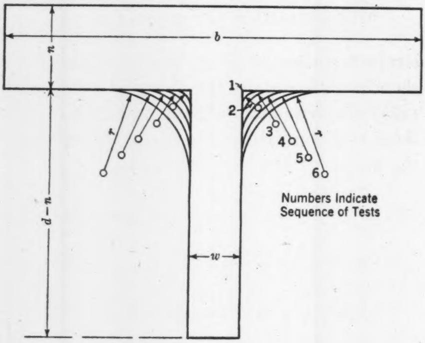


FIG. 16.—TYPES OF SECTIONS STUDIED BY SOAP FILM.

$$M = \frac{T\,a}{h}\tanh\frac{l}{2\,a}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(54)$$

The value of l should be measured as the over-all length. Let Q = the total shear of the beam in the stiffening plate; and s = the distance between the stiffening plates. Then, if the stiffening plates alone are assumed to fix the ends of the beam:

$$M = Q\,s\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(55)$$

Substituting in Equation (54):

$$Q = \frac{T\,a}{h\,s} \tanh \frac{l}{2\,a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (56)$$

The stiffener plate is welded to both flanges and to the end plate as well. The stiffener and the adjoining part of the end plate act as a short fixed-ended beam holding the flanges in place. No attempt was made to analyze the load distribution, and the design of the test beams was largely a matter of judgment.

The following tentative suggestions are made as the result of the tests:

(1) The length of the stiffener along the beam should be equal to about three-fourths the width of the flange for **H**-sections and to the full flange width for **I**-beams;

(2) The thickness of the stiffener plate material should be greater than that of the web thickness or greater than one-tenth the length of the stiffener plate along the beam;

(3) The stiffeners should be machined to a tight fit between the flanges and should be welded to flange and end plate continuously on the outer part;

(4) The end plates should have a thickness equal to twice the maximum thickness of the beam material; and

(5) The beam should be cut square and welded to the end plate with a continuous fillet weld about the entire beam end.

The stiffener plate and the weld between it and the flange should be designed to resist the shear as computed by Equation (52).

Design Examples

General Remarks.—The most economic structural **H**-beam or **I**-beam for torsional strength is one in which the material is most nearly of constant thickness throughout and is as thick and compact as obtainable. Column sections with parallel sided flanges and of the heaviest rolling in each series most nearly satisfy these requirements.

The torsional design should be made with ends assumed to be free in the case of riveted or bolted end connections; any percentage of end fixity incidentally present will simply provide an additional factor of safety. Only shearing stresses as computed by Equations (25) and (27) need be considered in free-end design.

Beams with boxed in and continuously welded end connections will be somewhat stiffer and stronger depending on the length. Both longitudinal stresses and shearing stresses must be considered (see Fig. 14). Tests indicate that the shearing stresses generally determine the yield point of the beam as a whole. The local direct stresses at the ends affect initially only a small part of the beam and are in the nature of secondary stresses. Shearing yield on the other hand occurs along the entire beam length. The allowable direct fiber stress will be made 22 000 lb per sq in. in the present discussion. It is suggested that allowable fiber stresses usual in secondary stress design be applied in general to these stresses.

General Data.—The following data apply to all the examples: Allowable working normal stress, $\sigma = 22\ 000$ lb per sq in., for secondary stresses due to fixed-end torsion; allowable working shear stress, $\tau = 12\,000$ lb per sq in.; $E = 29\ 000\ 000$ lb per sq in.; $G = 11\ 150\ 000$ lb per sq in.; Poisson's ratio, $\mu = 0.30$; l = over-all length of a beam, including stiffeners, along which a uniform torsional moment is assumed to act; $1° = 0.01745$ radian; and 1 radian = 57.30 degrees. Computations in these problems were made with a 10-in. slide-rule.

Design Example A.—A long beam with torsional deflection limited: Assume a beam 20 ft long designed to resist a total torsional moment of 20 000 in-lb with maximum total twist under the load limited to 1.2 degrees. The procedure for designing the beam as free ended involves three steps: (1) Determine the unit angle of twist, θ, in radians per inch, thus, $\theta = \dfrac{1.2 \times 0.01745}{20 \times 12} = 0.0000872$ radian per inch; (2) calculate the required K-value from Equation (5), thus, $K = \dfrac{T}{G\theta} = \dfrac{20\,000}{11\,150\,000 \times 0.0000872} = 20.6$ in.^4; and (3) refer to standard tables of K-values[6] and pick out the most economical section. In this manner, a Bethlehem section, 10 by 10 in., at 124 lb per ft (with $K = 20.37$) will be satisfactory. The end connection will provide additional rigidity and will allow a small tolerance in picking sections.

Design Example B.—Analysis of the torsional strength of a short beam (B8b, 8 by 8, at 67 lb per ft), with different end connections: The general data applying to this case are: $l = 66$ in., over-all; $K = 5.145\ \text{in.}^4$; $I_y = 88.6\ \text{in.}^4$; $n = 0.933$ in.; $b = 8.287$ in.; $D = 1.206$ in.; $h = 9.000 - 0.933 = 8.067$ in.; $a = 0.806\,h\sqrt{\dfrac{I_y}{K}} = 27.0$ in.; $\dfrac{l}{2a} = \dfrac{66}{54} = 1.22$; $\cosh \dfrac{l}{2a} = 1.8412$; and $\tanh \dfrac{l}{2a} = 0.8397$.

The free-ended working strength is computed by Equations (25) thus:

$$T = \frac{2\,K\,\tau}{D + n}\ \frac{(2)\ (5.145)\ (12\ 000)}{1.206 + 0.933} = 57\ 700\ \text{in-lb.}$$

To determine the fixed-ended working strength, based on shear, compute the equivalent torsion constant, C_c, for the center of the beam by Equation (46), thus:

$$C_c = 5.145\left(\frac{1.8412}{1.8412 - 1}\right)\left(\frac{1}{1 + 2.95\left(\dfrac{8.29}{66}\right)^2}\right) = 10.77\ \text{in}^4.$$

Then, from Equation (47),

$$T = \frac{12\,000}{\dfrac{8.29^2}{4 \times 8.067 \times 88.6 \times 1.841} + \dfrac{1.206 + 0.933}{2 \times 10.86}} = 108\,000\ \text{in-lb}$$

---

[6] See, for example, Bethlehem Manual of Steel Construction, Catalog S-47, 1934, p. 285.

To determine the fixed-ended working strength, based on longitudinal fiber stresses at ends (tension or compression), apply Equation (40):

$$T = \frac{22\,000}{\dfrac{27.0 \times 8.287 \times 0.8397}{8.067 \times 88.6}} = 84\,000 \text{ in-lb}$$

The longitudinal stresses, therefore, determine the design of the beam, and the allowable torsional moment is 84 000 in-lb.

The shear to be resisted by the end plate is computed by Equation (56); thus, if s is assumed as 6.5 in.,

$$Q = \frac{84\,000 \times 27.0}{8.067 \times 6.5} \times 0.8397 = 36\,300 \text{ lb.}$$

A $\frac{5}{8}$-in. plate fitted into the 7.13-in. space between the flanges and 6 in. in length along the beam, will satisfy the requirements suggested. Assume a $\frac{5}{8}$-in. fillet weld between the stiffener and the flange. If $s = 8.827 - 3 \times \frac{5}{8} = 6.41$ in.,

$$Q = \frac{6.5}{6.41} \times 36\,300 = 36\,800 \text{ lb}$$

The stress in the plate is:

$$\tau = \frac{36\,800}{\dfrac{5}{8} \times 6} = 9\,800 \text{ lb per sq in.}$$

and in the weld:

$$\tau = \frac{36\,800}{\dfrac{5}{8} \times 0.707 \times 6} = 13\,900 \text{ lb per sq in.}$$

which is too high. Make the plate $7\frac{1}{2}$ in. long rather than 6 in. Then the stress in the weld is:

$$\tau = \frac{6}{7.5} + 13\,900 = 11\,100 \text{ lb per sq in.}$$

which is less than the limit of 11 300 lb per sq in. recommended by the American Bureau of Welding.

Test Results

Soap Bubble Tests: Purpose and Program

The purpose of the series of tests reported herein was to evaluate, accurately, the torsion constant of structural **H**-beam and I-beam sections. Specifically, this problem narrowed down to determining the added torsional rigidity introduced by the juncture of two rectangles, with fillets at the re-entry corners, in excess of the torsional rigidity of these rectangles treated as separate members. The problem, therefore, was to determine α in Equation

(16). In order to establish the value of α for any shape of section it was necessary to consider two variables, $\frac{w}{n}$, the ratio of web to flange thickness, and $\frac{r}{n}$, the ratio of fillet radius to flange thickness. Furthermore, it was essential to study sections with sloping flanges as well as those with parallel sides.

A program of tests was outlined to cover a wide range of the two variables, $\frac{w}{n}$ and $\frac{r}{n}$. Although it would have been desirable to measure the slopes of the bubbles and thereby study the stresses, particularly in the fillets, such a study would have greatly reduced the total number of tests possible. It was thought better to establish the torsion constant definitely, in which case it was only necessary to measure the volume of the displaced bubble. In each series a basic web and flange thickness was adopted and after testing the section with zero fillet radius, the various fillets were cut away in sequence as shown in Fig. 16.

The curves obtained from the test results are shown in Fig. 7. It was found that scattered points occurred along the lines of 0.0 and 0.2 fillet radius. These variations may be due to the difficulty in machining the plates with the small fillets, a slight inaccuracy causing considerable variation in the diameter, D, of the inscribed circle. A further difficulty is encountered in the plates of zero fillet radius due to the tendency of the soap film to jump across these sharp corners. Most of the structural beams actually rolled have ratios of $\frac{w}{n}$ and $\frac{r}{n}$ both greater than 0.5 and in this area the data were quite consistent.

Tests of Steel Beams: Purpose and Apparatus

Torsion tests were made on steel beams, with several objects in view. The sections themselves were chosen so as to give a range of shapes and sizes as great as possible, and tests of certain unusual shapes, which are not at present standard, were nevertheless valuable in the investigation.

Tests of free-ended conditions were made on a number of beams in order to check the results of the soap film experiments and the corresponding method of calculating the torsion constant. In these tests the distribution of shearing stress was studied, and a check was obtained on the proposed approximate formulas for stress. Tests of fixed-end conditions were made on different shaped beams and the effect of variations in length was studied. A type of end-connection design was developed to give a considerable degree of fixity.

A standard torsion machine of 26 000 in-lb capacity was used to test 3-in., fixed-end I-beams, of various lengths. It was also used for torsion tests of round bar samples of all material to determine the shearing modulus of elasticity.

The cable torsion rig, shown in Fig. 17, with an ultimate capacity of 750 000 in-lb was used in the major tests.[7] Most of the large beams were tested in lengths of 6 ft, but two tests each were made on beams 1 ft 3 in. and 3 ft long by means of the same sheaves and cables adapted for use with shorter top and bottom beams. During the tests of light beams, cables $\frac{5}{8}$ in. in diameter were used because of their flexibility and ease of handling, but in the tests of the heavier and shorter sections the cable was changed to 1 in. in diameter in order to develop the full capacity of the machine.

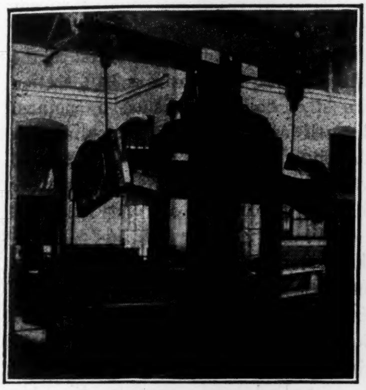

FIG. 17.—THE CABLE TORSION RIG.

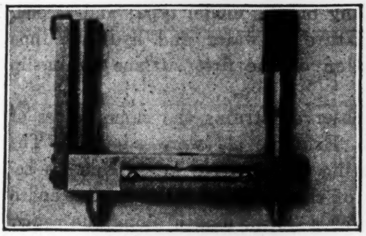

FIG. 18.—LEVEL BAR.

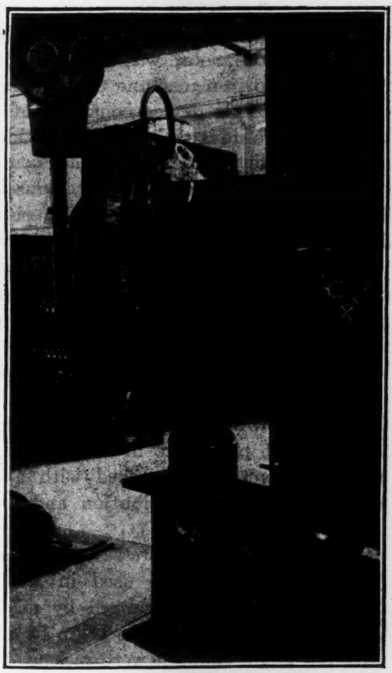

FIG. 19. — CONNECTION FOR FREE-ENDED BEAMS.

The sheaves were made of material 2 in. thick and were machined to a minimum diameter of 17 in. A hole bored through one of the diameters allowed continuous action and reversing of the cable without fouling or introducing bending moment. This machine gave perfect satisfaction in every respect and was easily set up and dismantled. During tests the apparatus was in such a state of balance that the heavy pulling beams could be easily tilted either way by hand while maintaining a heavy torsional load of the test specimen.

[7] "Torsion Testing Machine of 750 000-Inch-Pounds Capacity," by Bruce G. Johnston, Jun., Am. Soc. C. E., *Engineering News-Record*, February 28, 1935, p. 10.

Measuring Devices.—The level bar illustrated in Fig. 18 was built to measure the change in relative altitude of two points 3 in. apart. It was used to measure relative angle changes in all the beam tests. The micrometer vernier permitted readings to 0.0001 in. and the level bubble was sensitive to micrometer changes of about 0.0003 in. The total range of the instrument was about 9° 30′ ± from the original level position.

The torsion meter was used in the torsion tests of round bars in the 26 000-in-lb torsion machine to measure the angular twist over a 3-in. section of the bar. This device consisted of two steel collars attached by pointed thumb screws to the bar and provided with two 1:1 000 Ames dials for measuring the tangential displacements. The instrument was the same as that used and described in a previous investigation at the Fritz Laboratory.[8] Twenty tensometers were used to obtain the strains at all critical points during tests.

Test Procedure and Method.—In each torsion test, whether fixed or free-ended, there were three principal objectives: First, to learn as much as possible about the strain and stress distribution; second, to measure the torsional stiffness, or ratio of torsional load to angular twist; and, third, to learn the useful torsional load-carrying limit of the beam as a whole.

The strain and stress distribution was studied in two ways: First, by tensometers which were sensitive to changes in strain corresponding to from 150 to 300 lb per sq in. in stress, depending on the model type; and second, the beams were whitewashed with a mixture of water and hydrated lime which showed the distribution and location of the first surface strain-slip lines.

In computing the stresses from the observed strains the same values of E, G, and μ, as those used in Design Example A, were adopted. The torsional stiffness was gauged by measuring the relative angle changes between two points along the beam by use of the level bar. In the free-ended tests the angle changes were measured over a 36-in. length along the center part of the beam. In the fixed-ended beam the unit angle change varied along the length and a measure of the average stiffness was obtained by measuring the relative rotation of the end plates and of points a short distance from each end where the reinforcement ended.

The yield point of the beam as a whole was obtained by a study of the torque-twist diagrams and a knowledge of the load when the first strain-slip lines appeared. In a few cases a definite drop of the beam was noted and, in such cases, this was taken as the yield point. In most of the tests the yield point was taken as the torsional moment corresponding to the point on the torque-twist diagram where the co-tangent of the slope was 1.5 times the value of the co-tangent of the slope of the straight part.

Test Results.—Table 1, Appendix III, gives a general summary of all the tests made, including dimensions of beams and computed K-values based on actual dimensions. The dimensions were obtained by means of micrometers and calipers. Readings were taken at a number of different places on the beam, and averages from them were used to calculate the weight of the beam per foot of length. Furthermore, the beams were actually weighed and any discrepancy between computed and actual weight was taken care of by adjusting the average measured dimension to give the actual weight.

[8] "Shearing Properties and Poisson's Ratio of Structural and Alloy Steels," by Inge Lyse, M. Am. Soc. C. E., and H. J. Godfrey, *Proceedings*, A.S.T.M., 1933, Vol. 33, Pt. II.

Table 2, Appendix III, presents the physical properties based on tests of samples taken from the test beams. The tensile values are based on the average of two tests of American Society of Testing Materials standard tension test specimens (2-in. gauge length). The torsion tests and slotted-plate shear tests were made in the same manner as described in a previous investigation at the Fritz Engineering Laboratory.[8] In most cases, the tensile specimens and round-bar torsion specimens were cut from the material where the flange and the web join, as it is at this point that critical torsional stresses develop. The material for the slotted-plate test specimens was cut from the webs of the beams.

Free-Ended Tests.—Free-ended tests were made on seven beams. Each specimen was held in the torsion rig by two bolts at each end which passed with a loose fit through the web and through the two angles, the angles being welded to end plates which, in turn, were bolted to the sheave plates of the testing rig. Torsional moment was applied by means of lugs welded to the end plates which engaged the flanges of the test specimens. The flanges were thus free to warp and the beams were almost entirely unrestrained at the ends. Fig. 19 shows the details at one end of the largest beam tested and is typical of all the free-end tests which were made. Figs. 20(a) and 21(a) show typical torque-twist diagrams of two of the tests. Figs. 20(b)

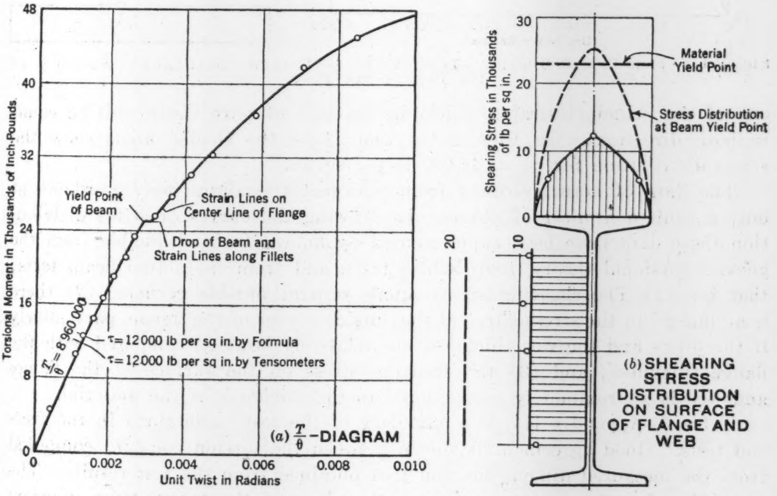

FIG. 20.—FREE-ENDED TORSION TEST T-26, A 12-INCH I-BEAM.

and 21(*b*) show the stress distribution based on tensometer readings taken in these same tests. The tensometers were placed on the flange and web surface at about the center cross-section of the beams and were set at an angle of 45° with the longitudinal axis of the beam, in order to measure one of the principal strains which, in the case of pure shear, will be equal in both directions. In Figs. 20(*b*) and 21(*b*) the shaded areas show the stress distribution for $\tau_m = 12\,000$ lb per sq. in.

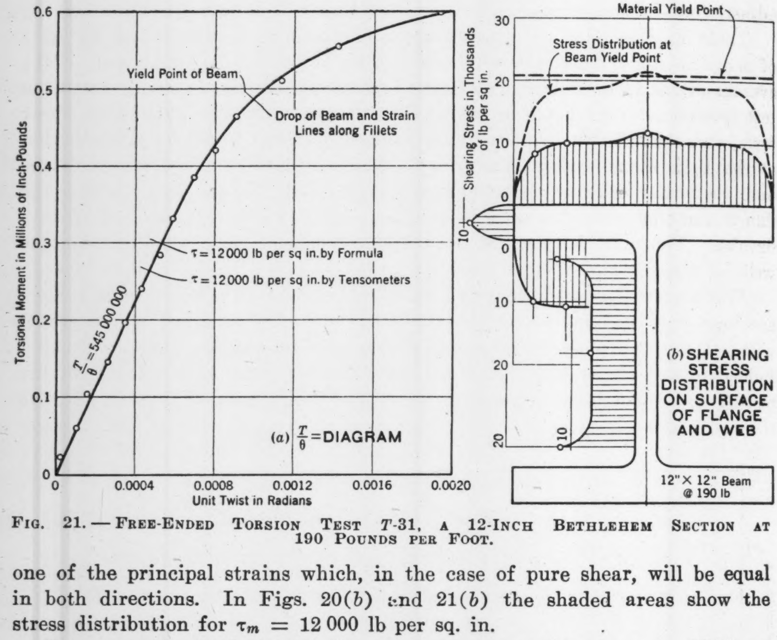

FIG. 21. — FREE-ENDED TORSION TEST *T*-31, A 12-INCH BETHLEHEM SECTION AT 190 POUNDS PER FOOT.

The data of actual stresses from tensometer readings were available at only a limited number of points. In drawing the curves of stress distribution these data have been supplemented by known facts, deducible from the general torsional theory, soap bubble tests, and from the actual beam tests; that is: (1) The shearing stress equals zero at outside corners; (2) there is a "hump" in the stress curve at the outside center of the flange, particularly if the fillets and the web thickness are relatively large as compared with the flange thickness; and (3) the shearing stress on the surface of the flange and web is approximately proportional to the thickness of the material.

Table 3, Appendix III, is a summary of the results obtained in the free-end tests. Good agreement is shown between the torsion constant computed from the measured dimensions and that obtained from the test results. The test value for K was obtained from the slope of the torque-twist diagram and from Equation (5); thus, $T = K\,G\,\theta$; or, $K = \dfrac{T}{G\,\theta}$.

The maximum variation for the K-value of test results was 6.7 and the average variation of seven tests was 2.26 per cent. It is noted that

K for the heaviest beam tested was about two hundred times greater than for the lightest beam and that the corresponding agreement for these tests was expressed by a variation of 0.9 and 0.0 per cent.

The shearing stress computed by Equation (25) gave average stresses 7% less than those based on tensometer readings. The stresses in the web by Equation (26) which, theoretically, should be correct, were much lower than as computed from tensometer readings. Equation (27) was suggested on the basis of these tests which, of course, are not complete enough to substantiate its adoption definitely. However, both Equations (25) and (27) are believed to be usable for practical design purposes with ordinary values of allowable shearing unit stress. The following special remarks apply to the individual free-end tests:

In Test *T*-12 strain lines appeared along the fillets at 13 500 in-lb; and along the outside center line of the flange at 15 200 in-lb. The yield point of the beam as determined by the slope of the torque-twist diagram was 15 900 in-lb.

In Test *T*-22 the freedom of the ends from restraint was checked by tensometers placed longitudinally near the ends. The strains were negligible. The first shear strain line along the center line of the flange appeared at 21 210 in-lb. At 25 610 in-lb, strain lines progressed rapidly along the flange and in the fillets, and a definite drop of the beam was noted.

In Test *T*-25 strain lines appeared along the fillets at 50 900 in-lb. Thereafter, the slope of the torque-twist diagram became nearly 50% greater than for lower loads, maintaining nearly the same slope up to 100 000 in-lb. The yield point was taken as 50 900 in-lb. Strain lines appeared along the outside of the flange at 77 340 in-lb.

In Test *T*-26 (see Fig. 20) a slight checking in the fillets was noted at 23 000 in-lb, with a drop-of-beam yield point at 25 000 in-lb; strain lines progressed along the outside of the flange at 26 500 in-lb.

In Test *T*-30 the yield of the beam was noted by the 1.5 on 1.0 slope of the torque-twist diagram at 64 000 in-lb. The first strain lines appeared over the web at an indeterminate load due to the presence of heavy scale on the section.

In Test *T*-31 (see Fig. 21) the beam and dropped strain lines occurred along the fillets at 48 800 in-lb. The yield point was noted by the 1.5 on 1.0 slope at 480 000 in-lb.

In Test *T*-33 strain lines occurred along the fillets at 65 600 in-lb. Yield point and strain lines appeared along the outside of the flange at 76 400 in-lb.

Fixed-End Tests.—Twenty-two fixed-end tests were made on beams of different sizes. Tests *T*-4 to *T*-13, inclusive, were made with different lengths of a 3-in., 7.5-lb I-beam. These specimens were welded to end plates, 1 in. thick, with a continuous $\frac{3}{8}$-in. fillet weld. The end plates were bolted to $1\frac{1}{4}$-in. plates which were attached to the jaws of the standard 26 000 in-lb torsion machine. The relative rotation of the end plates was measured by level-bar readings taken at each end. The remainder of the beams were tested in the cable-testing rig. All these beams were larger than the 3-in. I-beams

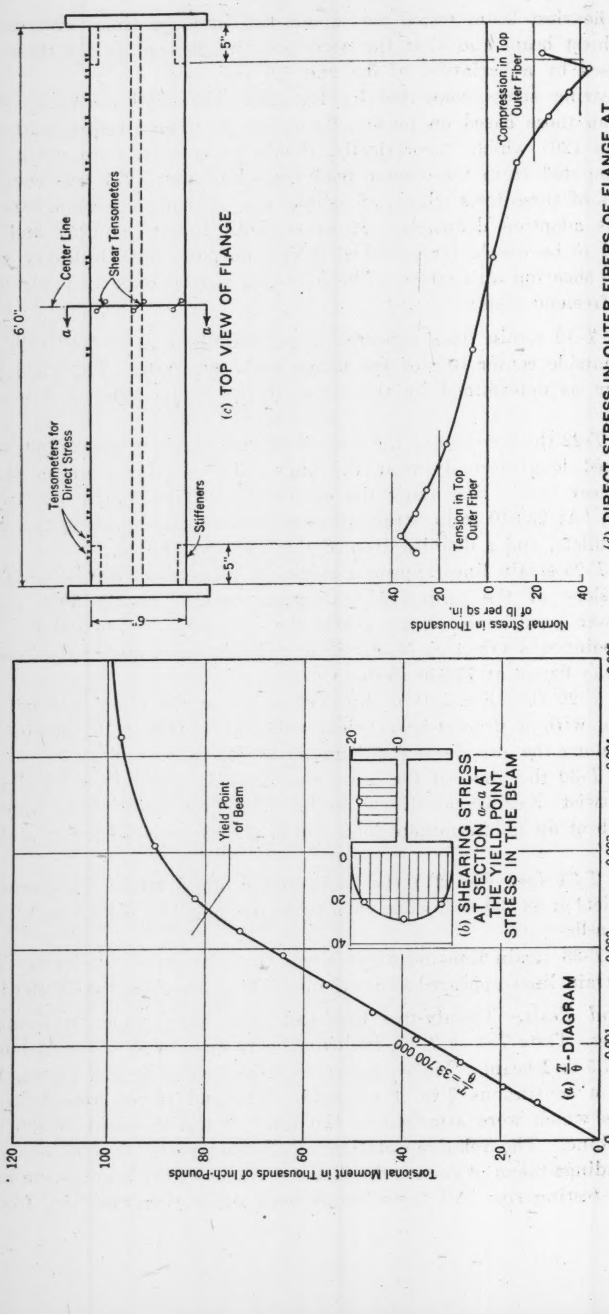

FIG. 22.—FIXED-ENDED TORSION TEST T-17, A 6-INCH H-BEAM AT 41 POUNDS PER FOOT.

and were welded to $1\frac{1}{4}$-in. end plates with additional end stiffeners, fitted and welded between the flanges, as was illustrated in Fig. 15.

Relative rotation of the end plates was observed on all beams by means of level-bar observations, and the twist of the large beams having stiffener plates was also measured at points just inside those plates. Strain readings for longitudinal and shearing strains were observed wherever feasible. Fig. 22(*a*) shows a typical fixed-end torque-twist diagram, and Fig. 22(*b*), 22(*c*), and 22(*d*) show the computed stresses from strain readings at the yield point of the beam. These observations are typical of all the fixed-end tests.

Table 4, Appendix III, gives the summary of the test results for fixed-end beams. In computing the values of C_0 and C_A the question arose as to the correct length to be used. If 100% end fixity were possible the correct length would be slightly less than the over-all length and somewhat greater than the length between the end stiffener plates. However, the over-all length is the simplest approximation, and it gives the best results by comparison with the tests, except in the case of very short beams with end stiffeners. In these two tests (*T*-19 and *T*-27, Table 4) the apparent percentage of end-fixity seems inconsistently high. Two tests have unusually low percentages of end fixity (see Tests *T*-16 and *T*-24). The explanation for this is given under the special remarks. The average percentage of end fixity with Tests *T*-16 and *T*-24 omitted is 88.3 and all the 6-ft beams, except *T*-24, have an end efficiency greater than 85 per cent.

In most cases the yield points of the beams were determined from the slope of the torque-twist diagrams and the theoretical direct stresses computed on the basis of this yield-point torque are given in Column (14), Table 4 (Appendix III). It is noted that, in spite of incomplete end fixity, these stresses, in every case, are above the tensile yield-point strength of the material as given in Table 2 (Appendix III). Hence, all the beams would have been designed safely on the basis of working, direct, fiber stresses. The average of Column (14), Table 3 (Appendix III), is 55% more than the average yield-point strength of the material in the test beams.

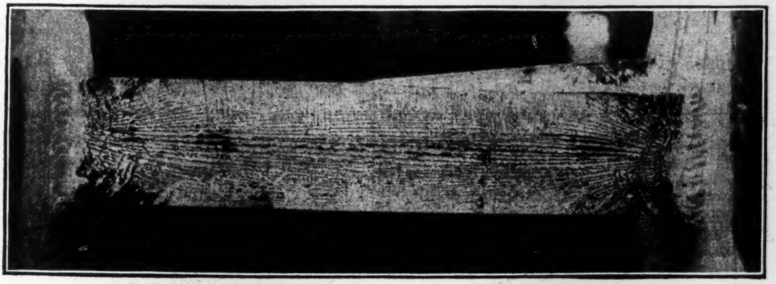

FIG. 23.—ILLUSTRATION OF STRAIN PATTERN.

The computed and measured shearing stresses in the flange agree well for all the 6-ft beams, with the exception of *T*-16 and *T*-24 in which the low

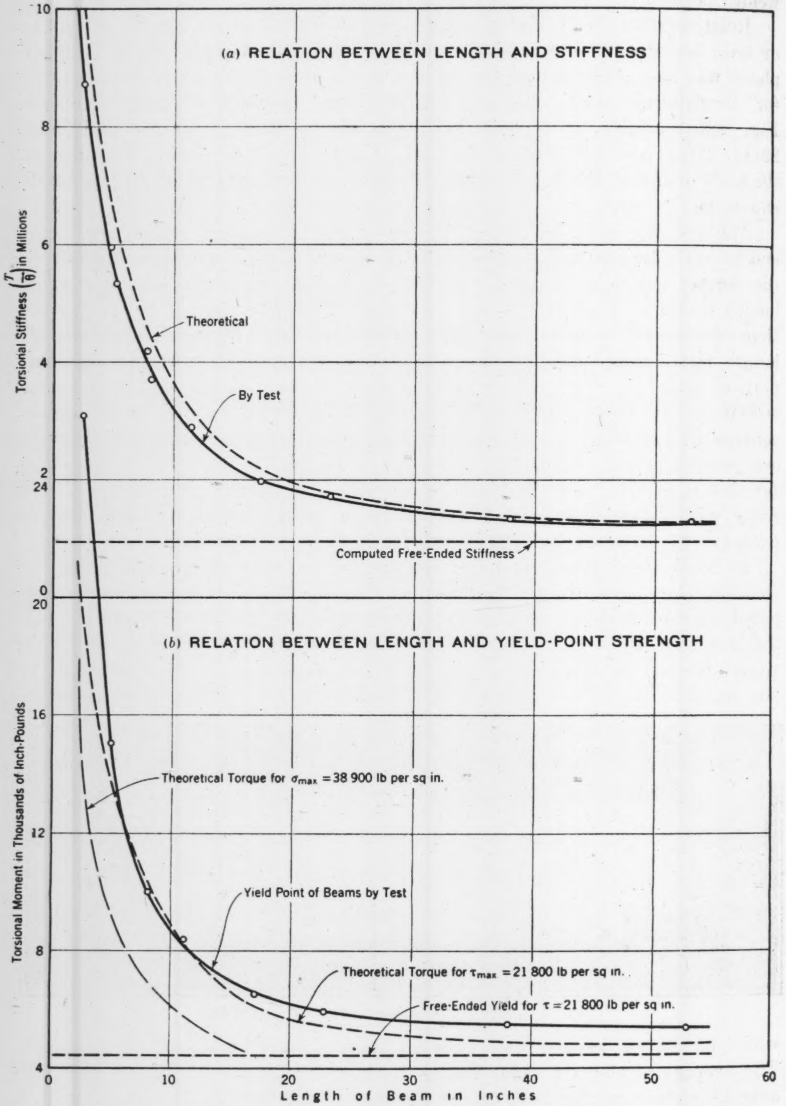

FIG. 24.—TEST OF 3-INCH I-BEAM AT 7.5 POUNDS PER FOOT, FIXED AT BOTH ENDS.

end fixity affects, directly, the shearing stress agreement. On the short 18-in. beams with stiffener plates (*T*-19 and *T*-27), the discrepancy between the computations and the test results is high, as might be expected. The computed stresses in the web give an approximate check on the stresses indicated by tensometers. Special remarks on fixed-end tests are, as follows:

Tests *T*-4 to *T*-12 were of different lengths of the same 3-in. **I**-beams and were well adapted to show the influence of end fixity on the strength and stiffness with the length of beam the only variable. The flange of each beam was whitewashed so that the appearance of first strain lines might be noted. Fig. 23 shows the strain line pattern on the flange of one of these beams after yield had taken place. Fig. 24(*a*) gives a graph of test results for this series showing the influence of length upon the rigidity, and Fig. 24(*b*) illustrates the influence of length upon the yield-point strength of the beams Special attention in this series of tests was given to Tests *T*-8 and *T*-10. Stress measurements were taken along the extreme fiber of the flanges at short intervals of length and the lateral bending moment in the flanges for a definite torque load was computed from these readings. The bending moments along the beam were plotted and the curves were differentiated to give the lateral shear in the flanges. These results are compared in Fig. 25 with the theoretical variation in shear by Equation (38).

Tests *T*-15 and *T*-16 should be compared with the free-end test, *T*-14, of the same section. Test *T*-16 was a special run with additional stiffeners placed midway along the section. These stiffeners were of the same type as the end stiffeners and were parallel in a plane with the web. No outstanding stiffener was provided. Although this additional stiffener gave the beam an average stiffness 42% greater than Test *T*-15, it provided only 40.1% of the theoretical stiffness of a beam 3 ft in length, rigidly fixed at each end. The design of this beam would have been safe for strength, however, if based on the 3-ft length and designed for the proper longitudinal working stress.

Test *T*-17, in contrast to Test *T*-15, was of the heaviest 6-in. section rather than the lightest. It should be noted that an effective fixity of 96.8% was attained in this test. The end stiffeners were $\frac{5}{8}$ in. thick and 5 in. long. The torque-twist diagram and data on stress distribution are given in Fig. 22 as typical of the results for fixed-end tests.

Test *T*-18, of a subway column, provided an opportunity to observe a section of extreme proportions.

Tests *T*-19 to *T*-21, together with free-end Test *T*-22 on the same sized section, provided a series of different lengths of 8-in. **H**-section. It is noted that the shortest beam tested showed an end-fixity efficiency of 101%, whereas the general trend for shorter beams should be less end fixity because of the greater strains placed upon the end connection. This effect is explained by the fact that the over-all length was used in the computations. Although this is good approximation for the longer beams, the stiffness changes rapidly in the short length range and the correct length is some-

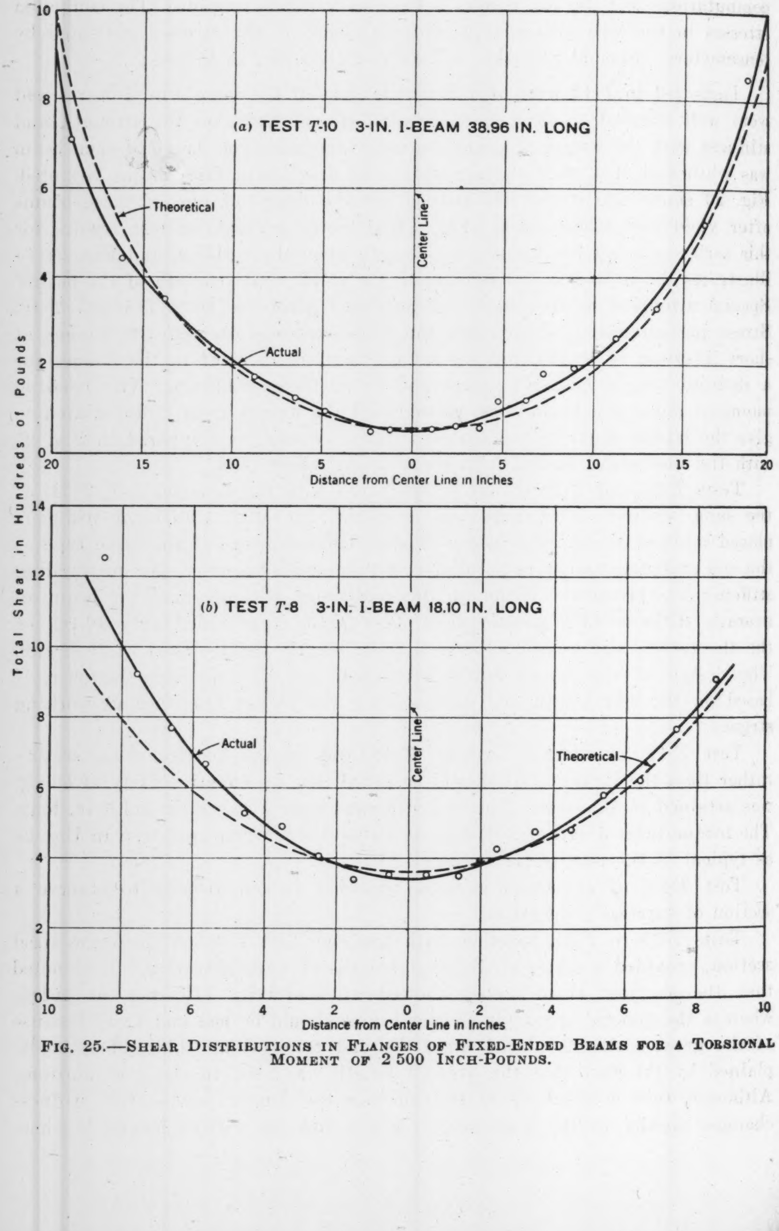

FIG. 25.—SHEAR DISTRIBUTIONS IN FLANGES OF FIXED-ENDED BEAMS FOR A TORSIONAL MOMENT OF 2 500 INCH-POUNDS.

value less than that used. Fig. 26 shows the strain-line distribution near the end of Beam *T*-21 after yielding had occurred.

Test *T*-23 is of the heaviest section of the 8-in. **H**-sections, whereas Tests *T*-19 to *T*-22 were of the lightest weight section.

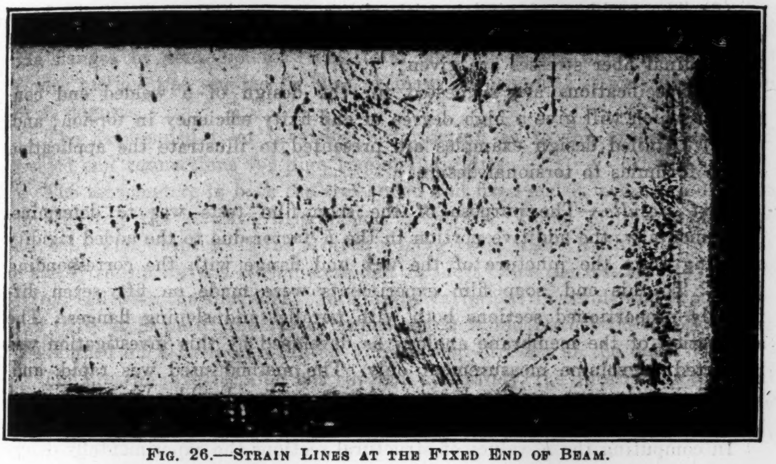

FIG. 26.—STRAIN LINES AT THE FIXED END OF BEAM.

Test *T*-24 is of interest because it had the lowest end-fixity efficiency of the 6-ft beam sections, with an end fixity of only 45.5 per cent. The remaining 6-ft sections were more than 85% efficient in end fixity. The explanation is found in the fact that the end stiffeners in this base were not properly designed, and the beam not only pulled loose at the weld from the end plate, but the end plate was badly warped during the test. The stiffeners were $\frac{3}{16}$ in. thick and 6 in. long. Had they been 9 in. long and 1 in. thick, as provided in the tentative Design Suggestions (1) and (2) (see heading, "Design of End Connection"), it is believed that much higher efficiency would have resulted.

Tests *T*-27 to *T*-29 are of three different lengths of 12-in. **I**-beam. The remarks concerning Tests *T*-19 to *T*-21 appear to apply in the case of these beams also.

SUMMARY AND CONCLUSIONS

Torsional Theory and the Torsion Constant.—The material presented in this paper may be outlined under eight divisions, as follows:

(1) The essential features of the general torsion problem are outlined;

(2) The application of Prandtl's membrane analogy is presented;

(3) An accurate and detailed method of evaluating the torsion constant of structural **H**-beams and **I**-beams is presented (this method is based on a known theoretical evaluation combined with factors determined by experiment from the membrane analogy);

(4) Formulas are proposed for the shearing stress in the flange and web due to pure torsion;

(5) The effect of shearing stress concentration in the fillets due to both torsion and bending is discussed;

(6) The problem of torsion with either one or both ends of the beam restrained is studied in detail and formulas for maximum shearing and longitudinal fiber stresses are given;

(7) Specifications are suggested for the design of a welded end connection which will give a high degree of end-fixity efficiency in torsion; and,

(8) Detailed design examples are presented to illustrate the application of the formulas to torsional design.

Test Results.—The purpose of the soap film tests was to determine, experimentally, the additive portion in the K-factor due to the added rigidity accruing from the juncture of the web and flange with the corresponding fillets. To this end, soap film experiments were made on fifty-seven differently proportioned sections both with parallel and sloping flanges. The application of the membrane analogy as developed by this investigation was restricted to volume measurement only. The method used was rapid, and, it is believed, gave results having an error considerably less than ± 1 per cent.

In computing the K-values of structural sections the experimentally determined part of K amounts, in the most extreme case, to 10% of the total K. Hence, an experimental error of ± 1% would give a possible error of only 0.1% in the total K-value.

Free-end torsion tests were made on seven different beams ranging in size from a 6-in. **H**-beam @ 20 lb per ft to a 12-in. **H**-beam @ 190 lb per ft. The heaviest beam had a torsion constant about two hundred times as great as the lightest beam.

The method of applying the torque to the ends of the beam provided a high degree of end freedom. By measuring the unit twist of the free-ended beams and obtaining the slope of the torque-twist diagram, the free-ended torsion tests provided (through Equation (5)) a definite check on the torsion constant as computed by the proposed method. Using $G = 11\,150\,000$ lb per sq in., which is theoretically correct for $E = 29\,000\,000$ lb per sq in. and $\mu = 0.30$, the test results checked well with computed K-values. The maximum variation was 6.7% and the average for the seven tests was 2.26 per cent.

The yield point of the beams in both free-ended and fixed-ended tests was determined by a study of the torque-twist diagram and in some cases by a drop of the beam. In the free-ended tests the distribution of shearing stress across the flange was studied by measuring, with tensometers, the principal stress at an angle of 45° around the center section.

The fixed-ended tests provided a means of studying the additional rigidity and strength over the free-ended tests, due to fixing the ends of the beams. Twenty-two various lengths and sizes of beams were tested ranging from a 3-in. I-beam at 7.5 lb per ft, to a 10 by 12-in. beam at 62 lb per ft. The heaviest beam had a K-factor fifty-seven times greater than the least, and with ends fixed the most rigid fixed-end beam had a rigidity three hundred and ten times as great as the least rigid with ends fixed.

The distribution of longitudinal direct stresses in the extreme fibers of the flanges was studied by strain measurements taken along the outer edges of the flanges by tensometers. The total shearing stress distribution at the center section was studied by measurement of principal strains at an angle of 45 degrees.

The fixed-ended tests furnished information as to the proper design of welded end connections for high torsional rigidity.

The tensometers in both the free-ended and fixed-ended tests were of value in studying the relative distribution of stress. Some of the results are erratic. The warping of the section during twist made it difficult to obtain a steady set-up for the tensometers, but in most cases the test results checked fairly well with the formulas. In spite of variations in result and incomplete end fixity it is noted that every beam tested would have been amply strong if designed on a basis of working longitudinal stresses at the ends.

The present investigation has covered, accurately, the question of torsional rigidity and the evaluation of the torsion constant. The formulas for stresses which are proposed are not exact but will be satisfactory for practical design purposes.

ACKNOWLEDGMENT

The torsional investigation was conducted as a co-operative project, the McClintic-Marshall Corporation, subsidiary to the Bethlehem Steel Company, furnishing the steel beams and the material for constructing the test apparatus, and Lehigh University bearing all other expenses.

Through the courtesy of the Baldwin-Southwark Corporation, of Philadelphia, Pa., sixteen tensometers were loaned to the University (without charge), during these tests.

Special acknowledgment is due Jonathan Jones, M. Am. Soc. C. E., Chief Engineer; C. H. Mercer, M. Am. Soc. C. E., Consulting Engineer, and Sterling Johnston, M. Am. Soc. C. E., Engineer, all of the McClintic-Marshall Corporation, and V. E. Ellstrom, Manager of Sales Engineering, Bethlehem Steel Company, for their co-operation in the investigation.

The study was conducted as a regular research project of the Fritz Engineering Laboratory, Lehigh University. C. C. Keyser, Laboratory Assistant, and all others associated with the Laboratory contributed valuable help throughout. Professor J. B. Reynolds, of the Department of Mathematics, gave his assistance to the theoretical studies.

APPENDIX II

NOTATION

The following symbols, adopted for use in this paper, are presented as a guide to discussers:

a = a torsional factor in fixed-ended beams.
b = length of a rectangular section.
d = depth; total depth of beam.
e = eccentricity.
f = a subscript denoting "flange."
h = distance between flange centroids.
i = $\frac{1}{2}(d - h)$.
m = major flange thickness.
n = breadth of a rectangular section; also, where defined, n = minor flange thickness.
p = pressure per unit area.
r = radius of a fillet (authors' duplicate); also, where defined, r = variable thickness of a section.
s = distance between stiffening plates.
t = thickness; as a subscript, t, denotes "due to bending."
u = a substitution factor in Equation (37); as a subscript, u, denotes "free ended."
w = web thickness; as a subscript, w, denotes "web."
y = deflection.
A = area; cross-section area; also, where specifically defined, A, B, C, and D are coefficients in a general equation; as a subscript, A, denotes "average."
B = a substitution factor in Equation (23) (see, also, Symbol A).
C = constant; torsion constant equivalent to K for a fixed-ended beam; $C_c = C$ at the center; C_A = average value of C (see, also, Symbol A).
D = diameter; diameter of an inscribed circle (see, also, Symbol A).
E = elasticity; modulus of elasticity in tension and compression.
F = torsion stress function.
G = shearing modulus of elasticity.
I = rectangular moment of inertia; I_x and $I_y = I$ for a cross-section with respect to the X-axis and the Y-axis, respectively.
J = polar moment of inertia.
K = a torsion constant; K_f and K_w = values of K for flange and web, respectively.
L = length; as a subscript, L, denotes "large end."
M = bending moment.
Q = total shear over a cross-section.
S = total slope of a flange section $= \dfrac{m - n}{b}$; as a subscript, S, denotes "small end."
T = torque; torsional moment; T_a = torque required to twist a beam in a free-ended condition.

V = a factor depending on the $\frac{b}{n}$ -ratio, but practically constant for $\frac{b}{n}$ greater than 3; V_L and V_S = value of V for large end and small end, respectively, of the flange.

α = a factor that depends on two ratios, $\frac{w}{m}$ and $\frac{r}{m}$.

ε = unit elongation.

θ = angle of twist, in radians per unit length; $\theta_c = \theta$ at the center.

μ = Poisson's ratio.

ρ = radius of curvature.

σ = unit stress; normal stress; σ_t = longitudinal fiber stress in a flange due to bending.

τ = unit shearing stress; $\tau_f = \tau$ for flange sections; $\tau_w = \tau$ for web sections.

ψ = total angle change between two cross-sections.

APPENDIX III

TABLES

The tables presented herewith are introduced and adequately discussed in the text of this paper.

TABLE 1.—GENERAL SUMMARY OF ALL TESTS

Test No.	Nominal size	Weight, in Pounds per Foot		Length, in inches	Measured Dimensions, in Inches, Adjusted to the Actual Weight (See Fig. 6)						Measured diameter, D, of inscribed circle, in inches	Torsion constant, K

DISCUSSION

H. M. Westergaard,[9] M. Am. Soc. C. E., and **R. D. Mindlin,**[10] Jun. Am. Soc. C. E. (by letter).—In Fig. 9 the authors show curves which represent different formulas for the concentration of torsional shearing stresses at fillets. The curve which is identified by the names of the writers was derived as a result of correspondence with the authors, and for this reason its derivation is given herein.

The process of approximate analysis is closely related to those used by A. and L. Föppl[11] and by S. Timoshenko,[12] but differs in the following respects:

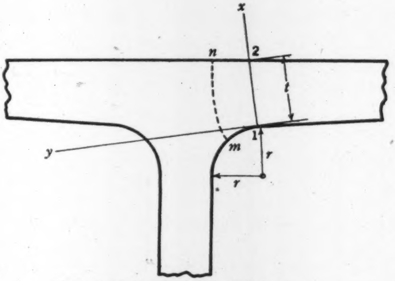

Fig. 27.—I-Beam in Torsion.

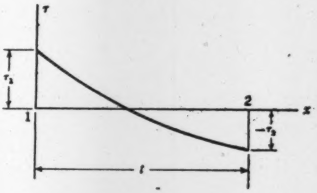

Fig. 28.—Shearing Stresses at Section 1-2, in Fig. 27.

First, consideration of the influence of the straight edge of the cross-section opposite the fillet led to a slightly greater concentration factor near the beginning of the fillet, at Point 1 in Fig. 27, than that obtained by Timoshenko's formula; and, second, the writers had before them the detailed data obtained by P. A. Cushman[13] in tests with soap films. These data show clearly that the maximum shearing stress occurs at a point such as *m* in Fig. 27, and that there is a notable increase of stress from Point 1 to Point *m*. Special consideration was given to this increase.

Let τ_0 denote the shearing stress that would exist at Point 1 in Fig. 27 if the edge of the cross-section at that point were straightened out by moving the beginning of the fillet toward the left, when, at the same time, the thickness of the flange, *t*, the torsion factor, *K*, and the total twisting moment, *T*, are left unchanged. The stress, τ_0 is defined by the formula:

$$\tau_0 = \frac{T\,t}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(57)$$

Let τ_1 and τ_m denote the actual shearing stresses at Points 1 and *m*, τ_m being the maximum stress at the fillet. Then $\frac{\tau_1}{\tau_0}$ is the concentration factor at Point 1 and $\frac{\tau_m}{\tau_0}$ is the desired concentration factor for the fillet.

[12] "Theory of Elasticity," by S. Timoshenko, 1934, p. 259.

[13] "Shearing Stresses in Torsion and Bending by Membrane Analogy," by P. A. Cushman, Doctoral Dissertation, Univ. of Michigan, 1932.

Prandtl's soap film analogy, which the authors have used advantageously, furnishes the key to the solution. It is noted that the soap film is stretched over an opening shaped like the cross-section and is inflated a small amount by an excess air pressure on one side. The shearing stresses on the original cross-section follow the contour lines on the film, the edge being one of the contour lines. Furthermore, the shearing stresses are proportional to the slopes of the film, or proportional to the density of the contour lines.

The contour lines at Section 1–2 in Fig. 27 must be approximately perpendicular to that section. Accordingly, the shearing stresses, τ, at that section are approximately in the direction of y. Since the slope of the film is $c\tau$, c being a constant, the curvature of the film at Section 1–2 in the direction of x becomes $c\,\frac{d\tau}{dx}$. The curvature of the film in the direction of y at Section 1–2 is accounted for by the curving of the contour lines. If the radius of curvature of the contour lines at a particular point is R, then the curvature of the film in the direction of y at the same point becomes $c\,\frac{\tau}{R}$. The curvature of the surface is the sum of the curvatures in the directions of x and y; that is, $c\left(\frac{d\tau}{dx} + \frac{\tau}{R}\right)$.

The equilibrium of the film requires that this combined curvature be constant. Since $R = r$ at Point 1 and $R = \infty$ at Point 2, it follows that,

$$\left[\frac{d\tau}{dx}\right]_1 + \frac{\tau_1}{r} = \left[\frac{d\tau}{dx}\right]_2 \quad\dots\dots\dots\dots\dots\dots\dots (58)$$

Since Points 1 and 2 are on the same contour line, it is also required that,

$$\int_0^t \tau\, dx = 0 \quad\dots\dots\dots\dots\dots\dots\dots\dots (59)$$

The diagram of the shearing stresses at Section 1-2 must be shaped about as shown in Fig. 28. Equation (60) has been constructed so that it satisfies this general requirement of shape as well as the specific requirements in Equations (58) and (59), and, therefore, it may be assumed to represent the shearing stress approximately:

$$\tau = \tau_1\left[1 - \left(2 + \frac{t}{3r}\right)\frac{x}{t} + \frac{x^2}{2\,tr}\right] \quad\dots\dots\dots\dots (60)$$

The constant curvature of the film may be computed as:

$$c\left[\frac{d\tau}{dx}\right]_2 = -\frac{2\,c\,\tau_1}{t}\left(1 - \frac{t}{3r}\right)\dots\dots\dots\dots\dots (61)$$

If the fillet were some distance away, this curvature would remain the same, τ_1 would be replaced by τ_0, and the term containing r would disappear. Consequently,

$$\tau_0 = \tau_1 \left(1 - \frac{t}{3r}\right) \quad \text{.....................(62)}$$

which gives the concentration factor at Point 1,

$$\frac{\tau_1}{\tau_0} = \frac{1}{1 - \dfrac{t}{3r}} \quad \text{.......................(63)}$$

The important indications of Equation (63) are preserved when the following simpler formula is substituted:

$$\frac{\tau_1}{\tau_0} = 1 + \frac{t}{3r} \quad \text{.........................(64)}$$

As was mentioned, the maximum stress, τ_m, occurs at a point such as m in Fig. 27. Equation (64) can be used to obtain an estimate of this stress by making the following replacements: t is replaced by a distance, t_m, measured along a curved section as drawn from m to n; and τ_0 is replaced by a stress corresponding to straight edges and a thickness, t_m: that is, according to Equation (57), by $\tau_0 \dfrac{t_m}{t}$. Thus, the concentration factor becomes,

$$\frac{\tau_m}{\tau_0} = \frac{t_m}{t}\left(1 + \frac{t_m}{3r}\right) \quad \text{......................(65)}$$

A reasonable estimate of t_m is,

$$t_m = t + 0.3\,r \quad \text{........................(66)}$$

This value, substituted in Equation (65), leads directly to the formula represented graphically by the authors,

$$\frac{\tau_m}{\tau_0} = 1.2 + \frac{1}{3}\left(\frac{t}{r} + \frac{r}{t}\right) \quad \text{.................(67)}$$

JOSEPH B. REYNOLDS,[14] ESQ. (by letter).—The problem of the twisting of I-beams has been studied thoroughly by the authors for special cases. It is the purpose of this discussion to compare the authors' results with a more general theory for the twisting of I-beams under differing types of loading. Only the effect of twisting is considered. The assumptions and the notation are the same as those used in the paper.

Consider the requirements for equilibrium at a section of the beam at a distance, x, from the fixed end as shown in Fig. 29. The inner moments at

---

[14] Prof. of Math. and Theoretical Mechanics, Lehigh Univ., Bethlehem, Pa.

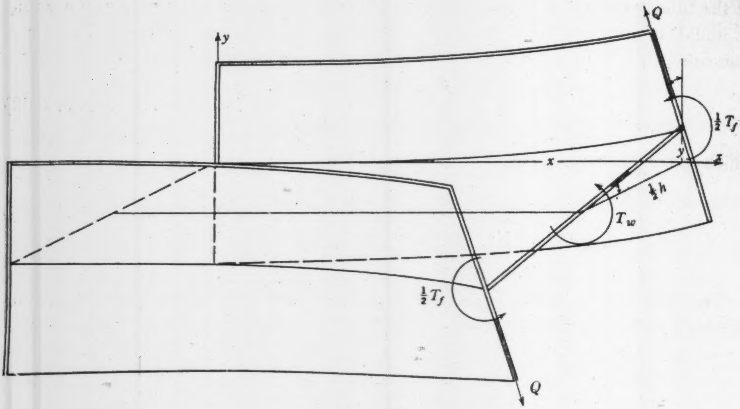

FIG. 29.

this section, together with the moment of the shears, must balance the outer moment applied to the beam to the right of the section. This outer twisting moment, T_x, will vary in general with the position of the section; that is, with x. For equilibrium at this section one must have:

$$T_f + T_w + Q\,h = T_x \quad \text{.....................} (68)$$

in which T_f, T_w, and T_x indicate twisting moments of flanges, web, and total of section, respectively.

In terms of the co-ordinates of points on the neutral axis, $y = f(x)$, the following approximate relation may be written:

$$\frac{1}{2}\;h\;d\theta = dy \quad \text{.....................} (69)$$

and the twist per unit length is $\frac{d\theta}{dx}$, hence:

$$T_f + T_w = KG\,\frac{d\theta}{dx} = \frac{2\,K\,G}{h}\,\frac{dy}{dx} \quad \text{................} (70)$$

From the relation between shear and bending moment:

$$\frac{1}{2}\;E_y\,I\;\frac{d^3\,y}{dx^3} = -\,Q \quad \text{.....................} (71)$$

By means of Equations (70) and (71) and the value of a, Equation (68) can be written:

$$a^2\;\frac{d^3y}{dx^3} - \frac{dy}{dx} + X = 0 \quad \text{..................} (72)$$

in which, $X = \frac{h\;T_x}{2\;K\;G}$.

The differential in Equation (72), has the general solution:

$$y = A \sinh \frac{x}{a} + B \cosh \frac{x}{a} + C + y_1 \ldots\ldots\ldots\ldots (73)$$

in which y_1 is the particular solution satisfying Equation (72) and the values of A, B, and C are determined by the boundary conditions for the beam. Equation (73) is the same as the authors' Equation (34) for the case considered. The value of y_1 is:

$$y_1 = \int X\, dx - \frac{1}{2}\, a\, e^{\frac{x}{a}} \int e^{\frac{-x}{a}}\, X\, dx - \frac{1}{2}\, a\, e^{\frac{-x}{a}} \int e^{\frac{x}{a}}\, X\, dx \quad \ldots . (74)$$

For the usual types of loading, X can be written in the form:

$$X = X_0 + X_1\, x + X_2\, x^2 + \ldots + X_n\, x^n \ldots\ldots\ldots (75)$$

in which, X_0, X_1, X_2, . . . X_n, are constants. When Equation (75) holds successive integration by parts shows that Equation (74) may be written in the form:

$$y_1 = \int X\, dx + a^3 \left(\frac{d\,X}{dx} + a^2\, \frac{d^3 X}{dx^3} + a^4\, \frac{d^5 X}{dx^5} + \ldots \right) \ldots . (76)$$

If n is even in Equation (75) the last term in Equation (76) is $\frac{d^{n-1} X}{dx^{n-1}}$; if n is odd, the last term is $\frac{d^n X}{dx^n}$. With the value of y_1 thus determined one may, by Equation (73) and the relation, $M = \frac{1}{2}\, EI\, \frac{d^2 y}{dx^2}$, write:

$$M = \frac{2\, K\, G}{h^2} \left[A \sinh \frac{x}{a} + B \cosh \frac{x}{a} + a^2 \left(\frac{d\,X}{dx} + a^3\, \frac{d^3\, X}{dx^3} + a^5\, \frac{d^5\, X}{dx^5}, \ldots \right) \right] . (77)$$

and, since the shear is given by $Q = \frac{1}{2}\, EI\, \frac{d^3\, y}{dx^3}$:

$$Q = \frac{2\, K\, G}{a\, h^2} \left(A \cosh \frac{x}{a} + B \sinh \frac{x}{a} + a^3\, \frac{d^2\, X}{dx^2} + a^6\, \frac{d^4\, X}{dx^4} + \ldots \right) .. (78)$$

The longitudinal stresses along the outer fibers of the flange will be given by $\sigma = \frac{M\, b}{I_y}$, or by:

$$\sigma = \frac{Eb}{2\, a^2} \left(A \sinh \frac{x}{a} + B \cosh \frac{x}{a} + a^2\, \frac{d\,X}{dx} + a^5\, \frac{d^3\, X}{dx^3} + a^7\, \frac{d^5\, X}{dx^5} + \ldots \right) .. (79)$$

and the lateral shearing stresses in the flanges by $\tau = \frac{Qb^2}{4\, I_y}$, or by:

$$\tau = \frac{Eb^2}{8\, a^3} \left(A \cosh \frac{x}{a} + B \sinh \frac{x}{a} + a^3\, \frac{d^2 X}{dx^2} + a^6\, \frac{d^4 X}{dx^4} + \ldots \right) \ldots (80)$$

The angle through which the beam twists comes from the relation, $\theta = \frac{2\,y}{h}$, and has the value:

$$\theta = \frac{2\,A}{h} \sinh \frac{x}{a} + \frac{2\,B}{h} \cosh \frac{x}{a} + \frac{2\,C}{h} + \frac{2}{h} \int X\,dx + \frac{2\,a^3}{h} \times \frac{dX}{dx} + \frac{2\,a^5}{h} \times \frac{d^3 X}{dx^3} + \frac{2\,a^7}{h} \times \frac{d^5 X}{dx^5} + \ldots \ldots \ldots \ldots \ldots (81)$$

In this manner, general values are derived for the principal variables of interest in the case of twisted beams. The maximum values of these quantities will occur for differing values of x, depending upon the conditions surrounding the strained beam. Example (a) demonstrates that Equations (73) to (81) reduce to those given by the authors when the proper limitations are applied.

Example (a).—*Beam Twisted by Constant Torque, T, Applied at Its Ends, with Both Ends Restrained.*—In this case, $T_x = T$, a constant, and, therefore, $X = \frac{h\,T}{2\,K\,G}$. The constants A, B, and C are determined by the requirements that for $x = 0$, $y = 0$, and $\frac{dy}{dx} = 0$. Furthermore, for $x = \frac{l}{2}$, $\frac{d^2\,y}{dx^2} = 0$. Since the derivations of X are all zero, Equation (76) yields $y_1 = \frac{h\,T\,x}{2\,K\,G}$; and, by Equation (73):

$$y = \frac{T\,h\,a}{2\,K\,G}\left(\cosh \frac{x}{a} \tanh \frac{l}{2\,a} - \sinh \frac{x}{a} + \frac{x}{a} - \tanh \frac{l}{2\,a}\right) \ldots (82)$$

which is the same as that presented by the authors in Equation (35). The maximum displacement, y_m, occurs where $x = l$ and has the value given in the authors' Equation (36).

Similarly, Equation (77) reduces to the authors' Equation (37) for the moment in each flange, which has (where $u = \frac{1}{2}\,\frac{l}{a}$, or $x = 0$), a maximum value:

$$M_m = \frac{T\,a}{h} \tanh \frac{l}{2\,a} \ldots \ldots \ldots \ldots \ldots \ldots (83)$$

Equation (78) reduces to Equation (38) and Equation (79) becomes Equation (39).

By use of Equation (80):

$$\tau = \frac{T\,b^2}{4\,I_y}\;\frac{\cosh u}{\cosh \frac{l}{2\,a}} \ldots \ldots \ldots \ldots \ldots \ldots (84a)$$

and,

$$\tau_{\max} = \frac{T\,b^2}{4\,I_y} \quad \text{.............................(84}b\text{)}$$

which corresponds to the authors' Equation (42), and by Equation (81):

$$\theta = \frac{T\,a}{G\,K}\left(\cosh\frac{x}{a}\tanh\frac{l}{2\,a} - \sinh\frac{x}{a} + \frac{x}{a} - \tanh\frac{l}{2\,a}\right) \text{...(85)}$$

from which,

$$\theta_{\max} = \frac{T\,a}{G\,K}\left(\frac{l}{a} - 2\tanh\frac{l}{2\,a}\right) \text{...............(86)}$$

Example (b).—Beam with One End Fixed, the Other Free, Under Constant Torque, T.—In this case, $X = \frac{h\,T}{2\,K\,G}$ as in Example (*a*). The conditions determining *A, B,* and *C* are that for $x = 0$, $y = 0$, and $\frac{dy}{dx} = 0$, and for $x = l$, $\frac{d^2y}{dx^2} = 0$. The value of the deflection obtained is:

$$y = \frac{T\,h\,a}{2\,K\,G}\left(\cosh\frac{x}{a}\tanh\frac{l}{a} - \sinh\frac{x}{a} + \frac{x}{a} - \tanh\frac{l}{a}\right) \text{....(87)}$$

From this all the other principal variables are readily found as in Example (*a*).

Example (c).—Beam with Both Ends Fixed and a Uniform Eccentric Load Along Its Length Producing an External Moment, T.—In this case, $T_x = T\left(1 - \frac{2\,x}{l}\right)$, and, $X = \frac{h\,T}{2\,K\,G}\left(1 - \frac{2\,x}{l}\right)$, giving,

$$y_1 = \frac{h\,T}{2\,K\,G}\left(x - \frac{x^2}{l}\right) - \frac{a^3\,h\,T}{K\,G\,l} \text{...............(88)}$$

The values of *A, B,* and *C* are determined by the requirements that for $x = 0$, $y = 0$, and $\frac{dy}{dx} = 0$, and for $x = \frac{l}{2}$, $\frac{dy}{dx} = 0$. The deflection found is:

$$y = \frac{T\,h\,a}{2\,K\,G}\left(\frac{\cosh u}{\sinh\frac{l}{2\,a}} - \coth\frac{l}{2\,a} + \frac{x}{a} - \frac{x^2}{a\,l}\right) \text{......(89)}$$

Example (d).—Beam with One End Fixed and the Other Free, Uniform Eccentric Load Along Its Length.—Here, $Tx = T\left(1 - \frac{x}{l}\right)$ and,

$$y_1 = \frac{h\,T}{2\,K\,G}\left(x - \frac{x^2}{2\,l}\right) - \frac{T\,h\,a^3}{2\,K\,G\,l}$$

The constants, A, B, and C, are determined by the requirements that for $x = 0$, $y = 0$, and $\frac{dy}{dx} = 0$, and for $x = l$, $\frac{d^2y}{dx^2} = 0$. The deflection proves to be:

$$y = \frac{T\,h\,a}{2\,K\,G}\left[\frac{\sinh\left(\frac{l}{a} - \frac{x}{a}\right)}{\cosh\frac{l}{a}} - \tanh\frac{l}{a} + \frac{a}{l}\operatorname{sech}\frac{l}{a}\left(\cosh\frac{x}{a} - 1\right) + \frac{x}{a} - \frac{x^2}{2\,a\,l}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (90)$$

It is thus shown that the formulas developed and substantiated by test results in the authors' investigation, are identical with those obtained by a general mathematical treatment of the subject of torsional resistance.

HAROLD E. WESSMAN,[15] ASSOC. M. AM. SOC. C. E. (by letter).—Structural engineers seem to be displaying an increasing interest in the effects of torsional resistance on stresses in structural members. This curiosity does not restrict itself solely to the member in torsion, but also embraces study of the resulting effects on bending moments of connecting members. The paper is a timely contribution to the subject. Although the problem is more apparent in the monolithic reinforced concrete building frame, it occurs also in steel structures where some connections insure full continuity and practically all types of connections develop at least a modicum of restraint.

In most structural units torsion may prove to be quite unimportant. One is not justified in dismissing it, however, simply because he considers it unimportant. Every one is prone to do this at times with knotty problems, because it is the easiest course. It is better to be an "agnostic" rather than an "atheist" in such matters, however, until a basis of scientific research, both analytical and physical, justifies conclusions. In the matter of torsion, that basis will be provided by papers such as this one and additional researches involving other structural cross-sections and their relation to the structure as a whole.

The writer has suggested that torsion may fall into the category of knotty problems. It is complex, both in its broad aspects and in its details. A thorough consideration of torsion in the field of structures takes the problem of analysis away from planar confines and puts it in the space realm. This will discourage many from further consideration of the subject because, as a rule, structural engineers prefer to be "two-dimensional analysts," despite the fact that they live in a space world.

The details of the problem, likewise, are not simple of solution. One needs only to look at the disagreement apparent in Fig. 9 to confirm this statement. Various difficulties are involved in the study of torsion stresses in a single twisted unit, quite apart from those which come to light when one considers related effects in connecting members.

---

[15] Assoc. Prof., Dept. of Structural Eng. and Mechanics, Coll. of Eng., Univ. of Iowa, Iowa City, Iowa.

As the authors note, only a few simple cross-sections, such as the circle, ellipse, rectangle, square, equilateral triangle, and certain hollow sections, are susceptible to pure mathematical analysis. The membrane analogy, or soap bubble, is called upon to serve as an aid in the solution of other sections, such as the familiar rolled steel shapes used in structural practice. It is difficult, however, to get accurate measurements of the slopes of the soap bubble at the boundaries because of the curving or "meniscus" effect of the film. Since the slope of the film at the boundary is a measure of the unit shear stress at corresponding points, the modification in curvature makes accurate interpretation somewhat difficult. The materials testing laboratory is another aid for the determination of the torsion constant by twisting actual specimens; but it is difficult to "look inside" the beam to find out what happens, and at points on the exterior at fillets, it is hard to measure strains.

This paper emphasizes the co-operation possible between mathematical analysis, mathematical aids such as the membrane analogy, and the physical testing laboratory. The preceding comments by the writer indicate briefly that this co-operation is necessary in securing an answer to torsion problems. The authors are to be congratulated for using all the available tools at their command.

It is unfortunate, however, that they did not present their soap film tests in more detail. It would be interesting to know precisely how they determined the volume under the film and the coefficients, α, in Fig. 7. Was any attempt made to obtain an independent curve for stress concentration at fillets similar to those in Fig. 9 (which exhibit a considerable lack of agreement both in values and trends)? At the ratio, $\frac{r}{n} = 0.40$, the percentage increase of stress in fillets ranges from about 45 to 140. At the ratio, $\frac{r}{n} = 1.00$, the range is from 25 to 90 per cent. For ratios of $\frac{r}{n} > 1$, Westergaard's and Mindlin's curve and Taylor's soap film tests,[16] portrayed in Fig. 9, show increasing values of stress concentration. All other curves continue the downward trend. In other words, they conform to the thesis that an increase in the radius of the fillet always reduces the stress concentration. Cushman's soap film tests[18] were not carried far enough to give values in the range, $1 < \frac{r}{n} < 2$, although the general trend is downward.

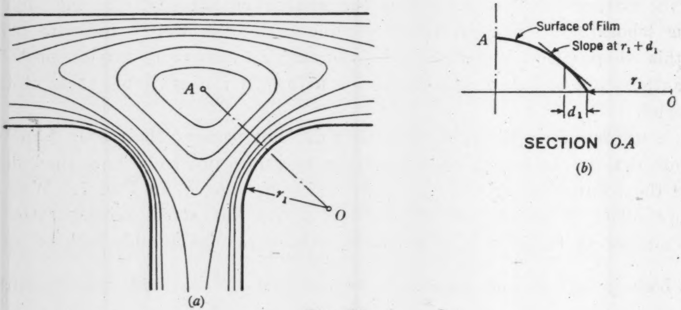
Incidentally, the following question may be raised at this point: "Are the ordinates in Fig. 9, 'Percentage of Increase of Stress in Fillets,' or do they actually give 'Percentage of Increase of Stress Concentration Factor'"? This question is pertinent, because, as the fillet size increases, the torsion constant also increases; hence, for a given twisting moment, the stress at the fillet might actually decrease, even if the ratio of stresses, $\frac{\tau_m}{\tau_o}$, increases. It is to be noted that Equation (67) is expressed in terms of this ratio. Föppl, who derives an equation from a consideration of Stokes' theorem, expresses results in terms of a similar ratio.[11]

---

[16] Technical Repts., Advisory Committee for Aeronautics, No. 33, June, 1917 (Rept. covers experimental work with soap films by Messrs. A. A. Griffith and G. I. Taylor).

If the authors plotted contours to determine the volume under each film for different fillet radii, the following procedure would give an approximate check on the curves in Fig. 9 with little additional labor. Even if contours were not plotted, the determination of a slope at one point on the fillet near the edge, but far enough away to eliminate edge influence, should not take much additional time, considering the extent of the laboratory testing that was done.

In Fig. 30(a), Section OA bisects the fillet, and Fig. 30(b) shows a profile of the section. The differential equation of curvature in terms of the stress function for torsion is given by the authors in Equation (1). This equation, of course, follows directly from the differential equation of equilibrium of forces expressed in terms of displacement rather than stress. Moreover, it is the same as the one for curvature of the soap bubble surface, except that the constant, $2\,G\,\theta$, is replaced by the constant, $\frac{p}{S}$, in which p is the unit pressure normal to the surface of the film, and S is the constant tension in the film.



(a) (b)

FIG. 30.

In polar co-ordinates, Equation (1) becomes,

$$\frac{\partial^2 F}{\partial r^2} + \frac{1}{r}\,\frac{\partial F}{\partial r} + \frac{1}{r^2}\,\frac{\partial^2 F}{\partial \theta^2} = C \;\ldots\ldots\ldots\ldots\ldots\ldots (91)$$

in which C is the constant, $-2\,G\,\theta$, or $-\frac{p}{S}\cdot$

For a surface of revolution, $\frac{\partial F}{\partial \theta} = 0$ and Equation (91) takes the simpler form,

$$\frac{\partial^2 F}{\partial r^2} + \frac{1}{r} \frac{\partial F}{\partial r} = C \qquad (92)$$

The solution of this differential equation is,

$$F = \frac{Cr^2}{4} + A \log r + B \qquad (93)$$

The equation for the slope, which measures the unit shear is,

$$\frac{\partial F}{\partial r} = \frac{Cr}{2} + \frac{A}{r} \qquad (94)$$

At the fillet of a rolled section, part of the soap film is approximately a surface of revolution with its axis passing through the center of the fillet; contours over this part will be parallel to the edge of the fillet, as in Fig. 30(*a*). Radius r in Equation (94) is, therefore, the radius relative to the center of the fillet. The value of the constant, C, has already been noted. It only remains for Constant A to be evaluated. In one approximate solution proposed, A is found by assuming that the slope is zero at a distance, $\frac{n}{2}$, in from the edge of the fillet,[12] and that the surface is one of revolution for at least this same distance in from the edge. The assumption of zero slope at the distance noted is open to question.

By an inspection of contours, or by one or two measurements, either of slope or of elevation, F, of the surface, at a point a small definite distance in from the edge, the authors could have obtained a finite value for the slope, $\frac{\partial F}{\partial r}$, at a finite distance from the center of the fillet. By substituting this in Equation (94), the constant, A, can then be evaluated more closely.

The writer realizes that this involves fairly precise measurement. One might also raise the question, "Why not measure the slope right at the edge and get the shear stress at the critical point directly"? If one can eliminate edge influence on curvature, this would be the logical solution. The writer suggests the preceding steps, however, to get away from edge influence and to obtain a more accurate determination of the constant, A. He ventures to predict that the resulting curve for the stress concentration factor will exhibit a rising trend for values of $\frac{r}{n} > 1$.

F. B. SEELY,[17] ESQ., AND W. J. PUTNAM,[18] ESQ. (by letter).—It may be of value to study the results of the experiments discussed in this paper, on the torsional properties of H-beams and I-beams, in connection with the results of somewhat similar, but less exhaustive, tests on several rolled steel channels conducted by the writers in 1930.

[18] Prof. of Theoretical and Applied Mechanics, Coll. of Eng., Univ. of Illinois, Urbana, Ill.

For a bar or shaft having a circular cross-section, the relation between the twisting moment, T, and the angle of twist per unit of length, θ, as given by Equation (4), is $T = J\ G\ \theta$. Similarly, the authors point out that for members having non-circular cross-sections, Equation (4) becomes $T = K\ G\ \theta$ (see Equation (5)), in which K is the torsion constant for the given section. For a narrow rectangle Saint Venant gave the approximate value of $K = \frac{1}{3}\ n^3\ b$ (see Equation (6)) in which n is the short dimension and b the long dimension of the rectangle. Likewise, for a section made up of narrow rectangles, such as a ship channel, the approximate value of K for the entire section is $K = \Sigma(\frac{1}{3}\ n^3\ b)$; but for a (trapezodial) section with sloping sides, such as the flanges of most rolled steel channels, the value of K is expressed by Equations (9) and (10) of the paper.

For a channel section, then, the expression for K, would be,

$$K = \frac{1}{3}\ w^3\ d + 2\ \frac{b}{12}\ (m + n)\ (m^2 + n^2) \ldots\ldots\ldots\ldots (95)$$

in which the symbols are identified by reference to Fig. 31. As noted by the authors, the value of K is proportional to the volume under a soap film that is stretched across an opening of the same shape as that of the cross-section, the soap film being inflated slightly by a difference of pressure on the two sides of the film. In Equation (95) the factor corresponding to the "hump" or "hill" that occurs in the soap film at the junctions of the flanges and web is omitted. The "end loss" corresponding to the "sloping down" of the soap film to meet the edges of the short dimensions of the rectangular or trapezodial sections, is also omitted. In their studies, the writers concluded that corrections for these two effects could be omitted in view of the deviation of the actual dimensions of rolled sections from the tabular handbook values. Furthermore, these effects in a channel section are relatively less than in an I-section or in an H-section.

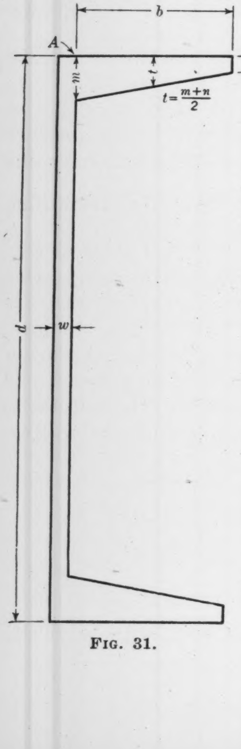

FIG. 31.

Comparison of Test and Calculated Values of K.—Four channels ranging in depth from 6 to 15 in., as listed in Table 5, were tested as free-ended members in pure torsion to determine the torsional constant, K, from Equation (4), namely,

$$K = \frac{1}{G} \times \frac{T}{\theta} \ldots\ldots\ldots\ldots (96)$$

The value of G was taken to be 12 000 000 lb per sq in.; T was measured in a 23 000 in-lb torsion machine, and the angle of twist, $\phi = \theta L$, in a given length, L, was measured by means of a 20-in. level bar on flat bars attached to the top flange of the channel, as shown in Fig. 32.

* Ship channel. † Heavy channel.

The relations between T and ϕ for several lengths along a 10-in., 15.3-lb channel are shown in Fig. 33(a). The values of K found from the curves

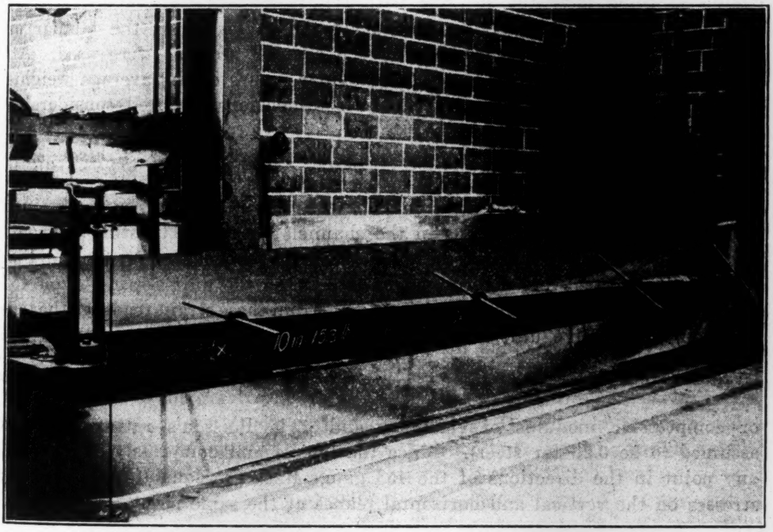

FIG. 32.—VIEW OF CHANNEL IN TESTING MACHINE.

similar to those shown in Fig. 33(*a*), together with the values of K computed from Equation (95), are given in Table 5, Column (3) for each of the four channels tested. It will be observed that the values computed from Equation (95) are not in close agreement with the values obtained from test results

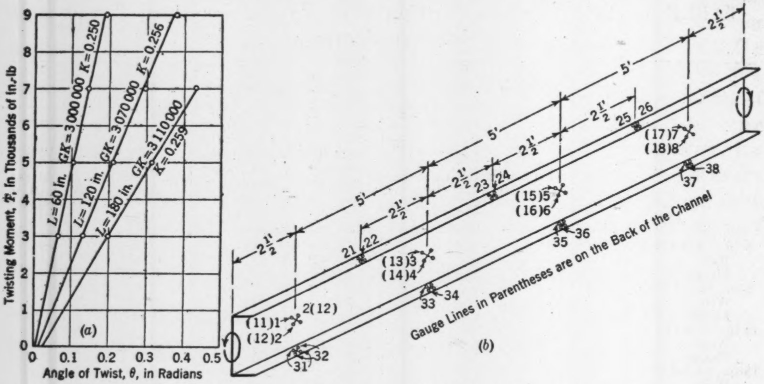

FIG. 33.—LOCATION OF 2-INCH GAUGE LINES ON 10-INCH, 15.3-POUND CHANNEL SUBJECTED TO PURE TORSION.

(Column (2), Table 5), but they indicate that Equation (95) may be used satisfactorily for approximate results. The computed values in Column (3) that deviate most from the test values apply to the 10-in. and the 15-in. channels, which have the sections with relatively thin webs and relatively thick and tapering flanges. In computing the values of K, the tabular or handbook values of the dimensions of the channel sections were used. All the channels tested checked closely the tabular values of the average weights per foot of length, but some of the linear dimensions deviated considerably from the tabular dimensions.

Comparison of Test and Calculated Values of Shearing Stresses.—The approximate values of the elastic shearing stresses at the center of each flange and at the center of the web on each channel at several sections were obtained by measuring the elastic strains in the channels caused by twisting moments at the ends. The locations of the gauge lines are shown in Fig. 32 and Fig. 33(*b*). The stresses were determined by measuring the unit strains, ϵ, on 45° gauge lines by means of a 2-in. strain-gauge. From these strain readings the tensile and compressive unit stresses in the directions of the gauge lines can be found from the expression, $\sigma = \dfrac{E\,\epsilon}{1+\mu} = 0.8\,E\,\epsilon$, in which E is the tensile or compressive modulus of elasticity and μ is Poisson's ratio (which is assumed to be 0.25 for steel). Since the tensile and compressive stresses at any point in the directions of the 45° gauge lines are equal to the shearing stresses on the vertical and horizontal planes at the same point,

$$\sigma = \tau = 0.8\,E\,\epsilon \qquad \text{.......................(97)}$$

The relations between the twisting or torsional moment, T, and the values of ϵ (or of $E\ \epsilon$, in which E is assumed to be 30 000 000 lb per sq in.) for several gauge lines are shown in Fig. 34. Similar curves were found for all the gauge lines on all the channels tested. The average of the values of $E\ \epsilon$ and the corresponding values of τ and σ in the web and flanges of each of the four channels tested, are shown in Table 5, together with the calculated values of the shearing stresses from the equation,

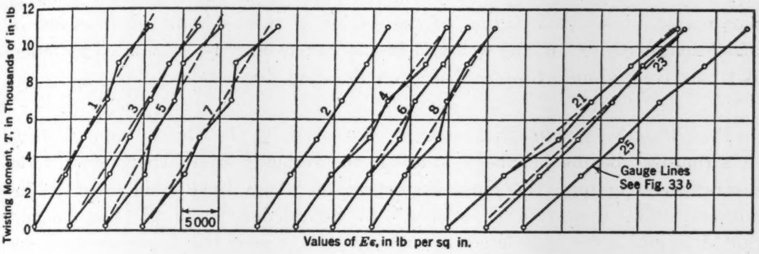

FIG. 34.

$$\tau = \frac{T\,t}{K} \tag{98}$$

in which t is the thickness of the section at the location of the gauge line (see Fig. 31). It will be observed that Equation (98) is consistent with the soap film analogy. The larger t becomes, the more will the soap film puff up; the greater will be the slope of the film; and, therefore, the greater the shearing stress. Equation (98) yields only approximate values, but leads to useful and reliable results as may be seen from Table 5, in which it is shown that the calculated and test results are in reasonably satisfactory agreement (compare Column (5) and Column (6)). It should be noted that since the strain-gauge used had a 2-in. gauge length, the stresses obtained from the measured strains are the average in the region of the point considered rather than the stress at the given point.

The computed values in Column (6), Table 5, that deviate most from the test values apply to the 6-in. 15.5-lb, and the 10-in. 15.3-lb channels. For these sections the 2-in. gauge line included too much of the relatively short flange width for satisfactory stress determinations at the point considered.

The maximum value of τ in the flange (not considering the stress at the fillet) would be (on the basis of the soap film analogy) at the point where the largest inscribed circle is tangent to the face of the flange, since the soap film would have the greatest slope at this point; the maximum shearing stress would occur, therefore, at about the point, A, Fig. 31. The approximate value of the maximum shearing unit stress on the outside face of the flange, should, then, be given by the equation,

$$\tau = \frac{T\,m}{K} \tag{99}$$

The values of τ found from Equation (99) are given also in Table 5, Column (7).

The results of these tests of rolled steel channels in pure torsion are in substantial agreement with the results of the similar but more exhaustive tests of **I**-beams and **H**-beams presented in the paper under discussion, in showing that reasonably reliable values of the angles of twist of the members and of the shearing stresses in the web and in the flanges may be calculated by means of a relatively simple formula based on the soap film analogy.

P. WILHELM WERNER,[19] ASSOC. M. AM. SOC. C. E. (by letter).—Torsion in structural beams has been studied, theoretically and experimentally, by several investigators, the most important of whom have been cited by the authors. The names of C. Weber,[20] C. Schmieden,[21] and H. Engelmann.[22] should be added for completeness. Weber[20] has treated the double-flanged type of section in general, and obtains the **H**-beam and **I**-beam sections as a special case of the general solution. In this connection he also explains the apparent relative weakness of channels in bending when compared with beams of symmetrical cross-section with the same moment of resistance.

Perhaps the most important result of the reported investigation is the method of evaluating the torsion constant, which is defined theoretically and substantiated by the tests. In view of the extensive tests presented in the paper, it would be of interest to know whether some data are also available regarding the influence of rivet holes upon the torsional rigidity and stresses in structural beams. As far as the writer is aware, this question has hitherto been neglected entirely in problems dealing with torsion. From the hydrodynamical analogy in the torsion theory,[23] however, it is known that a small hole, or cavity, near the edge of a twisted circular shaft will cause a considerable increase of the shearing stresses around the hole. It may be expected that a similar stress concentration will occur also around rivet holes in structural beams, although the holes may not materially influence the yielding of the beam as a whole.

With reference to the theoretical analysis, the paper deals exclusively with the case of a beam twisted by a constant torque, T, applied at its ends. It is of interest to note, that the results thus obtained may also be derived as a special case of a more general problem—a beam twisted by a concentrated torque, T_p, applied at an arbitrary point on the span. This general case is of considerable importance for practical design purposes.

[23] "Theory of Elasticity," by S. Timoshenko, 1934, p. 264.

Referring to Fig. 35, the general expression for the twisting moment is,

$$T_x = \frac{2\,K\,G}{h}\left(\frac{dy}{dx} - a^2\,\frac{d^3y}{dx^3}\right) \dots\dots\dots\dots\dots\dots (100)$$

which is also the differential equation for the deflection of the flanges. It should be observed, however, that Equation (100), like the author's Equation (33), is strictly applicable only when the deflection is due to bending alone, which implies small ratios of $\beta = \frac{b}{L}$, or, that the flange width may be considered as small in relation to the span. From the general theory of beams in flexure it may be concluded that the ratio should be $\beta \leqq 0.25$ in order to keep the error in the calculated stresses within about 5 per cent.

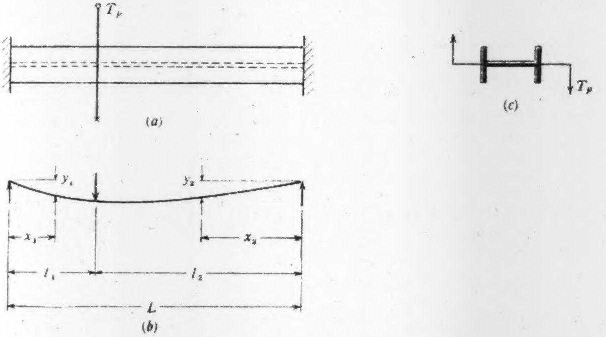

FIG. 35.—DIAGRAMMATICAL REPRESENTATION OF TWISTED I-BEAM.

If T_1 and T_2 denote the constant torque on the left and right-hand side of T_p, respectively:

$$T_1 = \frac{2\,K\,G}{h}\left(\frac{dy_1}{dx_1} - a^2\,\frac{d^3y_1}{dx^3{}_1}\right) \dots\dots\dots\dots\dots (101a)$$

and,

$$T_2 = \frac{2\,K\,G}{h}\left(\frac{dy_2}{dx_2} - a^2\,\frac{d^3y_2}{dx^3{}_2}\right) \dots\dots\dots\dots\dots (101b)$$

The solution of Equations (101) is,

$$y_1 = A_1 \sinh\frac{x_1}{a} + B_1 \cosh\frac{x_1}{a} + D_1\,x_1 + C_1 \dots\dots\dots (102a)$$

and,

$$y_2 = A_2 \sinh\frac{x_2}{a} + B_2 \cosh\frac{x_2}{a} + D_2\,x_2 + C_2 \dots\dots\dots (102b)$$

By differentiating Equations (102) and substituting in Equations (101):

$$T_1 = \frac{2\,K\,G}{h}\,D_1 \dots\dots\dots\dots\dots\dots\dots (103a)$$

and,

$$T_2 = \frac{2\,KG}{h}\,D_2 \qquad \text{(103b)}$$

From the equilibrium condition, $T_p = T_1 + T_2$:

$$T_p = \frac{2\,KG}{h}\,(D_1 + D_2) \qquad \text{(104)}$$

The integration constants may be derived for two typical examples, as shown subsequently in Cases (*a*) and (*b*).

Case (*a*).—*Both Ends Free.*—For this case the boundary conditions are, for $x_1 = x_2 = 0$: $y = 0$ and $\frac{d^2y}{dx^2} = 0$; and, for $x_1 = l_1$ and $x_2 = l_2$: $y_1 = y_2$; $\frac{dy_1}{dx_1} = -\frac{dy_2}{dx_2}$; and, $\frac{d^2y_1}{dx^2_1} = \frac{d^2\,y_2}{dx^2_2}$.

According to these requirements and Equation (104), the coefficients, *A*, *B*, *C*, and *D*, are determined, as follows:

$$A_1 = -\frac{a\,h\,T_p}{2\,KG}\;\frac{\sinh\frac{l_2}{a}}{\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}} \qquad \text{(105a)}$$

$$A_2 = -\frac{a\,h\,T_p}{2\,KG}\;\frac{\sinh\frac{l_1}{a}}{\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}} \qquad \text{(105b)}$$

$$B_1 = B_2 = C_1 = C_2 = 0 \qquad \text{(105c)}$$

$$D_1 = +\frac{h\;T_p}{2\,KG}\,\frac{l_2}{L} \qquad \text{(105d)}$$

and,

$$D_2 = +\frac{h\;T_p}{2\,KG}\,\frac{l_1}{L} \qquad \text{(105e)}$$

By making $l_1 = l_2 = l = \frac{L}{2}$ and $T_p = 2\,T$:

$$A_1 = A_2 = -\frac{a\,h\,T}{2\,KG}\,\frac{l}{\cosh\frac{l}{a}} \qquad \text{(106a)}$$

and,

$$D_1 = D_2 = +\frac{h\,T}{2\,KG} \qquad \text{(106b)}$$

Then the deflection function for this case may be written,

$$y = \frac{a\,h\,T}{2\,K\,G}\left[\frac{x}{a} - \frac{\sinh\frac{x}{a}}{\cosh\frac{l}{a}}\right] \text{.................} (107)$$

Equation (107) also represents the special case of a beam with one end fixed, the other free, and twisted by a constant torque applied at its ends—which case has been treated by Professor J. B. Reynolds,[24] although his solution is given in a somewhat different form. The very simple expression obtained in Equation (107) is due to the suitable choice of the origin of co-ordinates.

Case (b).—Both Ends Fixed.—For this case the boundary conditions are, for $x_1 = x_2 = 0$: $y = 0$ and $\frac{dy}{dx} = 0$; and, for $x_1 = l_1$, and $x_2 = l_2$: $y_1 = y_2$; $\frac{dy_1}{dx_1} = -\frac{dy_2}{dx_2}$; and $\frac{d^2y_1}{dx^2_1} = \frac{d^2y_2}{dx^2_2}$.

These requirements, together with Equation (104) give the following values of the coefficients, *A*, *B*, *C*, and *D*,

$$A_1 = -D_1\,a = -\frac{a\,h\,T_p}{2\,K\,G}\left[\sinh\frac{l_2}{a}\left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)\right.$$
$$\left.+\left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)\left(\cosh\frac{l_2}{a} - 1\right) - \frac{l_2}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right)\right]$$
$$\div\left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)^2 - \left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)^2$$
$$-\frac{L}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right) \text{..........} (108a)$$

$$A_2 = -D_2\,a = -\frac{a\,h\,T_p}{2\,K\,G}\left[\sinh\frac{l_1}{a}\left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)\right.$$
$$\left.-\left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)\left(\cosh\frac{l_1}{a} - 1\right) - \frac{l_1}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right)\right]$$
$$\div\left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)^2 - \left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)^2$$
$$-\frac{L}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right) \text{..........} (108b)$$

$$B_1 = -C_1 = -\frac{h\,T_p}{2\,K\,G}\left[\sinh\frac{l_2}{a}\left(l_2\sinh\frac{l_1}{a} - l_1\sinh\frac{l_2}{a}\right)\right.$$
$$-\left(\cosh\frac{l_1}{a} - 1\right)\left(a\sinh\frac{l_2}{a} - l_2\cosh\frac{l_2}{a}\right)$$
$$\left.-\left(\cosh\frac{l_2}{a} - 1\right)\left(a\sinh\frac{l_1}{a} - l_1\cosh\frac{l_2}{a}\right)\right] \div \left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)^2$$
$$-\left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)^2 - \frac{L}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right). (108c)$$

---

[24] See p. 903.

and,

$$\begin{aligned} B_2 = - C_2 = - \frac{h\,T_p}{2\,KG} \Bigg[& \sinh\frac{l_1}{a}\left(l_1 \sinh\frac{l_2}{a} - l_2 \sinh\frac{l_1}{a}\right) \\ & - \left(\cosh\frac{l_1}{a} - 1\right)\left(a \sinh\frac{l_2}{a} - l_2 \cosh\frac{l_1}{a}\right) \\ & - \left(\cosh\frac{l_2}{a} - 1\right)\left(a \sinh\frac{l_1}{a} - l_1 \cosh\frac{l_2}{a}\right)\Bigg] \\ & \div \left(\sinh\frac{l_1}{a} + \sinh\frac{l_2}{a}\right)^2 - \left(\cosh\frac{l_1}{a} - \cosh\frac{l_2}{a}\right)^2 \\ & - \frac{L}{a}\left(\sinh\frac{l_1}{a}\cosh\frac{l_2}{a} + \sinh\frac{l_2}{a}\cosh\frac{l_1}{a}\right) \quad \ldots\ldots\ldots\ldots (108d) \end{aligned}$$

By making $l_1 = l_2 = l = \frac{L}{2}$ and $T_p = 2\,T$:

$$A_1 = A_2 = - D_1\,a = - D_2\,a = - \frac{a\,h\,T}{2\,KG} \quad \ldots\ldots\ldots\ldots (109a)$$

and,

$$B_1 = B_2 = - C_1 = - C_2 = + \frac{a\,h\,T}{2\,KG} \tanh\frac{l}{2\,a} \quad \ldots\ldots\ldots (109b)$$

and the deflection function for this case may be written,

$$y = \frac{a\,h\,T}{2\,KG}\left(- \sinh\frac{x}{a} + \tanh\frac{l}{2\,a}\cosh\frac{x}{a} + \frac{x}{a} - \tanh\frac{l}{2\,a}\right) \quad \ldots (110)$$

Equation (110) also represents the special case treated by the authors, namely, a beam twisted by a constant torque, T, applied at its ends, with both ends restrained.

In the "General Remarks" under "Design Examples" the authors state that "the local direct stresses * * * are in the nature of secondary stresses" and suggest that "allowable fiber stresses usual in secondary stress design be applied in general to these stresses." Referring, for instance, to Loading Cases (*a*) and (*b*) in this discussion, which represent typical torsion problems in practical design, the writer would not feel inclined to accept a specification that the direct fiber stresses obtained in the flanges should generally be classed as secondary stresses. As a matter of fact, the twisting of the beam may be conceived as pure bending of the two flanges, which are supported by an elastic medium, the reacting forces of which are reflected by the torsional rigidity of the twisted elements of the beam.

Consider, now, a beam which is simply supported in both ends and subjected to a twisting moment, T_p, applied at the center. The deflection function for this case, according to Equation (107), may be written,

$$y = \frac{a\,h\,T_p}{4\,KG}\left(\frac{x}{a} - \frac{\sinh\dfrac{x}{a}}{\cosh\dfrac{L}{2\,a}}\right) \quad \ldots\ldots\ldots\ldots\ldots (111)$$

The bending moment in each flange is,

$$M = -\frac{E I_y}{2}\frac{d^2y}{dx^2} = \frac{a\,T_p}{2\,h}\,\frac{\sinh\frac{x}{a}}{\cosh\frac{L}{2\,a}} \quad\ldots\ldots\ldots\ldots\ldots(112)$$

and thus the maximum moment (at the center of the beam), is,

$$M_o = \frac{a\,T_p}{2\,h}\tanh\frac{L}{2\,a} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(113)$$

If, momentarily, the beam is assumed to have no torsional rigidity (that is, if the flanges are required to take the entire superimposed torsional load) the corresponding maximum bending moment in each flange would be,

$$M_f = \frac{T_p}{h}\,\frac{L}{4} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(114)$$

The ratio between the two moments is,

$$\kappa = \frac{M_o}{M_f} = \frac{\tanh\lambda}{\lambda} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(115)$$

in which, $\lambda = \frac{L}{2\,a}$. The value of κ is given in Fig. 36 for various ratios, λ.

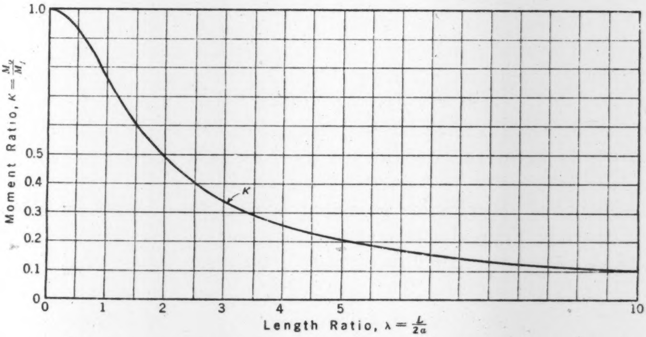

FIG. 36.—GRAPHICAL REPRESENTATION OF EQUATION (115)

As indicated, the writer's derivations are applicable only for $\beta \leqq 0.25$, and the inaccuracy increases as β increases. Equation (115), however, gives a clue as to how the problem may be approached for $\beta > 0.25$. Consider, for example, a beam with the same dimensions as in the authors' "Design Example B"—that is, with $b = 8.29$ in. and $2\,a = 54$ in. For $\beta = 0.25$ in this case, $L = 33.2$ in. and $\lambda = 0.615$. According to Fig. 36 this corresponds to $\kappa = 0.9$, or M_f varies as 1.11 M_o. This means that for $\beta > 0.25$ one may compute—at least for the beam under consideration—approximately (the inaccuracy is maximum 11% on the safe side) the stresses in the flanges under the assumption that each flange acts as a beam, or rather as a narrow plate, the depth of which cannot be considered as small in relation to the span width and which is stressed by a force, $P = \frac{T_p}{h}$, in its own plane.

F. L. EHASZ,[25] JUN. AM. SOC. C. E. (by letter).—In Fig. 9 the authors demonstrate the fact that there has been considerable diversity of opinion regarding the problem of stress concentration in the fillets of twisted bars. Several analytical and experimental solutions giving widely varying results have been proffered. Consequently, the effect of size and shape of structural members on torsional behavior was investigated in an attempt to help in the final solution of this problem. More than eighty experimental solutions involving various structural shapes were found. The membrane analogy provided a fairly rapid method for determining the increase of shearing stress in fillets by means of soap films. Torsion constants were also obtained for most of the sections analyzed.

The following variables were studied: The radius of fillets, length and thickness of the components of the member, and the shape of the member, angle, or I-section. In each series, the fillet varied from about $\frac{1}{8}$ in. to $1\frac{1}{2}$ in. Eight series of angles having $\frac{1}{2}$-in. to 1-in. thicknesses and 3 to 6-in. lengths; and three series of I-beams with wide flanges, corresponding to three of the angle series, were analyzed to determine the change of the hump at the junctures. An angle formed by taking half the I-section (that is, a T-section), and clipping one wing of the flange with the web intact will be said to correspond to that particular I-section. For the sake of clarity it is mentioned that an angle having long sides of 4 in. and 3 in., and a constant thickness of $\frac{3}{4}$ in., corresponds to a wide-flanged I-section having a depth of 8 in., a flange width of $5\frac{1}{4}$ in., and flange and web thicknesses of $\frac{3}{4}$ in. Torsion constants were evaluated for all the I-sections and for six of the angle series.

The radius of the circular hole that is used for comparison in soap-film analysis must be approximately equal to twice the area divided by the perimeter of the test hole. Volume-correction factors allowed for a slight deviation from this precaution. The errors due to the assumption that the sine equals the tangent and that the pressure acts vertically instead of normal to the surface of the film are largely eliminated, and pressure correction is achieved by resorting to the volume-correction curve which was procured by testing several sections of known torsional properties against each other, two at a time. The initial height of water in the flask, an essential part of the volume-displacement apparatus, was kept, at all times, approximately equal to that prevailing in the preliminary volume-correction tests.

In contour work, the height of the circular film was checked after every five or six points to insure that conditions remained constant. Elevations were correct to within 0.001 in. It was found that a boundary angle ranging between 15° and 25° was advisable for the circular film in order to obtain a precision of 2% in the stress concentration tests. For satisfactory volume measurements the boundary angle for the test film should not exceed 35 degrees. The minimum radius of the circular section in this investigation was ½ in., a value which, according to Taylor,[26] should be considered the minimum allowable for reliable results. In the case of a symmetrical shape, such as the I-beam, only one-half the section was studied. A vertical septum passing through the axis of symmetry provided the essential continuity. It was necessary to double the torsion constant of the reduced shape in order to obtain the desired constant.

---

[25] Lawrence Calvin Brink Research Fellow in Civ. Eng., Lehigh Univ., Bethlehem, Pa.

After a few complete contour diagrams were made, it was thought best to diminish the work required for a section by adopting the so-called cross-section method wherein points spaced from 0.03 to 0.1 in. apart along a normal to the boundary were located and their elevations recorded. Especial care and smaller spacings were taken immediately near the edge, since the crux of the slope determination lies there. Tangents to enlarged drawings of the films at the boundaries gave a direct measure of the border shearing stresses. Cross-sections were taken in the case of angles at the center of the fillet and at the center of the inner straight portion of the flanges. For I-sections additional slope data were recorded for the web. The shearing stress in the fillet could thus be compared with that in the arms of angles and with the shear in the flange and web of I-sections.

The effect of size and shape of members on stress concentration may be observed from Fig. 37, which gives the results of a few series. It is apparent from Fig. 37(*a*) that the stress concentrations of I-sections are considerably greater than for their corresponding angles. An angle, 4 by 3 in. by ½ in., is one having long sides, 4 in. and 3 in., with the thickness of both legs ½ in. An I-section, 8 by 5¼ in. by ¾ by ¾ in., has a depth of 8 in., a flange width of 5¼ in., with web and flange thicknesses of ¾ in. That the stress varies directly with the thickness may be concluded from the fact that

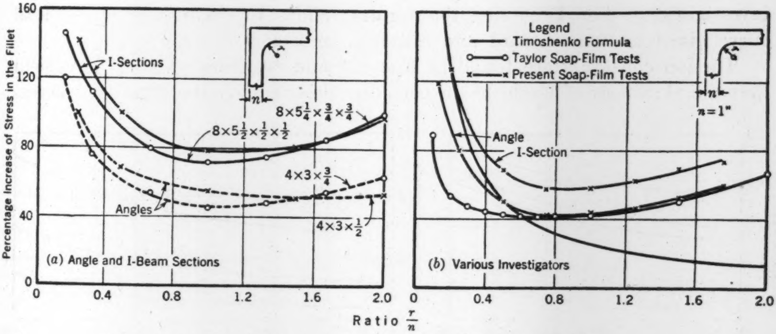

FIG. 37.—COMPARISONS OF STRESS CONCENTRATION.

---

[26] "The Mechanical Properties of Fluids: A Collective Work," 1924, p. 236.

the fillet-stress concentration factors are inversely related to the thickness. The lowest points on the curves are peculiar in two respects. As the thickness of the straight part increases, the ratio of fillet to thickness for the minimum concentration decreases linearly according to Fig. 38, which also shows a fairly straight-line variation of the magnitude of the minimum concentration factor. This was obtained by taking averages of all the angle series.

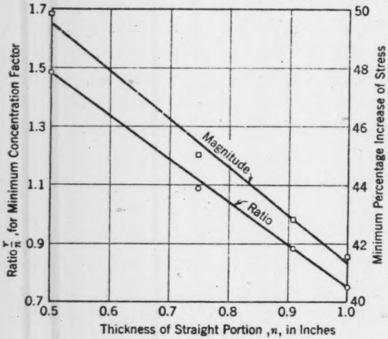

FIG. 38.

A comparison of the results of this investigation with those of Timoshenko's analytical solution and Taylor's soap-film tests is found in Fig. 37(*b*). For small fillets, including the usual radii, Timoshenko's formula proved to be superior to all others for angles. Timoshenko obtained his approximate theoretical solution[27] from the membrane analogy by assuming that the shearing stress in the fillet becomes zero at a point, $\frac{n}{2}$, from the boundary, in which n is the thickness of flange. Soap-film tests showed that this assumption is true for small radii of the fillet, r. For larger fillet sizes there is fair agreement between the tests of Taylor and those of the present investigation. For **I**-sections the results follow approximately the general curve given by Westergaard and Mindlin, in Fig. 9.

Torsion constants are found in Figs. 39 and 40, from which it is evident that the thickness of angle has a considerable effect on the rigidity, whereas the effect of length of arm is comparatively small. Experimental results were checked analytically and a fair precision was noted.

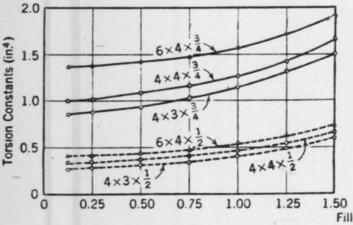

FIG. 39.—TORSION CONSTANTS FOR ANGLES

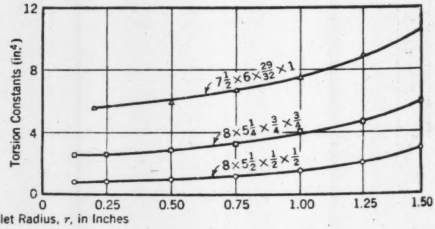

FIG. 40.—TORSION CONSTANTS FOR I-SECTIONS.

The following are the principal deductions drawn from these tests: (1) The inherent relations of the membrane analogy have proved especially useful in determining the stress concentration factors at the fillets of a twisted rod; (2) Timoshenko's formula for stress concentration proved suitable for the usual fillet radii in the case of angles, whereas that proposed by Westergaard and Mindlin (see Fig. 9) gave results having similar tendencies manifested in the present tests on **I**-sections; (3) observations of the soap films in the case of **I**-sections confirmed the fact mentioned by the authors that the critical shearing stresses prevail at the fillets and at the center of the outer side of the flange; (4) there is a linear relation between the minimum percentage increase of stress in the fillets of angles and the thickness of the straight portion (the ratio of fillet size to flange thickness, $\frac{r}{n}$, for minimum concentration factor also shifts linearly with variation in thickness); (5) the shearing stress, in general, increases linearly with the thickness (in **I**-sections, however, the stress in the web is slightly greater than in the flange for the same web and flange thickness. The stress falls off rapidly at the fillet, the rate being greater for small radii); and, (6) for ductile materials not subjected to alternating stress, the use of small fillets does not involve danger because of the redistribution of stress that follows local yielding. In the case of brittle materials, however, the weakening effect of the stress concentration should be mitigated by the use of greater fillet radii.

W. P. ROOP,[28] M. AM. SOC. C. E., and JOHN B. LETHERBURY,[29] JUN. AM. SOC. C. E. (by letter).—Although in this paper no procedure is outlined for estimating torsional rigidity of tubular sections, when the writers recently had occasion to deal with such a section, an effort was made to apply the methods of this paper. Interest was attached to a tube of square section, and some tests were made on a section about 1 in. on the side with walls $\frac{1}{8}$ in. thick. The polar moment of inertia is,

$$J = \frac{1}{3} b^2 A \ldots\ldots\ldots\ldots\ldots\ldots (116)$$

A being the sectional area and b the side of the square.

The authors' Equation (6) applies to a solid section, but by removing a small square from the interior of a large one, the value,

$$K = 0.28\, b^2 A \ldots\ldots\ldots\ldots\ldots\ldots (117)$$

is found. Such a procedure could be justified only if the walls were thick enough to act as if the interior square was not removed. This did not seem a severe assumption, as the tube contained heavy transverse diaphragms spaced about $\frac{3}{2} b$. Nevertheless, when such a tube was made and an experimental value of K was found by measuring torsional deflection under known load, it proved to be only about one-fourth the value calculated by Equations (116) and (117).

---

[28] Lt. Comdr. (C.C.), U. S. Navy; Office of Superintending Constructor, New York Shipbuilding Co., Camden, N. J.

[29] Hull Draftsman, New York Shipbuilding Co., Camden, N. J.

The next step was to make up another tube using more care. Both tubes were welded up, but in the second case the welding was continuous and more uniform. However, when allowance was made in the calculations for the area of the weld fillets, the result was almost the same as at first, that the effective value of K was only about one-third to one-fourth the calculated value.

One objective in this work was to obtain verification of a formula for torsion of a tube of toroidal form. When the toroid was constrained to lie in a plane, the angular deflection was found by calculation to be,

$$\theta = \frac{\pi}{8} \times \frac{M R}{K G} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (118)$$

in which θ is the angle of rotation, in radians, caused by a couple, M, applied in a radial plane, R being the ring radius and G the shearing modulus.

Equation (118) was rather closely verified by test, provided the experimental value of K from the straight tube was used. This afforded some additional evidence for the correctness of the value of K, being about one-fourth the calculated value.

It is noted that a square tube is shown in Fig. 8(*f*), but it is not clear how the data given can be applied to the writers' problem, as it appears that tubes of equal sectional area would differ in torsional rigidity according to the wall thickness and the corresponding size of the square chosen. Comparison between cases, Fig. 8(*f*) and Fig. 8(*h*), suggests that the closed section has much greater rigidity, but in this case also the basis of the comparison is uncertain.

Application of the methods described under "Torsion Constant for H-beams and I-beams," to the closed section very naturally leads to a value that is too low by a margin greater than that by which Equation (6) is too high. It is evident that the square tubular section has a rigidity intermediate between the values as calculated by these two quite different procedures.

As compared with the open section, two powerful influences work to give the tube increased rigidity. The first is that of closing the section, as shown in comparing Cases (*b*) and (*c*), Fig. 8. The benefit obtained by the short longitudinal plates at the ends, as in Fig. 15, may be only partly in the improved end constraint; part of the benefit may consist in the partial closure of the section. The question arises whether additional benefit might not be easily obtainable by introducing additional shear connections between toes of flanges at sections other than the ends.

The other influence is that of the diaphragms. Their function is like that of the fillets, but they are naturally much more effective than fillets. This suggests that the tripping brackets now commonly fitted in certain I-sections may be of considerable benefit for torsional rigidity.

For specific comparisons, the numerical data, referring to the sections tested, are given in Table 6.

In general agreement with the developments in this paper, under the heading "Fixed-Ended Torsion," the writers have had some success in devising a set of artificial assumptions that will give a value of K for a tubular section in fair agreement with observations. This is only hindsight, however, and the writers feel rather certain that such precarious assumptions as those which have thus been found to work (that is, flat sides are beams which remain flat under load) would not be very highly regarded if the effective value of K were not known from test data. Possibly, a solution of some merit might be found in this way, but it would require further verification by test and, therefore, would become no rational solution, but only a somewhat rational expression of empirical data.

TABLE 6.—NUMERICAL DATA.

Description	First bar	Second bar	Ring
Sectional area, A, in inches ^{2}	0.58	0.61	0.703
Equivalent side of Square b, in inches	1.06	1.08	1.06+
Polar moment of inertia, J, in inches ^{4}	0.218	0.237	0.307
K by Equation (6), in inches ^{4}	0.184	0.199	0.30 (?)
K by Equation (16), in inches ^{4} *	0.009	0.015	0.015—
Observed K, in inches ^{4}	0.053	0.080	0.128

* Ignoring webs.

In the light of these considerations the decision was made to use Equation (6) and calculate K for a tubular section by subtracting the value for the inner profile from that for the outer profile; but to apply a factor of from 2 to 3 to account for the deficiency of the effective value as compared with the value thus calculated.

The models referred to were made by the New York Shipbuilding Corporation and tested in its laboratory.

ALFRED T. WAIDELICH,[30] JUN. AM. SOC. C. E. (by letter).—An important research, for which there was a very real need, is described in this paper. An obvious application is in the design of spandrel beams and other beams with eccentric loading. Not only has this research indicated the method of analysis in such a case, but already it has made available for the designer one practical set of formulas and tables[31] for the two most common cases: A beam with a full uniform load applied with constant eccentricity; and a beam with a single eccentric concentrated load at the center of the span. It should be only a short time until the standard textbooks and handbooks will treat adequately the subject of torsional loads.

The dual practical problem of designing apparatus capable of twisting the larger steel sections and, at the same time, preserving a free end connection has been given a simple solution. This problem has prevented previous investigators from testing any but the smaller and lighter sections, with the result that the tests were inconclusive.

Definitely, the authors have settled the problem of determining the torsion constant for structural I-beams and H-beams. This constant is far more useful than the scant attention it has received would indicate. An early structural use of it was contained in a small book on the bow girder[32] which describes some torsion tests on small English joist beams. About the same time the constant appeared in aircraft design and in the study of the elastic stability of structures.

---

[30] Philadelphia, Pa.

[31] Bethlehem Manual of Steel Construction, 1934, pp. 279–289.

The principles of elastic stability are of increasing importance as the use of high-strength alloy steels increases, and as structural layouts become simpler. Thus, the modern catenary-supporting bent for railway electrification is a simple H-frame, consisting of three rolled shapes lying in one plane. Designers of such structures have been handicapped by the uncertainty of the value of the torsion constant. As a result, the few available tentative tabulations of the torsion constant[33] were considerably in error on the safe side, so that the full economy of this method of analysis could not be realized.

The measurement of fiber stresses in the beams under torsion furnishes a much needed check on the theoretical stresses. It is interesting that for the shear stress in the web, Equation (26) gives values that are definitely lower than those measured. The statement by the authors that Equation (26) is in accord with torsional theory is probably based on the assumption that the web acts as a part of an infinitely long rectangle undergoing the same degree of twisting as the flanges. Apparently, the proportions of the wide-flanged shapes (a relatively thin web tying together heavy flanges) prevents the web from playing such a simple rôle. It is unfortunate that the web stresses were not measured in the tests of the beams with web and flanges of nearly the same thickness. Since the governing shear stress will rarely occur in the web, Equation (27) is acceptable, although the introduction of the radius of the fillet does not seem logical—especially since this stress occurs at the center of the side of the web. Fig. 21 is interesting in that it shows an increase in the web shear stress as the fillet is approached (but before there is any increase in the web thickness). This is confirmed by the slope of the soap film, which increases on approaching the fillet because of the steep slope at the fillet and the "hump" at the junction of the web and the flanges.

INGE LYSE,[34] M. AM. SOC. C. E., AND BRUCE G. JOHNSTON,[35] JUN. AM. SOC. C. E. (by letter).—The original analysis by Professor Westergaard and Mr. Mindlin with regard to stress concentration in fillets is a most worthy contribution on this subject, which was subsequently expanded and studied in the light of experimental tests with soap films on both I-beams and angle sections by Mr. Ehasz, and so reported in his discussion. Mr. Ehasz found that their analysis applied well for the stress concentration in I-beams. Professor Reynolds gave close attention to the investigation and aided liberally in the analytical studies presented in the paper. His discussion of the more general study of I-beams subjected to torsion is a worthy addition to the typical cases considered by the writers. Mr. Werner has furnished additional bibliography on the subject of torsion and has contributed general formulas similar to those given by Professor Reynolds, for the case of a beam either fixed or free at the ends and twisted by a couple at any point along the beam.

[34] Research Associate Prof. of Eng. Materials, in Chg., Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

[35] Instructor in Civ. Eng., Columbia Univ., New York N. Y.

The writers still believe that the use of higher unit stresses for the direct longitudinal stresses at the extreme corners of the flanges of beams at their fixed ends is justifiable. All the fixed-end tests, as originally reported, show that at the torsional yield point of the beam both the theoretical and measured stresses at the ends of the beam were roughly 50% higher than the yield-point strength of the material in direct tension.

In connection with the more practical problems of combined bending and torsion, with the use of ordinary fabrication processes and present assumptions accepted in building design, the outer ends of beams at points where they are riveted to a column or girder will probably be considered unrestrained. Even in a heavily built-up welded end connection it would not be possible to rely upon 100% fixity. At some section along the beam, however, a plane of torsional fixity is maintained, but the accompanying direct stresses are localized in the outer edges of the flanges. Since each flange acts as a separate rectangular beam section, its reserve strength after plastic action commences is much greater than in the usual case of an **I**-beam in bending. Another factor, which does not lend itself readily to mathematical calculation, is the restraining action of walls, brickwork, intermediate floor-beams and the "giving" of the columns or girders into which the beam in combined bending and torsion is framed.

The questions raised by Professor Wessman have been answered in detail in the discussion by Mr. Ehasz and in a later descriptive paper.[36] The record of experimental data on the torsional properties of channel section as furnished by Professors Seely and Putnam is a valuable addition to the writers' experiments on **I** and **H**-sections. Mr. Ehasz's continuation of the writers' soap film experiments shows that this method serves well for the study of the concentration of torsional stress in structural sections as well as for the evaluation of the torsional rigidity. The remarkable uniformity in results obtained by Mr. Ehasz gives confidence in the experimental work and indicates how successfully the membrane analogy may be applied to analytical problems. The data given in Fig. 39 and Fig. 40 might have been presented also in a more general form with the known accurate formula (Equation (6)) for rectangles as a basis. The additional torsional rigidity due to the angular shape would then be represented as a definite function of fillet radius and the thickness of the legs of the angle.

The writers are interested in the results reported by Messrs. Roop and Letherbury on closed sections. Unfortunately, the writers did not investigate such sections and, therefore, are unable to account for the apparent loss in torsional rigidity shown in their tests. However, since the same effect was noted in the case of the ring, the torsional properties of which may readily be analyzed precisely and which have been corroborated by numerous tests, it is possible that the welded seam did not provide complete continuity of material.

---

[36] "Torsional Rigidity of Structural Sections", by Bruce G. Johnston, Jun. Am. Soc. C. E., *Civil Engineering*, November, 1935, pp. 698–701.

Professor Waidelich has raised questions which should rightly be the subject of further study. In conclusion, the writers are very grateful for the general interest evidenced in the paper by all the discussers. It is particularly gratifying to record the interest in more exact methods of analysis of structural members shown by the steel industry.

PHOTO-ELASTIC DETERMINATION OF SHRINKAGE STRESSES

BY HOWARD G. SMITS,[1] ESQ.

WITH DISCUSSION BY MESSRS. THOMAS H. EVANS, I. K. SILVERMAN, J. H. A. BRAHTZ, ARSHAG G. SOLAKIAN, L. N. G. FILON, AND HOWARD G. SMITS.

SYNOPSIS

Stresses due to shrinkage of concrete in masonry dams are of interest and importance, but the determination of these stresses is complex and difficult. In practice, the large masses of concrete used in gravity dams are not homogeneous; nor are they isotropic, as the structure is poured in blocks which present many planes of discontinuity. The indeterminate factors on these planes of discontinuity present such formidable difficulties that an accurate determination of shrinkage stresses is impossible. If the problem is idealized, however, by assuming a homogenous, isotropic, simple gravity dam subject to uniform shrinkage, it becomes possible to predict these stresses with some assurance. Although this idealized case is not truly consistent with actual practice, it creates a philosophical "picture," nevertheless, of the strained condition that should be of value to the judgment of the designing engineer.

One approach to the mathematical solution of this problem has been made by J. H. A. Brahtz,[2] of the United States Bureau of Reclamation. Considering the applicability of the solution of this problem, a complete diagrammatic representation of the stress distribution may be of more interest than the mathematical description. The former is herein presented. This problem was studied at the California Institute of Technology in the photo-elastic laboratory of the Guggenheim School of Aeronautics. The writer wishes to express his appreciation for the continued interest in this problem expressed by Theodor von Kármán, M. Am. Soc. C. E., who is the Director of the Guggenheim School.

NOTE.—Published in May, 1935, *Proceedings*.

[1] Structural Designer, O. G. Bowen, Los Angeles, Calif. Mr. Smits was elected Jun. Am. Soc. C. E., on July 8, 1935.

[2] "Stress Distribution in Wedges with Arbitrary Boundary Forces," *Physics*, Vol. 4, No. 2, February, 1933.

METHOD OF SOLUTION

The photo-elastic method is particularly adapted to this problem of determining shrinkage stresses as only a two-dimensional analysis is required. A complete description of the theoretical background of the photo-elastic method has been given by Messrs. L. N. G. Filon and E. G. Coker.[3]

The most desirable procedure would be to stretch the dam, *CDE* (Fig. 1), longitudinally, by heat or direct loading; then, in this elongated condition, fasten it securely along the base to the stress-free, elastic ground, *AB*. This is a true representation of uniform shrinkage in a theoretical gravity dam section. A line of discontinuity in the stress pattern is encountered along Line *AB*, which is evident from the discontinuity in the elongation on either side of that line. The following general conclusions are evident: (*a*) The crest of the dam, *E*, is free from stress; (*b*) horizontal compression occurs in the ground in the region near the center of the base of the dam; and (*c*) tension gradually dissipates in the regions from Point *G* to Point *A* and from Point *H* to Point *B*.

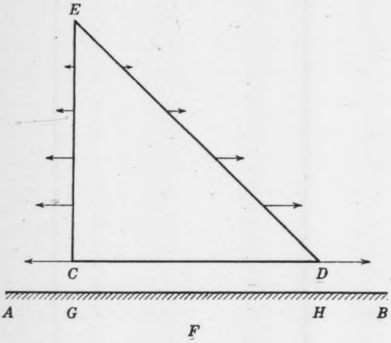

FIG. 1.

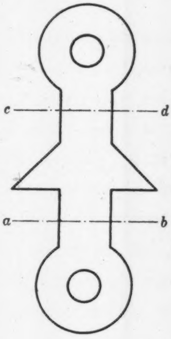

FIG. 2.

To obtain, experimentally, the effect of dam shrinkage upon an elastic foundation, M. Biot[4] suggested reversing the operation by elongating the base. A homogeneous model of the dam and ground was made in one piece, thus taking advantage of the fact that rock and concrete have approximately the same modulus of elasticity. The "ground" was then stretched with a direct tensional load, which produced a high tension of, say, p lb per sq in., in Regions *A* and *B* (Fig. 1), which is contrary to the foregoing description of the problem. Since this tension had to be corrected, a blanket horizontal compression of p lb per sq in. was applied to the ground, arbitrarily, after the complete stress analysis had been determined. The result was a stress of zero in the regions, *A* and *B* (Fig. 1); tension in the restricted regions,

[3] "Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge Press, 1931. (A working summary of the theory, together with some laboratory technique, is given by Mr. Coker in a series of five articles published every two months, in the *General Electric Review*, beginning with the issue for November, 1920.)

[4] "Contribution à la Technique Photo-élastique," *Annales* de la Société Scientifique de Bruxelles, LIII B., 1933.

G and H; and compression in the region, F. A decided discontinuity results along the base line, CD. (It is obvious that the addition of a blanket compression is not mathematically exact as (1) the principal tension stress in the ground is not exactly parallel to the ground surface except at infinity, and (2) the ground is partly restrained against movement perpendicular to the ground surface so that some relatively small stress perpendicular to this blanket compression should be added. In this case, however, the error introduced by not considering these two items is within the experimental error and, therefore, their omission is justified.)

The model was made so that the tension could be induced in the ground by means of pins as shown in Fig. 2. To be certain of pure axial loading the tension strap was made symmetrical about its axis; thus, the symmetry of the optical pattern was always a gauge of the degree of axial loading. The loading frame is shown with the model in place in Fig. 3. A load of 1 220 lb per sq in. was used in the strap of the model.

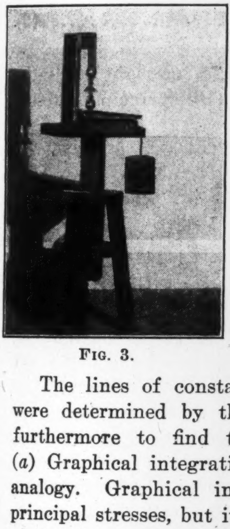

FIG. 3.

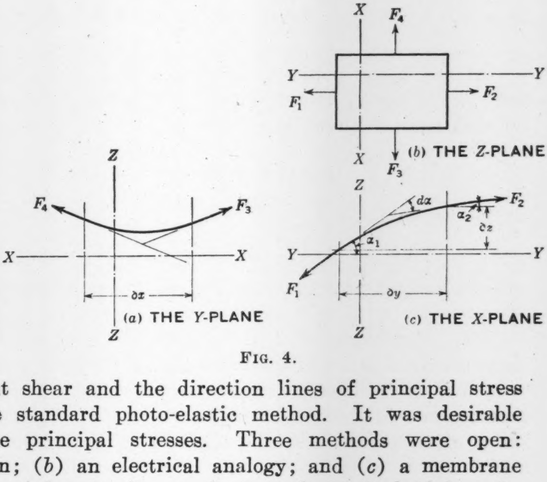

FIG. 4.

The lines of constant shear and the direction lines of principal stress were determined by the standard photo-elastic method. It was desirable furthermore to find the principal stresses. Three methods were open: (*a*) Graphical integration; (*b*) an electrical analogy; and (*c*) a membrane analogy. Graphical integration is the standard method of obtaining the principal stresses, but it is a long and tedious process. No record was found of the electrical analogy having been used in this work. The Prandtl membrane analogy has been used in the solution of Laplace's equation found in problems of shafts carrying torque. At approximately the same time that this problem was solved, E. E. Weibel, at the University of Michigan, was using a soap membrane to find values of $p + q$.[5] Dr. Biot[4] has generalized this analogy theoretically to make it applicable to the photo-elastic method.

THEORY OF NEW METHOD

Desiring a practical and relatively short convenient method of finding the principal stresses, it was decided to test the applicability of the membrane analogy. A rubber membrane was used with success. The analogy is based on the fact that both the sum of the principal stresses and the displacement of the membrane obey Laplace's equation. (This statement is true only if the slope of the membrane at every point is small. (See assumption under heading, "The Membrane.") In this experiment the slope of the membrane was excessive only in the restricted regions of the fillets at the toe and heel of the dam. It is in these two regions that the largest experimental errors occurred.)

---

[5] See his paper presented at the Annual Meeting of the Am. Soc. Mech. Engrs., December, 1933.

The Model.—For any given point let p and q be the principal stresses, p_x and q_y, the stresses acting parallel to the respective axes, and ψ, the unknown Airy stress function. Then,

$$\nabla^4 \psi = 0 = \nabla^2 \times \nabla^2 \psi \qquad (1)$$

in which ∇ = the differential operator. Furthermore, $p_x = \frac{\partial^2 \psi}{\partial y^2}$, and,

$$q_y = \frac{\partial^2 \psi}{\partial x^2} \qquad (2)$$

At any given point, however, the sum of the stresses at right angles to each other, having any direction, is equal to the sum of the principal stresses at that point. Therefore,

$$p + q = p_x + q_y = \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial x^2} = \nabla^2 \psi \qquad (3)$$

It follows that,

$$\nabla^2 (p + q) = \nabla^2 \times \nabla^2 \psi = 0 \qquad (4)$$

which demonstrates that the sum of the principal stresses satisfies Laplace's equation.

The Membrane.—Let the tension in the membrane be a constant, T, induced by a uniform stretch. Fig. 4 shows any element of the membrane which is in equilibrium, although deformed. (Forces F_1, F_2, F_3, and F_4, are components of the total tension, T; and α = the angle with the horizontal at a given point.) In the X-plane (Fig. 4(c)), the angle that the force makes with the Z-axis is $\tan^{-1} \frac{\partial z}{\partial y}$. If the angle is small, the tangent may be taken equal to the angle; then:

$$F_1 = T \frac{\partial z}{\partial y} dy \qquad (5a)$$

and,

$$F_2 = T \frac{\partial z}{\partial y} dx + T \frac{\partial}{\partial y} \left(\frac{\partial z}{\partial y} \right) dy\ dx \qquad (5b)$$

This gives a resultant component of force parallel to the Z-axis,

$$\frac{\partial}{\partial y} \left(\frac{\partial x}{\partial y} \right) T\ dy\ dx \qquad (6)$$

Similar reasoning in the Y-plane leads to,

$$\frac{\partial}{\partial y}\left(\frac{\partial z}{\partial x}\right) T\ dy\ dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

which is the component of force parallel to the Z-axis in the Y-plane. To have equilibrium the sum of the two components (Equations (6) and (7)) must equal zero; thus,

$$\left(\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2}\right) T\ dy\ dx = 0 \ldots\ldots\ldots\ldots\ldots (8)$$

or, $\nabla^2 z = 0$, from which it is to be noted that z and $(p + q)$ are interchangeable.

The difference, $p - q$, between the principal stresses at any point is determined from the isochromatic lines, a sample of which is shown in Fig. 5. Around the free boundaries of the dam and on the sides of the strap one principal stress must be zero, as there is no stress perpendicular to the model edge. If p or q is zero for any point, the difference, $p - q$, between the principal stresses, and the sum, $p + q$, of the principal stresses, are equal. Along Lines ab and cd in Fig. 2, the total tension is distributed uniformly across the strap so that the sum of the principal stresses is again known. Therefore, the sum, $p + q$, is known completely around the boundaries of the model.

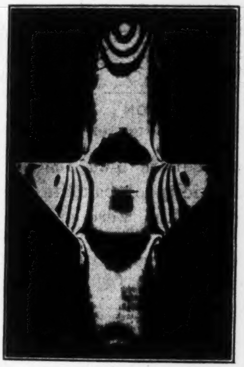

FIG. 5.

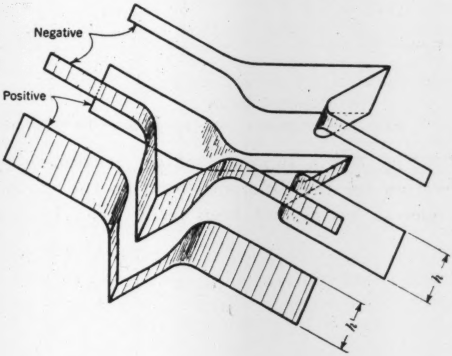

FIG. 6.

APPLICATION OF NEW METHOD

Strips were cut from a thin aluminum plate to form an outline of the model (see Fig. 6). The height, h, of these strips was made proportional at every point to $p + q$ which, as explained previously, was known. Another series of strips was cut to form a negative such that the two fit closely when set one on the other. A rubber sheet, $\frac{1}{64}$ in. thick, was stretched to a uniform tension, T (see Equation (5)), and clamped between the negative and positive dies. A survey of the height of the membrane at every point was made with a micrometer screw on a two-way carriage. This gave a contour map of the value of $p + q$ for every point. With both $p + q$ and $p - q$ determined (the latter having been found by the usual photo-elastic method), the individual stresses for every point in the model were known.

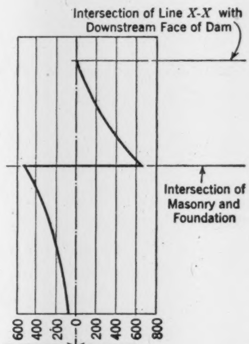

FIG. 10.—STRESSES IN A GRAVITY DAM AND ITS FOUNDATION DUE TO A UNIFORM SHRINKAGE OF 0.0006 INCH PER INCH ($E = 2\,000\,000$).

FIG. 11. — DISTRIBUTION OF MAXIMUM TENSION AND COHESION ALONG LINE *X-X*, FIG. 10.

Finally, a uniform compression is added to that part of the model representing the ground in accordance with the foregoing discussion. Figs. 10 and 11 show the complete stress diagrams for the theoretical condition of a unit shrinkage of 0.00165 in. per in. The line of discontinuity of stresses along the base of the dam is to be particularly noted. The relation between the stresses at any point and the unit shrinkage is a simple ratio. Thus, if the unit shrinkage is taken as 0.000825 in. instead of 0.00165 in., the stresses at every point are only one-half those shown.

CONCLUSION

The model test was that of a theoretical condition that does not occur in practice, and for that reason the results shown are only of philosophical interest; nevertheless, they are of value to the designer. Points of high stress are indicated and a general "feeling" for the behavior of shrinkage stresses can be obtained from the results. Of special interest is the high unit stress between the dam and the ground at the heel and the toe of the dam. In general, the larger the fillet at these points, the lower will be the shearing stress.

DISCUSSION

THOMAS H. EVANS,[6] JUN. AM. SOC. C. E. (by letter).—The problem of determining, with some exactness, the stresses in a concrete dam due to shrinkage seems well adapted to the photo-elastic method. Although the writer disagrees with the author's contention that the stress problem is only two-dimensional, it will not greatly affect the "philosophical picture" to consider it as such. The principal inaccuracy in the determination is not in the method itself but, as Mr. Smits points out, in the physical inconsistency between the prototype and the necessarily idealized model. However, the method does provide a rational first approximation to an extremely complex stress distribution. It should be a distinct aid in supplementing the engineering experience and judgment of the designer.

As indicated by the author, the "membrane analogy" as a supplement to photo-elastic analysis appears to have decided advantages over the method of graphical integration for the determination of the principal stress sum. There was also another excellent paper by Supper and McGivern[7] that exhibited in great detail the use of the membrane analogy for the determination of the quantity, $p + q$. The accuracy of this method decreases, however, as the slope of the membrane increases. This occurs in regions of high stress concentration, such as the heel and toe of the dam illustrated in the paper. Since a designer might have more interest in such regions than in others, it would be desirable to avoid the effects of this limitation of the membrane analogy.

Another supplementary procedure which seems to be adaptable to all cases is that proposed[8] by Professor V. Tesar. This is a purely optical method requiring even less additional apparatus than the membrane analogy, and its accuracy is independent of the concentration of stress in the model. Its fundamental principle is the interference of light waves as they are reflected from the bounding surfaces of a thin wedge of air. The surfaces in this case are a face of the model and an optically flat glass. Changes in thickness in the model (which are a function of the quantity, $p + q$), cause corresponding variations in the interference fringe pattern across the image of the model on a screen. These variations can be calibrated, and, therefore, $(p + q)$ can be found for a given load.

I. K. SILVERMAN,[9] JUN. AM. SOC. C. E. (by letter).—What would be the stress pattern in the bakelite model of a triangular dam resting on a continuous elastic foundation and subjected to shrinkage? In this paper, Mr. Smits has described a conception of this phenomenon. His description of how the stresses might vary seems logical. Based on this preconceived picture, he proceeds to load his model so as to obtain this possible distribution of stress and, in Figs. 10 and 11, presents curves for the resulting stress distribution near the base. He has failed to show, however, that this is the only way this stress pattern could have been produced and, for this reason, and for others cited herein, no great value can be attached to the numerical results shown in Fig. 10.

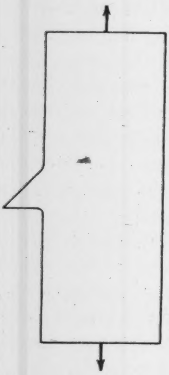

FIG. 12.

The author states that the form of the test specimen was chosen so that the stress pattern would be a gauge of the degree of axial loading. It is evident that in choosing this type of specimen, he has clouded the stress distribution in the very region that he is examining. The stress distribution in any model is dependent to a high degree on its geometry. From Fig. 8 the width of the strap is of the same order of dimension as that of the base of the dam. For this reason the stress distribution of Fig. 7 may be far different from that in a model which is of the form shown in Fig. 12.

By means of Fig. 9 Mr. Smits has shown the accuracy obtained in measuring the stresses shown in Fig. 7. It would be interesting if, in his closing discussion, he would present curves similar to those of Fig. 9 for the resultant stress distribution shown in Fig. 10. Evidently, the total areas under these curves should be zero.

J. H. A. BRAHTZ,[10] ESQ. (by letter).—The sections of the paper entitled "Method of Solution" and "Theory of New Method" are valuable contributions to the theory of photo-elasticity in that they demonstrate how to evaluate the stresses within the boundaries of a stressed body.[11] The membrane method described by the author has been successful in the photo-elastic laboratory of the U. S. Bureau of Reclamation. The over-all error in the experiments on heavy monolithic structures is estimated to be from 5 to 10%, depending on the type of structure and loading.

The section of the paper entitled "Application of New Method," gives numerical values of the shrinkage stresses in a gravity dam which are in good agreement with those obtained by the writer based on theoretical considerations and photo-elastic experimentation. For example, for the horizontal stresses along the bisector of the top angle of a 45° triangular dam (Poisson's ratio = 0.2), set on a rigid foundation, the writer finds the following approximate solution (taking the two first terms of an infinite series):

$$\sigma = \left\{ \left(\frac{r}{h}\right)^{4.39} \left[1.812 \cos\left(2.7 \log \frac{r}{h}\right) - 0.178 \sin\left(2.7 \log \frac{r}{h}\right) \right] - \left(\frac{r}{h}\right)^{12.66} \left[0.838 \cos\left(3.8 \log \frac{r}{h}\right) + 0.062 \sin\left(3.8 \log \frac{r}{h}\right) \right] \right\} K E \quad \text{..(9)}$$

in which r = the distance from the vertex; h = the height of vertex above the foundation (measured along the bisector); E = the elastic modulus of elasticity; and, K = the shrinkage per unit length. If $r = h$, the horizontal stress at the foundation becomes:

---

[10] Engr., U. S. Bureau of Reclamation, Denver, Colo.

[11] See, also, *Zeitschrift angew. Math.*, Vol. II, 1931, p. 156.

$$\sigma_1 = 0.974\ K\ E \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

which value is estimated to be correct within 5% due to the omission of the higher order terms in Equation (9). Using the value of K in Fig. 10, that is $K = 0.0006$, the stress becomes, $\sigma_1 = 0.0005844\ E$.

Assuming E to be 2 000 000 lb per sq in., the stress would be, $\sigma_1 = 1\,169$ lb per sq in.; and, with $E = 3\,000\,000$ lb per sq in., the stress would be, $\sigma_1 = 1\,753$ lb per sq in.

These quantities are not directly comparable with the author's stresses in Figs. 10 and 11, because he assumes an elastic foundation of the same modulus as the dam. Consequently, when the dam shrinks, there will be a compromise between the foundation and the dam, the former going into compression in the region directly below the dam and the latter into tension. It will not be an even division, however, because the foundation does not deform quite as readily as the dam with its much smaller mass; and, therefore, it imposes the greater part of the shrinkage as an elongation of the elements of the dam adjacent to the foundation.

Using the stresses given in Fig. 11 at the foundation (630 in the dam and 460 in the foundation) as a basis of the compromise, the computed stress in the dam would be, $\frac{630}{630 + 460}\ \sigma_1$, or 676 and 1 014, respectively, depending on the value of E introduced in Equation (10). The first value compares closely with the value (630) given in Fig. 11, corresponding to $E = 2\,000\,000$ lb per sq in. which the author adopted for his calibration.

Based on the writer's theory and experiments, he concludes that the average horizontal tensile stress along the base of a dam on an elastic foundation varies from 5 to 15 lb per sq in. per degree Fahrenheit of decrease in temperature, depending on the ratio of the elastic moduli in the dam and the foundation. This range of stress shows the dire necessity of providing against shrinkage effects during construction by cooling and pressure grouting.

ARSHAG G. SOLAKIAN,[12] ESQ. (by letter).—The experimental method used by Mr. Smits, namely, of stretching the base of the model to introduce shrinkage stresses in the body of an "idealized" dam, does not well represent the actual conditions prevailing in Nature, as will be demonstrated presently.

Shrinkage stresses in concrete dams of the gravity type are produced under several conditions, the most important of which are: (1) The setting of the cement in concrete, in a dam resting on a clay foundation or loose rock; (2) the setting of the cement in concrete, in a dam having a perfect bond with a solid rock foundation (Mr. Smits' paper deals only with this case); and (3) the daily (or weekly) and seasonal changes of atmospheric variations of temperature, in a dam having a perfect bond with a solid rock foundation.

---

[12] Lecturer in Civ. Eng., Columbia Univ., New York, N. Y.

Condition (1).—Stresses in this catagory are due to the premature setting of the cement at the two exposed surfaces of the dam, before such action begins to develop in the interior regions of the cross-section. As a result, a relatively harder crust is formed around the structure in Nature's attempt to resist subsequent shrinkage effects of the interior region. Such a phenomenon and the resulting stress distribution will be similar in Nature to that which occurs in every day foundry practice when dealing with cast metals.

Stresses of the intensity and direction produced under Condition (1) can be obtained by photo-elastic methods from a model cast under proper curing conditions. In a previous investigation[13] bakelite specimens revealed the existence of such stresses with a sufficient number of interference fringes. A model was prepared by filling with bakelite powder a metal form 1 in. deep, having the outlines of the profile of the dam with extended footings. The material was heated for several days at a constant temperature and then gradually cooled to room temperature. After being machined to a thickness of about $\frac{5}{8}$ in. for plane parallel surfaces, the cast plate was examined in circularly polarized light for the fringe pattern in Fig. 13. In this view each fringe line is a contour of the constant difference between the principal stresses, σ_1 and σ_2 acting at a point, with a relative intensity for each fringe line equal to its order as marked. Since the maximum shear stress intensity is known to be equal to one-half the difference of the principal stresses, the fringe pattern will also show the distribution of these types of stresses which is quite useful for actual design purposes under certain circumstances. The variation of these stresses across three typical sections, *A–A*, *B–B*, and *C–C* (Fig. 13)—coinciding, respectively, to the base, one-third, and two-thirds the height of the dam—are shown in Fig. 14(*a*). From Figs. 13 and 14(*a*) it is evident that sharp corners and fillets of small radii are regions of high stress concentrations under the conditions of structure as discussed (Condition (1)). Furthermore, the stress gradient increases from the center of the dam toward the outer surfaces, for all sections considered.

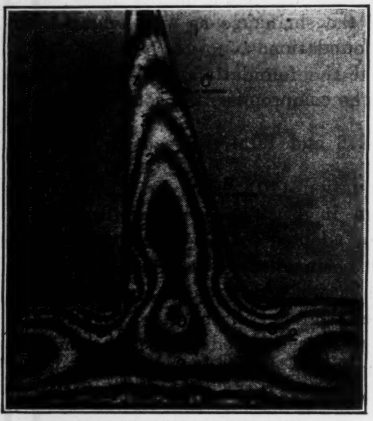

FIG. 13.—FRINGE PATTERN.

The orientation of the principal stresses, σ_1 and σ_2, is found by using plane polarized light at constant directions of vibration from 0° to 90°, with 10° intervals. The resulting isoclinic bands that are contours of constant orientation of these stresses are traced as in Fig. 14(*b*). From these curves, the stress trajectories of Fig. 14(*c*) are obtained by a graphical process. The existence of a singular point (known also as an isotropic or neutral point) near the base of the dam is clearly evident from Figs. 13, 14(*b*), and 14(*c*). At such a point the two principal stresses are at all possible orientations, and are of equal magnitude and sign (both tension or both compression). Note, for example, that $\sigma_1 - \sigma_2 = 0$, represents the zero order fringe in Fig. 13.

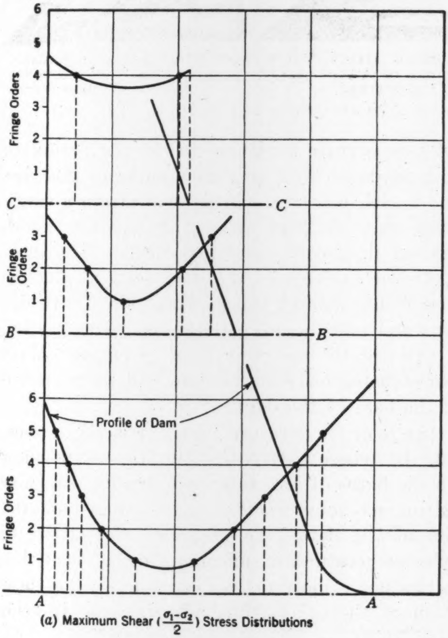
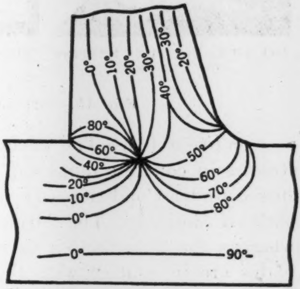
[13] "Photo-Elastic Analysis of Stresses in Composite Materials", by A. H. Beyer, M. Am. Soc. C. E., and A. G. Solakian, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E Vol. 99 (1934), p 1196.

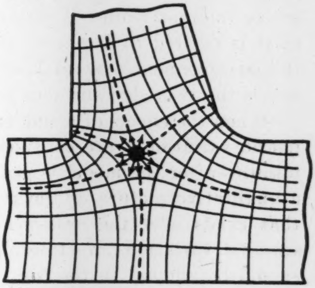
Condition (2).—When the dam has a perfect bond with an underlying foundation, the method outlined under Condition (1) does not apply. In this case a mass of infinite extent which forms an integral part with the base of the dam, is free from shrinkage phenomena, since it is underground and at a constant temperature. Such action, however, is developing within the entire body of the dam. The method proposed by Mr. Smits serves to introduce stresses only in the base region of the dam, whereas the larger part of the structure above this region is not affected. A logical method would be to make a model consisting of two pieces, a large block to represent the massive foundation and a small triangular plate to represent a thin section of the dam. The block is kept in a bath of hot water, whereas the thin plate is kept in dry ice, both long enough to establish a uniform temperature distribution throughout their entire mass. The two pieces then would be cemented together along the base of the dam, taking care that each section was kept at



(*a*) Maximum Shear ($\frac{\sigma_1-\sigma_2}{2}$) Stress Distributions



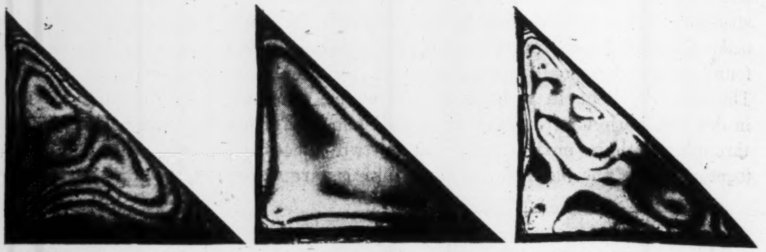
(*b*) Isoclinics



(*c*) Stress Trajectories

FIG. 14.—STRESSES IN A DAM ON CLAY FOUNDATION, DUE TO SETTING OF CEMENT IN THE CONCRETE.

its original uniform temperature during the final setting of the cement. The cemented model would then be introduced into a cell with glass walls and containing hot water, to raise the temperature of the dam section to that of its foundation and thus to make it expand, the block as a whole being unaffected. This action is similar to that which occurs under actual conditions in the structure considered. Fig. 15 is a fringe pattern of the stresses produced in a model examined by the method as described. A new photoelastic material with a greater stress-optical sensitivity, was used for the two parts of the cemented model. A special quick-setting cement was also used.[14] An inspection of Fig. 15 makes evident the existence of shrinkage stresses all over the cross-section of the dam, in variance with that of Fig. 5 in the paper.



(*a*) DUE TO THE SETTING OF CEMENT. (*b*) DUE TO DAILY VARIATIONS OF ATMOSPHERIC TEMPERATURE. (*c*) DUE TO SEASONAL VARIATIONS OF ATMOSPHERIC TEMPERATURE.

FIG. 15.—STRESSES IN A DAM ON ROCK FOUNDATION.

Condition (*3*).—The effect of temperature variation producing shrinkage stresses in concrete dams can be reproduced by a process similar to that discussed under Condition (2). The model, however, can be made from a single plate if desired. The large base plate is kept in a bath of hot water, whereas the dam section is enclosed in a cell with glass walls. The glass plates are in contact with the polished surfaces of the dam section, and the two compartments thus formed on either side of the dam are filled with dry ice, or the up-stream cell with hot water and the down-stream cell with dry ice, as it is desired to duplicate the cases of the reservoir filled or empty. With this arrangement, flow of heat through the body of the dam will be restricted across the two edge surfaces and the base of the dam.

When the effects of a sudden change of temperature (daily or weekly atmospheric variations) are considered, the fringe pattern in Fig. 15, taken a few minutes after the model is put in the baths of hot water and dry ice, will give a qualitative picture of the resulting momentary temperature-stress potential that exists over the cross-section of the dam. To duplicate the effects of seasonal variations of atmospheric temperature, a sufficient time of heat flow should be allowed in the test, to produce a more or less constant flow of heat from one part of the dam section to the other, thus affecting the interior points of the dam as well. Under these conditions, then, the fringe pattern will be quite steady provided the temperature of the source of heat and the sink is kept constant. Fig. 15(*c*) represents the latter situation.

---

[14] "A New Photoelastic Material", by A. G. Solakian, *Mechanical Engineering*, December, 1935.

Due to the necessity of certain improvements in the details of conducting the test, as described under Conditions (2) and (3), further analysis with curves showing the intensities and orientations of the stresses for the last two cases is disregarded. As a matter of fact, because of the small size of the models used in this discussion (3-in. legs of dam section) and by Mr. Smits, the experimental results should be considered only from a qualitative point of view.

The suggestions described herein, for the investigation of shrinkage stresses arising from various causes, combined with the centrifuge-polariscope method[15] of analyzing the stresses in dams due to gravity and hydrostatic pressure, should give the investigator sufficient tools for a complete and exact experimental solution of the dam problem.

L. N. G. FILON,[16] ESQ. (by letter).—In view of the importance of the problem treated in Mr. Smits' paper, the writer has studied a xylonite model made similar to Fig. 16, with a broad strap, there being a projecting "dam" on one side only. If the loads at the ends of the strap are properly centered the longitudinal tension, *Q*, is sensibly uniform throughout a region where the distance from the base line, *A B*, of the dam (Fig. 17) exceeds one-fifth the height of the dam.

However, when the stresses are measured at the point, *O*, of Line *A B* (Fig. 17), where the shear stress parallel to *A B* vanishes, *Q* is found to be (0.65) *T* and (– 0.35) *T*, respectively (after applying the corrective pressure, *T*, below *A B*), on the upper and lower sides of the line, *A B*, of discontinuity. For the case taken by the author ($T = 1\,220$ lb per sq in.), these forces would produce a tension of 793 lb per sq in., and a pressure of – 472 lb per sq in., results which differ appreciably from those deduced from Fig. 11. Apparently, this gives 650 lb per sq in., for the tension above, and 550 lb per sq in., for the pressure below, leading to a lesser tension in the dam proper than that

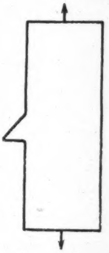


FIG. 16.

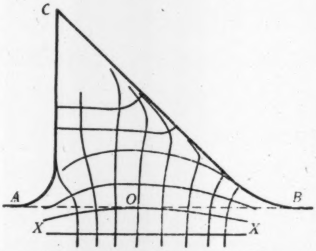

FIG. 17.—LINES OF PRINCIPAL STRESS IN DAM SUBJECT TO UNIFORM SHRINKAGE.

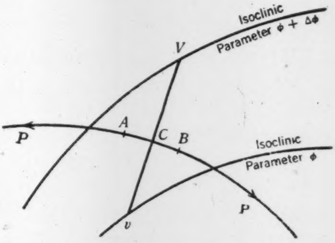

FIG. 18.—STEP-BY-STEP METHOD OF EXPLORATION OF PRINCIPAL STRESS.

---

[15] "Centrifuge Method of Testing Models", by P. B. Bucky, A. G. Solakian, and L. S. Baldin, *Civil Engineering*, May, 1935.

[16] Prof. of Applied Mathematics and Mechanics, University Coll., London, England.

now found. Furthermore, the stress appears to extend deeper into the base of the dam in Mr. Smits' experiment than in the present case.

The writer has also traced the isoclinics and lines of principal stress in this case. The latter are shown in Fig. 17 and appear to be different, in the upper part of the dam, from those given by the author in Fig. 7(*b*). Fig. 7(*b*) is probably incorrect, since the lines of principal stress should approach a free boundary tangentially and normally.

The device used by Mr. Smits to solve Laplace's equation empirically is an interesting application of a well-known method originally suggested by L. Prandtl[17] in connection with the torsion of rods, and further developed by A. A. Griffith and G. I. Taylor.[18] A soap film is preferable to an india-rubber membrane, owing to the difficulty of being certain that the tension in the latter is uniform at all points and in all directions. Even if this condition is satisfied initially, it is likely to be disturbed when the india-rubber sheet is clamped between templates as described, any rapid variations of height of the edge involving appreciable pinching, which must modify the tensions postulated. This seems to be a more serious source of error than the exaggeration of the slope, as it may well not be localized.

This method assumes, of course, that the equation to be solved is Laplace's equation; in other words, that the material under consideration is perfectly elastic. The same assumption is made in applying those methods which depend on measurement of lateral extension or contraction. So far as the writer's experience goes, bakelite is a material which is very far from being perfectly elastic, and it exhibits considerable strain creep and optical creep with time. The author does not state whether any precautions have been taken to eliminate them.

Mr. Smits is to be congratulated on having been able to obtain specimens of bakelite of adequate size apparently free from large initial double refraction. The bakelite obtainable in England is badly affected in this way, and comparatively useless for photo-elastic work.

It is not quite clear why the author (following Fig. 4) describes what he calls the method of graphical integration (but which the writer would prefer to call the step-by-step method) as "long and tedious." A similar statement appears in another paper.[19] It would seem that engineers are under a misapprehension as to the work involved in this method.

If A and B (Fig. 18) are two near points on a line of principal stress, P, through the middle point, C, of $A\,B$, draw a perpendicular to Line $A\,B$, meeting at U, V, respectively, any two neighboring isoclinics which correspond to inclinations, ϕ, $\phi + \Delta\,\phi$, of the polarizer and analyzer to any standard directions of reference. Then,

$$P_B - P_A = \frac{A\,B}{U\,V}\,\Delta\,\phi\;(Q - P)_C \ldots\ldots\ldots\ldots\ldots(11)$$

---

[17] *Physicalische Zeitschrift*, Vol. 4, 1903.

[18] *Engineering* (London), Vol. 104, 1917, pp. 658, 699.

[19] "The Stress Function and Photo-Elasticity Applied to Dams", by J. H. A Brahtz, Esq., *Proceedings*, Am. Soc. C. E., September, 1935, p. 1015.

in which $\Delta \phi$ is usually a small whole number of degrees, which must be multiplied by 0.01745 to yield $\Delta \phi$, in radians.

Now, in any photo-elastic investigation, both the isoclinics and the lines of principal stress are fundamental and will have to be drawn in any case; $Q - P$ at any required point can be obtained in a variety of ways: (1) By interpolation between isochromatics; (2) by direct measurement with a compensator; or (3) by varying all loads on the model together in such a ratio that an isochromatic of a given order passes through the point. Thus, the data entering into the right-hand side of Equation (11) are immediately to hand; the value of $P_B - P_A$ is then calculated in a few moments with a slide-rule.

In this manner it is possible to work along a line of principal stress and obtain the value of P, step by step, at a number of points. If the investigator suspects inaccuracies, owing to an accumulation of errors, there is an important check, which should be applied frequently. For example, the investigator may reach the same point, using different rectangular zigzag paths along lines of principal stress, and, if the values agree (as they do when the work has been done carefully), the stresses found can be accepted with considerable confidence and used as a basis for further exploration.

There is no necessity for "graphical" integration in the ordinary sense; nor need the steps, in general, be inconveniently small. What is essential, however, is that the isoclinic lines shall have been obtained accurately in the first instance. For this, visual observation, with bright illumination and a good graticule of reference, is necessary. An ordinary photograph is usually not adequate for this purpose.

This step-by-step method[20] is entirely independent of the elastic properties of the material and is not based on the assumption that the substance used is perfectly elastic. It does, however, involve the assumption that stress difference is proportional to optical retardation, and this law generally holds well beyond the elastic limit.

HOWARD G. SMITS,[21] JUN. AM. SOC. C. E. (by letter).—The writer is gratified with the variety of viewpoints expressed by the discussers of his paper, particularly since the mathematical solution of the problem is complex enough to make the approach extremely difficult and, at best, only approximate.

Mr. Silverman has questioned the shape of the tested model, feeling that the strap was too narrow in relation to the size of the dam. Fortunately, when Professor Filon performed a similar test, he used a model similar to that suggested by Mr. Silverman. The difference in results obtained by Professor Filon and the writer would indicate that this geometric change in the model has bearing on the quantitative result. It is unfortunate that a relatively wider strap was not used in the original experiment.

The agreement between the experimental results and the results obtained from the mathematical expression derived by Mr. Brahtz is very gratifying. Mr. Brahtz estimates that Equation (10) gives a value which is correct within

---

[20] Rept. of the British Assoc. for the Advancement of Science, 1923; also, *Engineering* (London), Vol. 116 (1923), pp. 511–512.

[21] Structural Designer, O. G. Bowen, Los Angeles, Calif.

5 per cent. Thus, when $K = 0.0006$ and $E = 2\,000\,000$, Equation (10) yields: $\sigma_1 = 1\,169$ lb per sq in. This is comparable to the sum of the maximum stresses on either side of the line of discontinuity at the ground line. From Fig. 11 these stresses are shown to be 525 lb per sq in. and 650 lb per sq in., giving a total of 1 175 lb per sq in. Professor Filon evaluated these two stresses at 793 lb per sq in. and 472 lb per sq in., for a total of 1 265 lb per sq in. The three values obtained (1 169, 1 175, and 1 265) fall in a narrow region, showing very good agreement between the three approaches.

Professor Filon takes exception to the lines of direction of principal stress as drawn by the writer in Fig. 7(*b*). At no time did the writer observe isoclinic lines which, when plotted, would give the sudden change of direction in the lines of principal stress, indicated in Professor Filon's Fig. 17, near the faces of the dam. It is to be noted that in all cases the lines of principal stress approach the free boundaries normally and tangentially in Fig. 7(*b*).

The advisability of using a rubber membrane is questioned by Professor Filon. Concentric circles were drawn on the rubber before stretching, and these were found to remain true circles in plan, both after stretching and after placing between the aluminum dies. It was only after observing this precaution that the writer felt justified in assuming a uniform tension in the membrane.

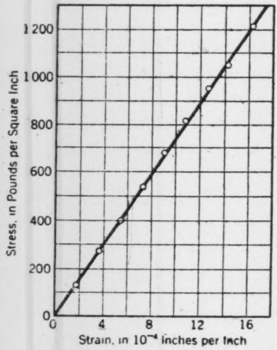

FIG. 19.

The bakelite used in this work was not free from initial double refraction until after the specimen had been carefully annealed. The annealing operation presented several difficulties. However, once properly heated and cooled, the model remained free of initial stresses for some time. In performing the experimental work on the model, the element of time was always considered to decrease the effect of optical creep.

Fig. 19 represents a stress-strain diagram for the bakelite used in the model. The relationship indicates a remarkably straight line, which showed little tendency to creep with time.

Mr. Solakian presented some very interesting material in the three conditions considered by him. It is unfortunate that more detailed information was not given, both quantitatively and qualitatively, particularly in relation to Condition (3). It is noted with particular interest that a bakelite cement has been perfected with physical qualities such that it is adaptable to photo-elastic work. The writer has long sought such a cement. The next step in approximating actual conditions with the photo-elastic method is now possible. Bakelite blocks can be cemented together simulating the manner in which they are now actually cast in the field and the entire model tested as a unit. Engineers interested in dam construction will look forward to the publication of the results of photo-elastic tests made on models built with construction joints.

THE SHEAR-AREA METHOD

By HORACE B. COMPTON,[1] ASSOC. M. AM. SOC. C. E., and
CLAYTON O. DOHRENWEND,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS, GEORGE E. LARGE, SAMUEL T. CARPENTER, ROLAND H. TRATHEN, A. W. FISCHER, J. CHARLES RATHBUN, HAROLD R. KEPNER, FRED L. PLUMMER, ALBIN H. BEYER, JOHN M. BEATTY, R. B. PECK, RALPH W. STEWART, C. W. JOHNSON AND H. W. BIRKELAND, GARRETT B. DRUMMOND, HAROLD E. WESSMAN, FANG-YIN TSAI, DAVID A. MOLITOR, F. MULSGUINOTTE, AND HORACE B. COMPTON AND CLAYTON O. DOHRENWEND.

SYNOPSIS

The shear diagram may be used in a manner similar to the moment diagram for the solution of the elastic functions of loaded beams. This procedure is not generally known although the moment-area methods are of common practice and are taught in most schools of engineering. Use of the shear diagram simplifies the solution of many beam problems, and, therefore, should be of interest to engineers. This type of solution is applicable to all types of beams, and this paper includes the analysis of statically determinate, and statically indeterminate, beams with concentrated loads, uniform loads, and couples.

Notation.—The symbols used throughout the paper are given in the Appendix. An effort has been made to conform as nearly as practicable with "Symbols for Mechanics, Structural Engineering, and Testing Materials," advanced by the American Standards Association.[3]

GENERAL

The use of the moment diagram to solve for slopes and deflections in statically determinate beams and for redundants in statically indeterminate

beams, is well known. Since corresponding values can be obtained by a similar treatment of the shear diagram (and in some cases, more easily), it is suggested that this method of using the shear diagram should be given more general consideration.

The shear-area method has the following advantages:

(*a*) It eliminates the moment diagram and, therefore (especially with uniform loading), it provides a simpler figure to work with than that of the moment-area method;

(*b*) It simplifies the solution for slope and deflection at any section and affords an easy means of locating the section of maximum deflection; and

(*c*) It provides a ready solution for the derivation of the "Theorem of Three Moments" for any type of loading.

For the student this method will bring into play certain "Mathematical Beams" which will aid his general knowledge of beam action. In the solution of the beam problems the shear diagram is used in the same manner as the moment diagram in the "Conjugate Beam Method."

In considering the shear-area method the following assumptions should be kept clearly in mind:

(1) The modulus of elasticity is considered constant in all the problems;

(2) The shear diagram divided by the moment of inertia is used as the loading on a mathematical beam if the moment of inertia is constant;

(3) The shear at any section of this mathematical beam represents the bending moment at the same section of the real beam;

(4) The bending moment at any section of this mathematical beam represents the slope at the same section of the real beam;

(5) The slope at any section of the mathematical beam represents the deflection at the same section of the real beam (this deflection can be expressed in terms of the moment of inertia of the shear diagram); and,

(6) The end conditions of the mathematical beam are determined by the given beam.

Referring to Assumption (2), when the moment of inertia is not constant the ratio, $\frac{V}{I}$, is replaced by,

$$E\,\frac{d^3y}{dx^3} = \frac{V}{I} - \frac{M}{I^2}\left(\frac{dI}{dx}\right) \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Equation (1) is derived as follows:

$$E\,\frac{d^2y}{dx^2} = \frac{M}{I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

and,

$$E\,\frac{d^3y}{dx^3} = \frac{d}{dx}\left(\frac{M}{I}\right) = \frac{I\,dM - M\,dI}{I^2\,dx} = \frac{V}{I} - \frac{M}{I^2}\left(\frac{dI}{dx}\right) \ldots\ldots (3)$$

in which, E = modulus of elasticity; y = deflection measured parallel to the Y-axis; x = a distance measured parallel to the X-axis; M = bending moment; I = moment of inertia; and V = shear. Assumptions (1) to (6) are concerned with the relations between beam loading, shear, moment, slope, and deflection. Their significance may be reviewed by reference to Fig. 1 in which:

For shear (Fig. 1(*b*)),

$$V_x = R - \int w_x \, dx \dots\dots\dots\dots\dots\dots\dots (4)$$

for moment (Fig. 1(*c*)),

$$M_x = \int V_x \, dx = \int dA \dots\dots\dots\dots\dots\dots\dots (5)$$

for slope (Fig. 1(*d*)),

$$\phi_x = \phi_L - \frac{1}{EI}\int M_x \, dx = \phi_L - \frac{1}{EI}\int x \, dA + C_1 \dots\dots\dots (6)$$

and, for deflection (Fig. 1(*e*)),

$$y = \int \phi_x \, dx = \phi_L \, x - \frac{1}{EI}\int\int x \, dA \, dx = \phi_L x - \frac{I_x}{2\,EI} + C_2 \dots (7)$$

in which R = a reaction; A = the area of a loading diagram on a mathematical beam; and $C_1 = C_2$ = a constant (= 0).

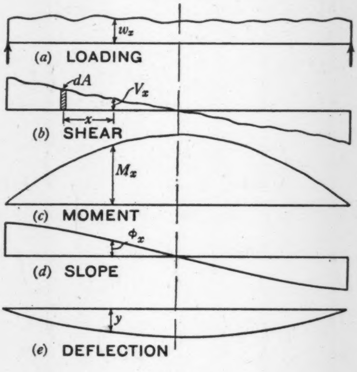

FIG. 1

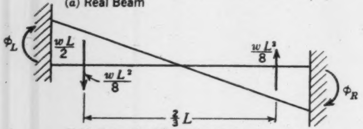
ANALYSIS OF STATICALLY DETERMINATE BEAMS

The following typical cases are given as a development of the shear-area method of solving problems applied to beams that are statically determinate.

Case 1.—Simple Beam with Uniform Load Over Entire Span.—In Case 1, the real beam (Fig. 2(*a*)) has slope at each end and, therefore, the mathematical beam (Fig. 2(*b*)) has a moment at each end. The real beam has no bending moment at the ends and, therefore, the mathematical beam has no shear at the ends. Hence, the reactions of this mathematical beam are couples. The loading is also a couple and is placed symmetrically about the center and, consequently, one-half the total couple is carried by each end reaction. This is evident since in this case the real beam has equal end slopes.

(a) Real Beam



(b) Mathematical Beam Loaded with Shear Diagram

FIG. 2

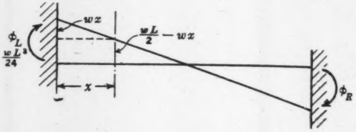


FIG. 3

The total moment of the loading is expressed by,

$$\phi_T = \frac{w\,L}{2} \times \frac{L}{2} \times \frac{1}{2} \times \frac{2}{3}\,L \times \frac{1}{E\,I} = \frac{w\,L^3}{12\;E\,I} \;\ldots\ldots\ldots\ldots(8)$$

With one-half assigned to each end, the end slope of the real beam is:

$$\phi_R = \phi_L = \frac{w\,L^3}{24\;E\,I} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(9)$$

Since the moment of the shear diagram gives the change in slope, the slope at any point can be computed by measuring a distance, x, from one end and then taking moments at the desired section, including the end reactions in the moment equations; thus (see Fig. 3):

$$E\,I\,\phi_x = \frac{w\,L^3}{24} - w \times x \times \frac{x}{2} \times \frac{2\,x}{3} - \left(\frac{w\,L}{2} - w\,x\right)\frac{x^2}{2}$$

or,

$$\phi_x = \left(\frac{w\,L^3}{24} + \frac{w\,x^3}{6} - \frac{w\,L\,x^2}{4}\right)\frac{1}{E\,I} \;\ldots\ldots\ldots\ldots\ldots(10)$$

To find the deflection, y, at any section integrate Equation (10):

$$E\,I\,y = \int_0^x \frac{w\,L^3\,dx}{24} + \int_0^x \frac{w\,x^3\,dx}{6} = \int_0^x \frac{w\,L\,x^2\,dx}{4}$$

$$= \frac{w\,L^3\,x}{24} - \left(\frac{w\,L\,x^3}{12} - \frac{w\,x^4}{24}\right) = \frac{w\,L^3\,x}{24} - \frac{I_x}{2} \;\ldots\ldots\ldots(11)$$

The maximum deflection occurs at the section where $x = \frac{L}{2}$:

$$y_m = \frac{5}{384}\,\frac{w\,L^4}{E\,I} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(12)$$

When concentrations occur in the shear diagram each value is multiplied by the square of its distance and included in Equation (11).

Case 2.—Simple Beam with Concentrated Load at Mid-Span.—For this case (see Fig. 4) the total moment of load is,

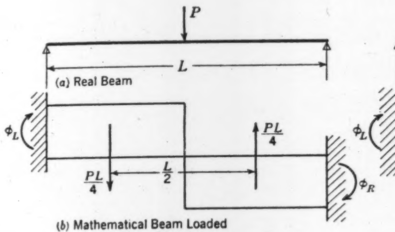
$$\phi_T = \frac{P\,L^2}{8\,E\,I} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(13)$$

and the end slope is,

$$\phi_L = \frac{P\,L^2}{16\,E\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

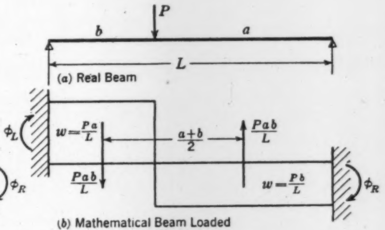
Taking moments for slope at any point:

$$\phi_x = \frac{P\,L^2}{16\,E\,I} - \frac{P\,x^2}{4\,E\,I} = \frac{P}{4\,E\,I}\left(\frac{L^2}{4} - x^2\right) \quad\ldots\ldots\ldots\ldots (15)$$



(b) Mathematical Beam Loaded with Shear Diagram

FIG. 4



(b) Mathematical Beam Loaded with Shear Diagram

FIG. 5.

The deflection at any point is equal to:

$$E\,I\,y = \frac{P\,L^2\,x}{16} - \frac{I_x}{2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

and the maximum deflection occurs at the section where $x = \dfrac{L}{2}$:

$$y_m = \frac{P\,L^3}{48\,E\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Case 3.—Simple Beam with Concentrated Load Not at Mid-Span.—To determine the end conditions of the mathematical beam for this case (see Fig. 5), write the general moment equation with the left end as the origin, thus, the moment of the mathematical beam is,

$$M_m = \phi_L - \frac{P\,a\,x^2}{2\,L\,E\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

and the slope of the mathematical beam is,

$$Q_m = \phi_L\,x - \frac{P\,a\,x^3}{6\,L\,E\,I} + (C = 0) \quad\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The moment equation of the mathematical beam, as derived from the right end is,

$$M_m = \phi_R + \frac{P\,b\,x^2}{2\,L\,E\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

or, the slope of the mathematical beam is,

$$Q_m = \phi_R\,x + \frac{P\,b\,x^3}{6\,L\,E\,I} + (C = 0) \quad\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equate the two tangents of the mathematical beam when x in Equation (19) is equal to b, and x in Equation (21) is equal to a, since the deflection of the real beam can be expressed by both equations at that point, thus:

$$-\phi_L\, b + \frac{P\,a\,b^3}{6\,L\,E\,I} = \phi_R\, a + \frac{P\,b\,a^3}{6\,L\,E\,I} \quad \text{.................(22)}$$

Furthermore, since $\phi_R = \phi_L - \phi_T$:

$$E\,I\,\phi_L = \frac{P\,a\,b}{6\,L}\,(L + a) \quad \text{........................(23)}$$

and,

$$E\,I\,\phi_R = -\,\frac{P\,a\,b}{6\,L}\,(L + b) \quad \text{......................(24)}$$

The equations for deflection and slope for any section can now be readily written: For slope,

$$E\,I\,\phi_x = \frac{P\,a\,b}{6\,L}\,(L + a) - \frac{P\,a\,x^2}{2\,L} \quad \text{...................(25)}$$

and for deflection,

$$E\,I y = \phi_L x - \frac{I_x}{2} \quad \text{........................(26)}$$

Since at the section of maximum deflection the slope is equal to zero in the real beam, the moment equation of the mathematical beam need only be set to zero and solved for the value of x; thus:

$$-\,\frac{P\,a\,b}{6\,L}\,(L + b) + \frac{P\,b\,x^2}{2\,L} = 0 \quad \text{..................(27)}$$

or,

$$x = \sqrt{\frac{a}{3}\,(L + b)} \quad \text{..............................(28)}$$

Substituting Equation (28) in the deflection equation,

$$y_m = \frac{P\,a\,b}{9\,E\,I\,L}\,\sqrt{\frac{a}{3}\,(L + b)^3} \quad \text{......................(29)}$$

(a) Real Beam

(b) Mathematical Beam Loaded with Shear Diagram

FIG. 7.

It is interesting to note that, as the value of b changes from zero to $\frac{1}{2}L$, the value of x varies from $\frac{1}{\sqrt{3}}L$ to $\frac{1}{2}L$. This means that x_m will always be such as to bring the section of maximum deflection within 8% of L, distant from the middle of the beam.

Case 4.—Simple Beam with Segment of Uniform Load at Any Position.—Equations (23) and (24) may be used to determine the end condition of the mathematical beam in the case of a simple beam with a segment of uniform load at any position (see Fig. 6). Then (see Fig. 6(*a*)),

$$EI\,\phi_L = \int_{a_1}^{a_2} \frac{w\,dx \times a_x\,(L - a_x)}{6\,L}\,(L + a_x)$$

$$= \frac{w}{6\,L}\left[\frac{L^2}{2}\,(a_2^2 - a_1^2) - \frac{1}{4}\,(a_2^4 - a_1^4)\right] \qquad (30)$$

The slope at any point can now be obtained from the moment equation of the mathematical beam; thus, for values of x from zero to $(L - a_2)$ with the origin at the left support,

$$\phi_x = \phi_L - w\,(a_2 - a_1)\left(\frac{a_1}{2} + \frac{a_2}{2}\right)\frac{x^2}{2\,L\,E\,I} \qquad (31)$$

The deflection at any point can be expressed in the same manner as in Case 3 (see Equation (26)).

Case 5.—Simple Beam with Couple Applied at Any Section.—Considering the real beam first, it will be noted that at the section where the couple is applied there is an abrupt change in the bending moment. Since the shear of the shear diagram is to represent the bending moment of the real beam, this means that a concentrated load must be placed on the shear diagram at that point equal to the magnitude of the couple (see Fig. 7).

The end conditions of the mathematical beam are determined as in Case 3. Taking moments from the left end (see Fig. 7), the moment of the mathematical beam is: $M_m = \phi_L - \frac{X\,x^2}{2\,L\,E\,I}$; and,

$$Q_m = \phi_L\,x - \frac{X\,x^3}{6\,L\,E\,I} \qquad (32a)$$

in which, X, Fig. 7, is the couple in question. Taking moments from the right end, the moment of the mathematical beam is, $M_m = \phi_R + \frac{X\,x^2}{2\,L\,E\,I}$; and, the slope of the mathematical beam is,

$$Q_m = \phi_R\,x + \frac{X\,x^3}{6\,L\,E\,I} \qquad (32b)$$

Equate tangents when $x = b$ in Equation (32*a*), and $x = a$ in Equation (32*b*), remembering that the sum of the reaction couples must equal the couple due to the loading. In other words, $\phi_L + \phi_R = \frac{X}{L\,E\,I} \times L\left(\frac{L}{2} - a\right)$; or,

$\phi_L + \phi_R - \frac{X\,L^2}{L\,2\,E\,I} + \frac{Xa}{E\,I} = 0$; and,

$$\phi_L = \left(\frac{X\,b^3}{6\,L^2} + \frac{X\,a\,b^2}{2\,L^2} - \frac{X\,a^3}{3\,L^2}\right)\frac{1}{E\,I} \quad \text{.............(33a)}$$

and,

$$\phi_R = \left(-\frac{X\,a^3}{6\,L^2} - \frac{X\,b\,a^2}{2\,L^2} + \frac{X\,b^3}{3\,L^2}\right)\frac{1}{E\,I} \quad \text{...........(33b)}$$

The slope and deflection at any point are quickly computed, as before (in *b* segment):

$$\phi_x = \phi_L - \frac{X\,x^2}{2\,L\,E\,I} \quad \text{......................(34)}$$

and,

$$y = \phi_L\,x - \frac{I_x}{2\,E\,I} \quad \text{......................(35)}$$

Case 6.—Cantilever Beam with Concentrated Load at the End.—For Case 6, refer to Fig. 8:

$$\phi_A = \frac{M\,L}{E\,I} - \frac{P\,L^2}{2\,E\,I} = \frac{P\,L^2}{2\,E\,I} \quad \text{.................(36)}$$

$$\phi_x = \frac{M\,x}{E\,I} - \frac{P\,x^2}{2\,E\,I} \quad \text{.....................(37)}$$

and,

$$E\;I\;y = \frac{I_x}{2} = \frac{Mx^2}{2} - \frac{Px^3}{6} \quad \text{.....................(38)}$$

FIG. 9

The maximum deflection occurs when $x = L$, or,

$$y_m = \frac{P\,L^3}{3\,E\,I} \quad \text{.........................(39)}$$

Case 7.—Cantilever Beam with Uniform Load Over Entire Span.—For this case, (see Fig. 9):

$$\phi_A = \frac{M\,L}{E\,I} - \frac{w\,L^2}{2\,E\,I} \times \frac{2}{3}\,L = \frac{w\,L^3}{6\,E\,I} \quad \text{..............(40a)}$$

$$\phi_x = \frac{w\,L^2 x}{2\,E\,I} - \frac{w\,(L-x)}{E\,I}\,\frac{x^2}{2} - \frac{w}{E\,I} \times x \times \frac{x}{2} \times \frac{2\,x}{3} \quad \text{......(40b)}$$

and, $E\ I\ y = \frac{I_x}{2}$ (see Equation (38)) $= \frac{M\,x^2}{2} - \frac{w\,x^4}{8} - \frac{(w\,L - w\,x)}{6}\,x^3$. The maximum deflection occurs where $x = L$, or,

$$y_m = \frac{w\,L^4}{8\,E\,I} \quad \text{.........................(41)}$$

Case 8.—Simple Beam with Variable Moment of Inertia and with Concentrated Load at Mid-Span.—The concentrated load in Fig. 10 is due to the abrupt change in the moment of inertia which makes the shear curve of the mathematical beam drop directly at that point. Its value is determined by the extra area added, due to the difference in I. Since the mathematical beam is loaded symmetrically one-half the total loading moment will go to each end, or,

$$\phi_L = \phi_R = \left[\frac{P}{2} \times \frac{L}{2} \times \frac{L}{4} + \frac{P}{2} \times \frac{L}{4} \times \frac{3}{8} L - \frac{P\,L}{8} \times \frac{L}{4}\right] \times \frac{1}{E\,I} = \frac{5}{64}\,\frac{P\,L^2}{E\,I} \quad .(42)$$

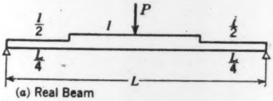
The maximum deflection can be found in the usual manner (see Equation (35)). It occurs at the section where $x = \frac{L}{2}$, or,

$$y_m = \frac{3}{128}\,\frac{P\,L^3}{E\,I} \quad \text{.......................(43)}$$

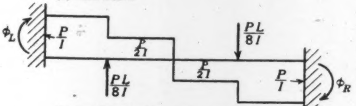
Example of Statically Determinate Beam

As an example, consider the loading in Fig. 11. By Equation (23),

$$E I\,\phi_A = \sum \frac{P\,a\,b}{6\,L}\,(L + a) = \frac{2000 \times 8 \times 10 \times 26 + 1000 \times 14 \times 4 \times 32}{108} = 55\,111$$

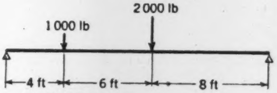


(a) Real Beam

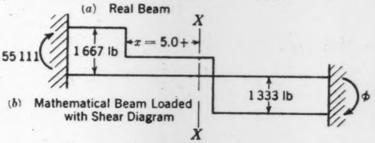


(b) Mathematical Beam Loaded with Shear Diagram, Divided by I

FIG. 10



(a) Real Beam



(b) Mathematical Beam Loaded with Shear Diagram

FIG. 11

The moment of the mathematical beam being equal to zero at the section of maximum deflection: $M = 0 = 55\,111 - 1\,667 \times 4\ (2 + x) - 667\ \frac{x^2}{2}$; and $x = 5.0 +$ (use $x = 5$).

By Equation (26),

$$y = \phi_a x - \frac{I_x}{2\,E\,I}$$

$$E\,I\,y = 55\,111 \times 9 - \frac{1}{2}\left(1\,667 \times \frac{4^3}{12} + 1\,667 \times 4 \times 7.0 + 667 \times \frac{5^3}{3}\right)$$

and,

$$y_m = \frac{314\,300}{E\,I}$$

Analysis of Statically Indeterminate Beams

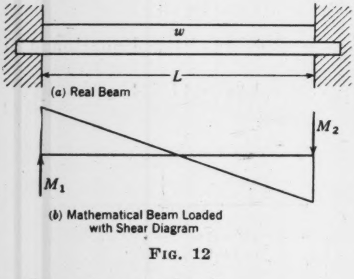
The following typical problems are given as a development of the shear-area method of solving problems applied to beams that are statically indeterminate.

Case 9.—Fixed Beam with Uniform Load Over Entire Span.—The mathematical beam for this case (see Fig. 12) has a symmetrical load and is held in equilibrium by end shears, each of which is the end moment of the real beam. In other words,

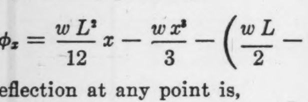
$$M_I = \frac{w\,L}{2} \times \frac{L}{2} \times \frac{1}{2} \times \frac{2\,L}{3} \times \frac{1}{L} = \frac{w\,L^2}{12} \quad \ldots\ldots\ldots\ldots(44)$$

The moment at the center of the beam is,

$$M_m = \frac{w\,L^2}{12} - \frac{w\,L^2}{8} = -\frac{w\,L^2}{24} \quad \ldots\ldots\ldots\ldots\ldots\ldots(45)$$

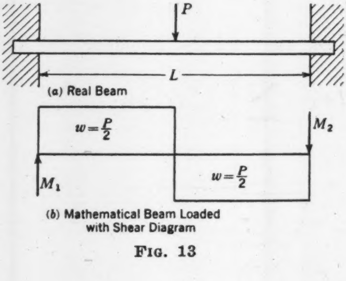


(a) Real Beam

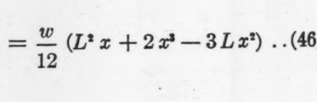


(b) Mathematical Beam Loaded with Shear Diagram

FIG. 12



(a) Real Beam



(b) Mathematical Beam Loaded with Shear Diagram

FIG. 13

the slope at any point is,

$$E\,I\,\phi_x = \frac{w\,L^2}{12}\,x - \frac{w\,x^3}{3} - \left(\frac{w\,L}{2} - w\,x\right)\frac{x^2}{2} = \frac{w}{12}\,(L^2\,x + 2\,x^3 - 3\,L\,x^2) \quad ..(46)$$

the deflection at any point is,

$$E\,I\,y = \frac{I_x}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(47)$$

and the deflection is a maximum at the section where $x = \dfrac{L}{2}$, or,

$$y_m = \frac{1}{2\,E\,I}\left[\frac{w\,L^2}{12}\left(\frac{L}{2}\right)^2 - \frac{w\,L}{2}\left(\frac{L}{2}\right)^3\frac{1}{4}\right] = \frac{w\,L^4}{384\,E\,I} \quad \ldots\ldots(48)$$

The points of inflection will occur where the shear of the mathematical beam is equal to zero; that is, $\frac{w\,L^2}{12} - \frac{w\,x^2}{2} - \frac{w\,L\,x}{2} + w\,x^2 = 0$; or, $x = 0.211\ L$, or $0.789\ L$.

Case 10.—Fixed Beam with Concentrated Load at Mid-Span.—For this case (see Fig. 13), the end moment is:

$$M_1 = \frac{P\,L^2}{8\,L} = \frac{P\,L}{8} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(49)$$

the slope at any point is,

$$E\,I\,\phi_x = \frac{P\,L\,x}{8} - \frac{P\,x^2}{4} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(50)$$

the deflection at any point is equal to $E\,I\,y = \frac{I_x}{2}$; and this deflection is a maximum at the section where $x = \frac{L}{2}$; that is,

$$y_m = \frac{1}{2\,E\,I}\left[\frac{P\,L}{8}\left(\frac{L}{2}\right)^2 - \frac{P}{2}\left(\frac{L}{2}\right)^3\frac{1}{3}\right] = \frac{P\,L^3}{192\,E\,I} \quad\ldots\ldots\ldots(51)$$

A point of inflection of the real beam will occur at the section (see Fig. 13) where the shear of the mathematical beam is zero. Consequently, $\frac{P\,L}{8} - \frac{P\,x}{2} = 0$; and, $x = \frac{L}{4}$.

Case 11.—Fixed Beam with a Concentrated Load Not at the Mid-Span.—Consider the shear diagram in two parts; the first (Fig. 14(*b*)) as if the span were simply supported, and the second (Fig. 14(*c*)) with constant shear produced by the fixing moments. Since the slope at each support due to the combined effect is zero, one may solve end slopes due to a general beam carrying end moments only and equate to the end slopes of the same beam as a simply supported one carrying the load. This method then permits solving the fixing moments of the real beam.

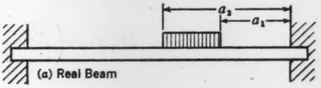
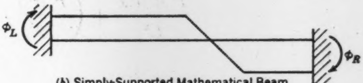
(*c*) Fixed-End Mathematical Beam
Loaded with Shear Diagram

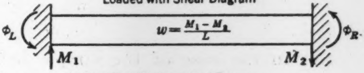
FIG. 14



(*a*) Real Beam



(*b*) Simply-Supported Mathematical Beam
Loaded with Shear Diagram



(*c*) Fixed-End Mathematical Beam
Loaded with Shear Diagram

FIG. 15

A derivation of the end moments of a mathematical beam loaded with constant shear (see Fig. 14(*c*)) is as follows: The moment of the mathematical beam is expressed by,

$$M_m = \phi_L - \frac{M_1 x}{E I} + \left(\frac{M_1 - M_2}{L E I}\right)\frac{x^2}{2} \qquad (52)$$

and the slope of the mathematical beam is:

$$Q_m = \phi_L x - M_1 \frac{x^2}{2 E I} + \left(\frac{M_1 - M_2}{L E I}\right)\frac{x^3}{6} \qquad (53)$$

Since Equation (53) equals zero when $x = L$:

$$E I \phi_L = \frac{M_1 L}{3} + \frac{M_2 L}{6} \qquad (54)$$

and,

$$E I \phi_R = \frac{M_1 L}{6} + \frac{M_2 L}{3} \qquad (55)$$

The combined end slope of the real beam is zero; therefore:

$$\frac{M_1 L}{3} + \frac{M_2 L}{6} = \frac{P a b}{6 L}(L + a) \qquad (56)$$

$$\frac{M_1 L}{6} + \frac{M_2 L}{3} = \frac{P a b}{6 L}(L + b) \qquad (57)$$

and, therefore,

$$M_1 = \frac{P b a^2}{L^2} \qquad (58)$$

and,

$$M_2 = \frac{P a b^2}{L^2} \qquad (59)$$

To determine the section of maximum deflection equate the moment equation of the complete mathematical beam to zero and solve for x, thus:

$$M_2 x + \left(\frac{M_1 - M_2}{L}\right)\frac{x^2}{2} - \left(\frac{Pb}{L}\right)\frac{x^2}{2} = 0 \qquad (60)$$

$$\frac{P a b^2 x}{L^2} + \left(\frac{P a^2 b}{L^3} - \frac{P a b^2}{L^3}\right)\frac{x^2}{2} - \frac{P b}{L}\frac{x^2}{2} = 0 \qquad (61)$$

and,

$$x = \frac{2 a L}{2 a + L} \qquad (62)$$

As in the case of the simple beam (Fig. 14(*b*)) it is interesting to note that as b varies from zero to $\frac{1}{2} L$ that x varies from $\frac{2}{3} L$ to $\frac{1}{2} L$. This means that the section of maximum deflection in this case can be displaced only 16.7% of L from the middle of the beam (compare with Case 3).

To determine the points of inflection of this beam write the general shear equation of the mathematical beam and equate to zero; solve the resulting equation for x:

$$\frac{P\,a\,b^2}{L^2} + \left(\frac{P\,a^2 b}{L^3} - \frac{P\,a\,b^2}{L^3}\right) x - \frac{P\,b\,x}{L} = 0 \quad \ldots\ldots\ldots\ldots (63)$$

or,

$$x = \frac{a\,L}{L + 2\,a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (64)$$

It is to be noted that in Equation (64), x is equal to one-half the distance to the point of maximum deflection (see Equation (62)).

Case 12.—Fixed Beam with Segment of Uniform Load at Any Position.—Applying the method in Case 11, and using the slope of the simply supported beam with a segment of uniform load as in Case 4:

$$\frac{M_1\,L}{3} + \frac{M_2\,L}{6} = \frac{w}{6\,L}\left[\frac{L^2}{2}(a^2_2 - a^2_1) - \frac{1}{4}(a^4_2 - a^4_1)\right] \ldots\ldots (65)$$

and,

$$\frac{M_1\,L}{6} + \frac{M_2\,L}{3} = \frac{w}{6\,L}\left[\frac{L^2}{2}\left\{(L - a_1)^2 - (L - a_2)^2\right\}\right.$$
$$\left. - \frac{1}{4}\left\{(L - a_1)^4 - (L - a_2)^4\right\}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

Solving for M_1 and M_2:

$$M_2 = \frac{w}{3\,L^2}\left[\frac{L^2}{2}\left\{2\,(L - a_1)^2 - 2\,(L - a_2)^2 - a^2_2 + a^2_1\right\}\right.$$
$$\left. - \frac{1}{4}\left\{2\,(L - a_1)^4 - 2\,(L - a_2)^4 - a^4_2 + a^4_1\right\}\right] \ldots\ldots\ldots\ldots (67)$$

$$M_1 = \frac{w}{3\,L^2}\left[\left(\frac{L^2}{2}\left\{2\,(a^2_2 - a^2_1) - (L - a_1)^2 + (L - a_2)^2\right\}\right.\right.$$
$$\left. - \frac{1}{4}\left\{(2\,a^4_2 - 2\,a^4_1) - (L - a_1)^4 + (L - a_2)^4\right\}\right] \ldots\ldots\ldots (68)$$

and,

$$M_1 = \frac{w}{L^2}\left[\frac{L}{3}\,(a^3_2 - a^3_1) - \frac{1}{4}\,(a^4_2 - a^4_1)\right] \ldots\ldots\ldots\ldots (69)$$

Case 13.—Fixed Beam with a Couple Applied at Any Point.—Applying the method developed in Case 11, and using the slope at the end of a simply supported beam loaded with a couple, which was developed in Case 5 (see, also, Fig. 16):

$$\frac{M_1 L}{3} + \frac{M_2 L}{6} = \frac{X b^3}{6 L^2} + \frac{X a b^2}{2 L^2} - \frac{X a^3}{3 L^2} \quad\ldots\ldots\ldots\ldots(70)$$

and,

$$\frac{M_1 L}{6} + \frac{M_2 L}{3} = - \frac{X a^3}{6 L^2} - \frac{X b a^2}{2 L^2} + \frac{X b^3}{3 L^2} \quad\ldots\ldots\ldots\ldots(71)$$

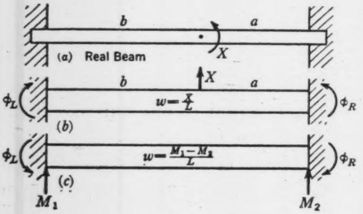


FIG. 16

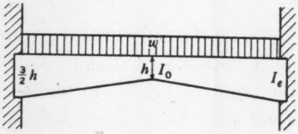

FIG. 17

From Equations (70) and (71),

$$M_2 = \frac{X}{L^3} (b^3 - 2 b a^2 - a b^2) \quad\ldots\ldots\ldots\ldots(72)$$

and,

$$M_1 = \frac{X}{L^3} (- a^3 + 2 a b^2 + a^2 b) \quad\ldots\ldots\ldots\ldots(73)$$

Case 14.—Fixed Beam with Variable Moment of Inertia and with Uniform Load Over Entire Span.—To solve the fixing moments, the beam in Fig. 17 is considered simply supported and the end slopes are found. The end moments (unknown) are then applied, bringing the end slopes to zero. The moment of inertia at any section (with the origin at the center) is,

$$I_x = \frac{I_o (L + x)^3}{L^3} \quad\ldots\ldots\ldots\ldots(74)$$

The loading is expressed by the formula:

$$\frac{V}{I} - \frac{M}{I^2}\left(\frac{d I}{d x}\right) = - \frac{w x L^3}{I_o (L + x)^3} - \frac{3 w L^5}{8 I_o (L + x)^4} + \frac{3 w L^3 x^2}{2 I_o (L + x)^4} \quad\ldots(75)$$

in which I_o = moment of inertia at the center of the beam (see Fig. 17). The end slope of a simply supported beam is:

$$E \phi_L = - \frac{w L^3}{I_o} \int_0^{\frac{L}{2}} \frac{x^2 \, dx}{(L + x)^3} - \frac{3 w L^5}{8 I_o} \int_0^{\frac{L}{2}} \frac{x \, dx}{(L + x)^4} + \frac{3 w L^3}{2 I_o} \int_0^{\frac{L}{2}} \frac{x^3 \, dx}{(L + x)^4}$$

$$= \frac{w L^3}{I_o} (- 0.0167 - 0.0162 + 0.00645) = - 0.0265 \frac{w L^3}{I_o} \quad\ldots\ldots(76)$$

For a beam loaded with Moment M at the ends, the intensity of loading equals $\frac{M}{I^2}\left(\frac{dI}{dx}\right)$. Then the end slope is:

$$E\,\phi_L = \frac{M\,L}{I_e^2} + \int_0^{\frac{L}{2}} \frac{M}{I^2}\,\frac{dI}{dx}\,x\,dx = \frac{4\,M\,L}{27\,I_o} + \int_0^{\frac{L}{2}} \frac{3\,M\,x\,dx\,L^3}{I_o\,(L+x)^4} \quad \ldots\ldots(77)$$

and,

$$E\,I_o\,\phi_L = M\,L\left(\frac{4}{27} + \frac{7}{54}\right) = \frac{5}{18}\,M\,L \quad \ldots\ldots\ldots\ldots\ldots(78)$$

Equate Equations (76) and (78) for ϕ_L: $\frac{5}{18}\,M\,L = -\,0.0265\,w\,L^2$; and,

$$M = -0.0954\,w\,L^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(79)$$

FIG. 19

Case 15.—Propped Cantilever with Concentrated Load at Mid-Span.— Applying the same method as in Case 11 where $M_1 = 0$ (Fig. 18): $\frac{M_2 L}{3} = \frac{P\,L^2}{16}$; $M_2 = \frac{3}{16}\,P\,L$; and,

$$\phi_L = \frac{P\,L^2}{16\,E\,I} - \frac{M_2\,L}{6\,E\,I} = \frac{P\,L^2}{32\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots(80)$$

Case 16.—Propped Cantilever with Uniform Load Over Entire Span.— For this case: $\frac{M_2 L}{3} = \frac{w\,L^3}{24}$; $M_2 = \frac{1}{8}\,w\,L^2$; and,

$$\phi_L = \frac{w\,L^3}{24\,E\,I} - \frac{M_2\,L}{6\,E\,I} = \frac{w\,L^3}{48\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots(81)$$

Case 17.—Propped Cantilever with Concentrated Load Not at Mid-Span.— When the concentrated load in Fig. 18 is off center: $\frac{M_2 L}{3} = \frac{P\,a\,b}{6\,L}\,(L + b)$; and $M_2 = \frac{P\,a\,b}{2\,L^2}\,(L + b)$.

Case 18.—Propped Cantilever with Couple Applied at End.—Using Equations (33*b*). and (55): $\frac{M_2 L}{3} = -\frac{X L^3}{6 L^2}$, when $a = L$ and $b = 0$. Then,

$$M_2 = -\frac{X}{2} \qquad (82)$$

and,

$$\phi_L = \frac{M_2 L}{2 E I} + \frac{X L}{2 E I} = \frac{M_2 L}{4 E I} \qquad (83)$$

Case 19.—Continuous Beam with Concentrated Loads in Each Span.—Using the general equations derived in Case 11 (Equations (54) and (55)), with the simple beam end slopes, the end slopes of any two adjoining spans (Fig. 20) are equated as follows:

$$\frac{P_1 a b}{6 L_1}(L_1 + b) - \frac{M_1 L_1}{6} - \frac{M_2 L_1}{3} = -\frac{P_2 c d}{6 L_2}(L_2 + c) + \frac{M_2 L_2}{3} + \frac{M_3 L_2}{6} \qquad (84)$$

and,

$$-M_1 L_1 - 2 M_2 (L_1 + L_2) - M_3 L_2 = -\frac{P_1 a b}{L_1}(L_1 + b) - \frac{P_2 c d}{L_2}(L_2 + c) \qquad (85)$$

Case 20.—Continuous Beam with Uniform Load Over Each Span.—For the case of an uniformly distributed load over the entire length of a continuous beam:

$$\frac{w_1 L^3_1}{24} - \frac{M_1 L_1}{6} - \frac{M_2 L_1}{3} = -\frac{w_2 L^3_2}{24} + \frac{M_2 L_2}{3} + \frac{M_3 L_2}{6} \qquad (86)$$

and,

$$-M_1 L_1 - 2 M_2 (L_1 + L_2) - M_3 L_2 = -\frac{w_1 L^3_1}{4} - \frac{w_2 L^3_2}{4} \qquad (87)$$

FIG. 21

Case 21.—Continuous Beam with Section of Uniform Load in Each Span (see Fig. (21a)).—Applying the same reasoning as in Case 19, using Equations (30), (54), and (55),

$$\frac{w_1}{6L_1}\left[\frac{L_1^2}{2}\left\{(L_1-a_1)^2-(L_1-a_2)^2\right\}-\frac{1}{4}\left\{(L_1-a_1)^4-(L_1-a_2)^4\right\}\right]-\frac{M_1L_1}{6}$$

$$-\frac{M_2L_1}{3}=-\frac{w_2}{6L_2}\left[\frac{L_2^2}{2}(c_2^2-c_1^2)-\frac{1}{4}(c_2^4-c_1^4)\right]+\frac{M_2L_2}{3}+\frac{M_3L_2}{6}\quad\ldots(88)$$

Therefore:

$$-M_1L_1-2M_2(L_1+L_2)-M_3L_2=-\frac{w_1}{L_1}\left[\frac{L_1^2}{2}\left\{(L_1-a_1)^2-(L_1-a_2)^2\right\}\right.$$

$$\left.-\frac{1}{4}\left\{(L_1-a_1)^4-(L_1-a_2)^4\right\}\right]-\frac{w_2}{L_2}\left[\frac{L_2^2}{2}(c_2^2-c_1^2)-\frac{1}{4}(c_2^4-c_1^4)\right]\quad.(89)$$

Case 22.—Continuous Beam with Couple, X, Applied in Each Span (see Fig. 21(b)).—Applying the same method as in Case 19, using Equations (33*a*), (33*b*), (54), and (55),

$$\frac{1}{6}\left(-\frac{X\,a^3}{L_1^2}-\frac{3\,X\,a^2\,b}{L_1^2}+\frac{2\,X\,b^3}{L_1^2}\right)-\frac{M_1L_1}{6}-\frac{M_2L_1}{3}$$

$$=-\frac{1}{6}\left(\frac{X\,d^3}{L_2^2}+\frac{3\,X\,c\,d^2}{L_2^2}-\frac{2\,X\,c^3}{L_2^2}\right)+\frac{M_2L_2}{3}+\frac{M_3L_2}{6}\quad\ldots\ldots(90)$$

Therefore,

$$-M_1L_1-2\,M_2\,(L_1+L_2)-M_3\,L_2$$

$$=+\frac{X_1}{L_1^2}\,(a^3+3\,a^2\,b-2\,b^3)-\frac{X_2}{L_2^2}\,(d^3+3\,c\,d^2-2\,c^3)\quad\ldots\ldots(91)$$

CONCLUSIONS

The shear-area method, which uses a type of elastic load, is not suggested as the shortest method for solving slopes and deflections for all problems; but it is suggested as particularly adapted for those problems involving distributed load. In the latter case the static moment and one-half the moment of inertia of the shear area are used more easily than the shear and the static moment of the curved moment area. For the concentrated loads the functions of the shear area are obtained quite as easily as those of the moment area. For a beam with varying moment of inertia the solutions by the shear and moment areas require about the same effort even though the loading for the former, $\frac{V}{I}-\frac{M}{I^2}\left(\frac{dI}{dx}\right)$, appears to be more cumbersome than the loading of the latter, $\frac{M}{I}$.

Any one who is interested in using a simpler elastic load than the shear area, or the shear area modified, can investigate the loading directly. In this case the functions of the slope and the deflection are given by the following equations,

For slope:

$$\phi_x EI = -\frac{1}{2}\int_0^x dA\, x^2 + \frac{Rx^2}{2} + M_e x + \phi_e EI \quad \ldots\ldots\ldots(92)$$

and,

$$y EI = -\frac{1}{6}\int_0^x dA\, x^3 + \frac{Rx^3}{6} + \frac{M_e x^2}{2} + \phi_e EI x + y_e EI \quad \ldots\ldots(93)$$

or,

$$\phi_x EI = -\frac{1}{2} I_x + M_e x + \phi_e EI \quad \ldots\ldots\ldots\ldots\ldots(94)$$

and,

$$y EI = -\frac{1}{6} Q_x + \frac{M_e x^2}{2} + \phi_e EI x + y_e EI \quad \ldots\ldots\ldots\ldots(95)$$

in which $\int dA = \int w\, dx$, or P; M_e = end moment; ϕ_e = end slope; and y_e = end deflection.

APPENDIX

NOTATION

In the following notation, presented for the convenience of reference, an effort has been made to conform as nearly as practicable with "Symbols for Mechanics, Structural Engineering, and Testing Materials" advanced by the American Standards Association[8]:

a = distance of a section from the right end of a beam ($=L - b$).
b = distance of a section from the left end of a beam ($=L - a$).
c = distance of a section (corresponding to a) from the right end of Span 2 of a continuous beam ($= L_2 - d$).
d = distance of a section (corresponding to b) from the left end of Span 2 of a continuous beam ($= L_2 - c$).
e = a subscript denoting "at the end."
m = a subscript denoting "maximum."
o = a subscript denoting "origin," or "at the center."
w = load per unit distance; load intensity per foot on a given beam.
x = a distance measured parallel to the X-axis; as a subscript, x refers to Section X–X;
y = deflection at any section, X–X, in a given beam (= slope at any section, X–X, of a mathematical beam); y_m = maximum deflection.
A = area of a loading diagram on a mathematical beam.
C = constants (see Equation (6)).
E = modulus of elasticity.

I = rectangular moment of inertia; I_x = moment of inertia of the shear diagram at any section, X–X; I_0 = moment of inertia at the center of a beam; I_e = moment of inertia at the ends of a beam.

L = length; span of a given beam; as a subscript, L denotes "left end."

M = moment of force; bending moment in a given beam; M_T = total moment of force.

P = concentrated load on a given beam.

R = reactions, or resultants; as a subscript, R denotes "right end."

T = a subscript denoting "total."

V = total shear in a given beam.

X = a force couple.

ϕ = slope of the elastic curve; ϕ_L = slope at the left end of a given beam (= bending moment at the left end of a mathematical beam); ϕ_R = slope at the right end of a given beam (= bending moment at the right end of a mathematical beam); ϕ_T = total change in slope; ϕ_x = slope at any section, X–X, in a given beam (= bending moment at Section X–X, in a mathematical beam).

DISCUSSION

GEORGE E. LARGE,[4] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has often noticed that many engineers do not fully understand the relationship of the beam diagrams so often drawn. The slope diagram shown in Fig 1 is almost a total stranger to them, yet a recognition of it as a member of the family of five curves is necessary to a full understanding of the very useful general relationships about to be mentioned. It so happens that the order of the diagrams, correct in Fig. 1, is also important, especially to the beginner, yet new textbooks are still appearing with cuts faulty in this respect. Instructors have been too facile with their calculus and too sparing with correct and complete sketches showing the geometry of the operations being performed.

It will be demonstrated herein that no new principles or devices are necessary for solving the authors' examples quickly if advantage is taken of a simple geometric relation which exists between the slope and shear diagrams, as well as between the deflection and moment diagrams.

The moment-area principles referred to by the authors are not usually applied to any diagrams except the moment and deflection diagrams. Note the restricted usage required by the usual statement of these principles:

(1) When a member is subjected to flexure, the change in slope of the elastic curve between any two points is equal in magnitude to the area of the $\frac{M}{EI}$ - diagram for the part of the member between the two points.

(2) When a member is subjected to flexure, the ordinate from any point, Q (Fig. 22), on the elastic curve, to a tangent drawn to the elastic curve at any other point, P, is equal in magnitude to the moment of the area of the $\frac{M}{EI}$ - diagram between the two points, about Point Q.

The generalized statement of these principles is much more useful because they may then be applied to any of the five beam diagrams, including the slope and shear diagrams so much used by the authors.

General Relationship of Beam Diagrams.—When the five diagrams, or curves, of any beam are arranged in the ascending order shown in Fig. 22, each curve is the integral of the one immediately below it. (The ascending order is somewhat preferable especially if the user thinks of successive integration as an ascending process.) An equation may be written for the lowest curve, successive integrations of which will yield the equations of all the higher curves, including the deflection curve. This procedure has long been used with conspicuous success by C. C. More, M. Am. Soc. C. E., in teaching structures at the University of Washington, Seattle, Wash. The relationship thus established makes it possible to state the moment-area principles in a more general form, so that their assertions may be utilized to determine all the curves completely. As stated by Professor More they are:

---

[4] Associate Prof., Civ. Eng., Ohio State Univ., Columbus, Ohio.

I.—The ordinate at any point on any curve equals the slope at the corresponding point in the next higher curve;

II.—The area between any two ordinates on any curve equals the difference of the corresponding ordinates in the next higher curve; and,

III.—The ordinate from any point (Point Q, Fig. 22) on any curve, to a tangent drawn to the curve at any other point (Point P) is equal in magnitude to the moment of the area of the second lower curve between the two points, about Point Q.

FIG. 22.—COMPLETE BEAM SOLUTION BY MOMENT-AREA PRINCIPLES.

In accordance with the foregoing laws, if the ordinates of one curve are positive and increase from left to right, the slope of the next higher curve will also be positive at that point and will increase from left to right. Corresponding statements may be made for negative ordinates, and for ordinates that decrease from left to right.

These principles enable one to sketch the curves of any beam in their correct relation, one after the other, and to evaluate their maximum points. In Fig. 22, a numerical example of the authors' Case 3 (Fig. 5), the uniform ordinates of the shear curve determine the uniform slopes of the moment curve (Law I). By Law II, the maximum bending moment may be found from the shear curve. The increasing positive ordinates of the left portion of the moment curve call for an increasing positive slope to the $E\,I\,\phi$-curve directly above it (Law I), $E\,I$ being constant. Upon drawing the $E\,I\,\Delta$-curve by inspection it is seen that the slope of the elastic line is negative at the left end, or that the Y-intercept on the $E\,I\,\phi$-curve is negative. The value of this intercept is determined as usual, by applying Law III to the moment and deflection curves; Thus, $QW = 36 \times 6 \times 4 + 36 \times 9 \times 9 = 3\,780$ kip-ft³; and $E\,I\,\phi_P = \dfrac{3\,780}{15}$ $= 252$ kip-ft².

The point of maximum deflection will be where the $E\,I\,\phi$-curve crosses the X-axis and this point is easily found without resort to any new principles by applying Law III to the slope and shear curves. Taking moments of the shear area about the unknown point, $Q'\!: 8\ (x) \left(\dfrac{x}{2}\right) = E\,I\,\phi_P = 252$; and $x = 7.94$ ft. Furthermore, by Law II, the maximum deflection is the area of the $E\,I\,\phi$-diagram: $E\,I\,\Delta_{\text{max.}} = \frac{2}{3} \times 252 \times 7.94 = 1\,333$ kip-ft³; and, $\Delta_{\text{max.}} = \dfrac{1\,333 \text{ kip-ft}^3}{E\,I}$.

Statically indeterminate beams can also be solved with corresponding facility, as compared to the authors' expressions.[5] The writer cannot refrain from suggesting that the introduction of an equivalent "mathematical beam" device may easily be a source of confusion, which is quite unnecessary, once the general relationship of all curves is recognized.

SAMUEL T. CARPENTER,[6] JUN. AM. SOC. C. E. (by letter).—Moment areas have proved their usefulness and shear areas are no doubt a unique application of moment-area principles. However, the writer doubts if "mathematical beams" are to be preferred to real beams. Engineers have used area moments as a tool, the principles being easily retained and recalled when the need arises; only two laws must be remembered. The shear-area method has at least five relations which must be remembered or reviewed before using. The authors suggest that for a student the "mathematical beam" will aid his knowledge of beam action; the writer would make an exception to this since area moments must necessarily be understood before shear areas could be grasped. It will be granted that teachers of applied mechanics have been lax in the past by not calling to the attention of students the relation of the third, second, and first derivatives of the elastic line, or the shear, moment, and slope curves as depicted in Fig. 1. C. C. More, M. Am. Soc. C. E., has taught those relations successfully at the University of Washington, at Seattle, Wash., without the aid of the "mathematical beam."

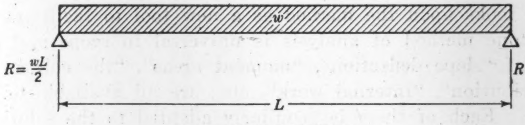
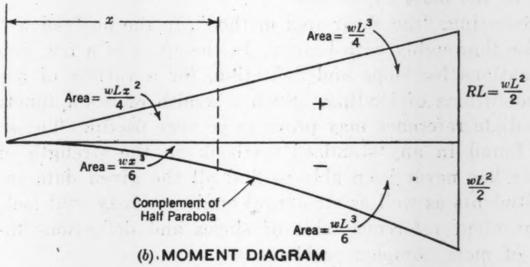
[5] See Appendix of *Bulletin 66*, Ohio State Univ. Eng. Experiment Station, "The Moment Distribution Method of Structural Analysis Extended to Lateral Loads and Members of Variable Cross-Section" (Revised Edition), by George E. Large, Assoc. M. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E.

[6] Instr., Civ. Eng., Swarthmore Coll., Swarthmore, Pa.



(a) LOAD DIAGRAM



(b) MOMENT DIAGRAM

FIG. 23.

The authors suggest that the shear-area method is particularly adaptable to problems involving a distributed load, stating that the shear areas are used more easily than the curved moment areas. This is true with the moment diagrams as ordinarily used. For some time the writer has followed the method suggested by Mr. James E. Boyd[7] for treating uniform loads, which places the parabola involved in a form easier to apply. To illustrate, take the authors' Case 1. Fig. 23 indicates how the moment diagram would be drawn, the diagram being divided into positive and negative areas; the curved negative area is the complement of a half parabola. This is convenient when finding deflections at any point on the beam. The end slopes are: $2\,E\,I\,\phi = \frac{wL^3}{4} - \frac{wL^3}{6} = \frac{wL^3}{12}$; and $\phi = \frac{wL^3}{24\,EI}$. The deflection at any point a distance, x from the left end is: $E\,I\,y = \frac{wL^3}{24}\,x - \left(\frac{wLX^2}{4} \times \frac{X}{3} - \frac{wX^3}{6} \times \frac{X}{4}\right)$; and $y = \frac{wX}{24\,EI}\,(L^3 - 2\,L\,X^2 + X^3)$.

This means of building up the moment curves is equally applicable to cases of concentrated loads and continuous beams, the component curves always being easily drawn by starting from the left end and considering all the loading elements.

---

[7] "Strength of Materials," by James E. Boyd, McGraw-Hill Publishing Co., 1924.

Roland H. Trathen,[8] Esq. (by letter).—The "shear-area method," presented by Professor Compton and Mr. Dohrenwend, supplies a new and novel procedure for the solution of the elastic functions of beams. There are many cases, of course, in which the method is not advantageous. This, in itself, in no way detracts from the usefulness of the concept.

The writer looks upon the method as a new tool to facilitate structural analysis. No one method of analysis is universal in scope and simplicity. The methods of "slope deflection", "moment areas", "the column analogy", "moment distribution", "internal work", etc., are all available to the structural engineer. Each of them is peculiarly adapted to the solution of particular problems. The structural engineer who is familiar with all methods is usually able to decide before beginning an analysis, which is likely to prove to be the most expedient.

In presenting, "the shear-area method", to the profession the authors have dealt quite thoroughly with beams. In the space of a few pages they have derived equations for slope and deflection, for a variety of beams, each under several conditions of loading. Such a wealth of beam functions if available for immediate reference may prove to be very useful. The same information may be found in any standard textbook on the strength of materials, but the writer has never been able to find all the given data in such condensed form. Students as well as structural engineers may well look upon the paper as a convenient reference table of slopes and deflections to be used in the solution of more complex problems.

The following simple problems are included to illustrate the usefulness of the paper when applied in this manner. The notation of the original paper is preserved throughout, with the following exceptions: ϕ_{BC} = partial slope at End B of Member BC; and ϕ_{TBC} = total slope at End B of Member BC.

Problem 1,—An L*-Frame with Concentrated Load Applied at Mid-Point of Deck.*—The structure shown in Fig. 24 is indeterminate to the first degree. In Fig. 25 it has been reduced to a determinate structure by cutting it at

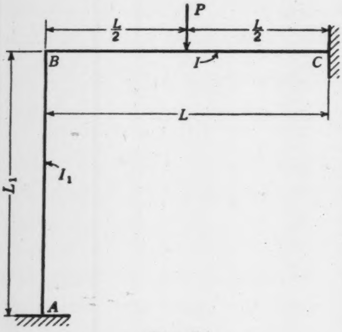


Fig. 24.

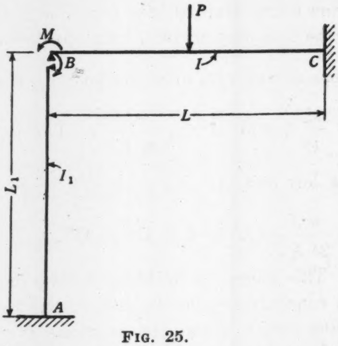

Fig. 25.

[8] Instr. in Civ. Eng., Rensselaer Polytechnic Inst., Troy, N. Y.

Point B. The determination of the moment, M, will be sufficient to make the structure statically determinate. The solution for the unknown moment at Joint B is as follows, using directly the slopes as derived in the paper: By Equation (80), the slope, ϕ_{BC}, due to the concentrated load, P, is $\frac{PL^2}{32\,EI}$; by Equation (83), the slope, ϕ_{BC}, due to the bending moment, M, is $-\frac{ML}{4\,EI}$; and the total slope, ϕ_{TBC} equals $\frac{PL^2}{32\,EI} - \frac{ML}{4\,EI}$.

By Equation (83) again, the total slope, ϕ_{TBA}, due to the bending moment $= -\frac{ML_1}{4\,EI_1}$. Since $\phi_{TBC} = -\phi_{TBA}$, it follows that $\frac{PL^2}{32\,EI} - \frac{ML}{4\,EI} = \frac{ML_1}{4\,EI_1}$; and,

$$M = \frac{PL^2}{8}\left(\frac{I_1}{L_1 I + L I_1}\right) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

Problem 2.—Two-Span Continuous Beam with Uniform Load on One Span and Concentrated Load at Center of Other Span.—The structure in Fig. 26 is statically indeterminate to the first degree. The solution for the moment over the support at Point B will make it statically determinate. The beam is reduced to a simple structure by cutting it as shown in Fig. 27. Then, by Equation (14), the slope, ϕ_{BA}, due to a concentrated load, P, on Span L, is $\frac{PL^2}{16\,EI}$; by Equation (33) (when $a = 0$ and $b = L$), the slope, ϕ_{BA}, due to the bending moment, M, on Span L, is $-\frac{ML}{3\,EI}$; and, as in Problem 1, the total slope, ϕ_{TBA}, is the sum, or $\frac{PL^2}{16\,EI} - \frac{ML}{3\,EI}$. Finally, by Equation (8), the slope, ϕ_{BC}, due to a uniform load, w, on Span L_1, is $\frac{wL^3_1}{24\,EI}$; by Equation (33) (when $b = 0$ and $a = L$), the slope, ϕ_{BC}, due to a moment, M, on Span L_1, is $-\frac{ML_1}{3\,EI}$; and, the total slope, ϕ_{TBC}, is $\frac{wL^3_1}{24\,EI} - \frac{ML_1}{3\,EI}$ Since $\phi_{TBA} = -\phi_{TBC}$, it follows that: $\frac{PL^2}{16\,EI} - \frac{ML}{3\,EI} = -\frac{wL^3_1}{24\,EI} + \frac{ML_1}{3\,EI}$ and,

$$M = \frac{3\,PL^2}{16\,(L + L_1)} + \frac{wL^3_1}{8\,(L + L_1)} \;\ldots\ldots\ldots\ldots\ldots (97)$$

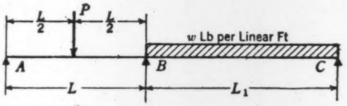

FIG. 26.

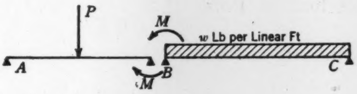

FIG. 27.

Problem 3.—Continuous Beam of Two Equal Spans, with Concentrated Load at Center of One Span.—The structure in Fig. 28(*a*) is indeterminate to the first degree. In this case the reaction at Point *B* will be chosen as the redundant. With the reaction at this point known, the structure is statically determinate, as shown in Fig. 28(*b*) and the shear diagram for this case is shown in Fig. 28(*c*). By Equation (17), the deflection, y_B, due to a unit load at Point *B*, is $\frac{L^3}{6\,EI}$; and, by Equation (24), the slope, ϕ_B, due to a concentrated load, *P*, is,

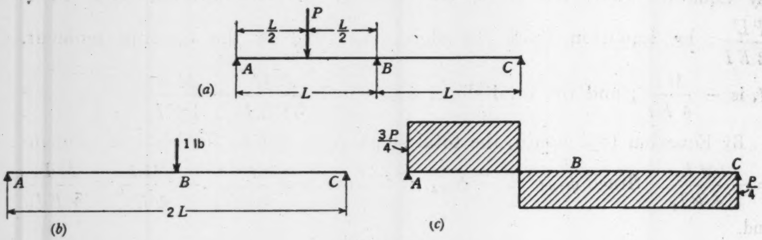

FIG. 28.

$$\phi_R = \frac{P\,a\,b}{6\,EIL}\,(L + b) = \frac{P \times \frac{3}{2}\,L \times \frac{1}{2}\,L}{12\,EIL}\left(2\,L + \frac{1}{2}\,L\right) = \frac{5\,PL^2}{32\,EI}\ .\ (98)$$

Then, by Equations (7), and (9) the deflection, y_B, due to a concentrated load, *P*, is,

$$y_B = \phi_R\,x - \frac{1}{2}\,I_x = \frac{5\,PL^2}{32\,EI} \times L - \frac{1}{2} \times \frac{P}{4} \times L^3 \times \frac{EI}{3}$$

$$= \frac{5\,PL^3}{32\,EI} - \frac{PL^3}{24\,EI} = \frac{11\,PL^3}{96\,EI}\ \ldots\ldots\ldots\ldots\ldots\ldots (99)$$

and, the reaction is,

$$R_B = \frac{y_B\ (\text{due to Load } P)}{y_B\ (\text{due to load of unity})} = \frac{11\,PL^3}{96\,EI} \times \frac{6\,EI}{L^3} = \frac{11\,P}{16}\ \ldots . (100)$$

A. W. FISCHER,[9] ESQ. (by letter).—An interesting method of calculating the deflection of beams is offered in this paper, but as stated in the "Conclusions," it is not suggested as the shortest method for solving slopes and deflections for all problems. This is a true statement because there are many problems in which slopes and deflections can be solved in less time than is required by the shear-area method.

As an example the writer will calculate the maximum deflection of the shaft shown in Fig. 29 by the shear-area method, to demonstrate that it is not the shortest. Furthermore, it is more complex than a comparable method presented by the writer[10] in that a simple differential equation must be used to obtain the required results, which may not appeal to every engineer.

(b) MATHEMATICAL BEAM LOADED WITH SHEAR DIAGRAM DIVIDED BY I

FIG. 29.

As E is a constant it will be assumed equal to unity which will somewhat simplify the equations. To determine the end conditions of the mathematical beam the general moment equation with the left end as the origin, is,

$$\frac{d^2 y}{dx^2} = \phi_L - \frac{1}{2}\,(56.50\, x^2) - \frac{1}{2}\,(14.71\, x^2) + 961.2\, x \;\ldots\ldots(101)$$

Integrating Equation (101):

$$6\,\frac{dy}{dx} = 6\,\phi_L\, x - 56.50\, x^3 - 14.71\, x^3 + 3\,(961.2\, x^2) \;\ldots\ldots.(102)$$

The moment equation as derived from the right end of the mathematical beam, is:

$$\frac{d^2 y}{dx^2} = \phi_R - \frac{1}{2}\,(90.68\, x^2) - \frac{1}{2}\,(19.24\, x^2) - \frac{1}{2}\,(2.267\, x^2) + 1\,072\, x \;.(103)$$

---

[10] "Shaft Deflections by the Method of Elastic Weights", by A. W. Fischer, *Product Engineering*, November, 1933, p. 428.

Integrating Equation (103):

$$6\,\frac{dy}{dx} = 6\,\phi_R\,x - 90.68\,x^3 - 19.24\,x^3 - 2.267\,x^3 + 3\,(1\,072\,x^2) \quad ..(104)$$

Equate, six times, the two tangents of the mathematical beam at a point 28 in. from the left end, since the deflection of the real beam can be expressed by both equations at that point, thus:

$$6\,\phi_L\,x\Big]_0^{28} - 56.50\,x^2\Big]_5^{28} - 14.71\,x^3\Big]_0^{5} + 3\,(961.2\,x^2\Big]_0^{5}$$
$$= 6\,\phi_R\,x\Big]_0^{32} - 90.68\,x^3\Big]_{17}^{32} - 19.24\,x^3\Big]_{12}^{17} - 2.267\,x^3\Big]_0^{12} + 3\,(1\,072\,x)^2\Big]_0^{17} \quad .(105)$$

Substituting the limits of x and reducing Equation (105):

$$28\,\phi_L - 206\,700 + 1\,177 - 306 + 12\,020$$
$$= 32\,\phi_R - 495\,200 + 74\,250 - 15\,750 + 5\,541 - 653 + 154\,900. (106)$$

Reducing Equation (106):

$$28\,\phi_L - 193\,809 = 32\,\phi_R - 276\,912 \ldots\ldots\ldots\ldots\ldots (107)$$

From the mathematical beam the total, ϕ_T, equals 33 477, and using the notation, $\phi_R = \phi_T - \phi_L$; then, from Equation (107):

$$28\,\phi_L - 193\,809 = 32(33\,477) - 32\,\phi_L - 276\,912 \ldots\ldots\ldots (108)$$

Reducing Equation (108), $\phi_L = 16\,470$; and $\phi_R = 33\,477 - 16\,470 = 17\,007$. (All computations in this discussion were made with a 20-in. slide-rule.)

The moment of the mathematical beam is equal to zero at the section of maximum deflection, thus, at Section *X–X*:

$$M = 0 = 16\,740 - 56.50 \times 23\,(11.5 + x) - \tfrac{1}{2}\,(14.71\,x^2) + 961.2\,x. (109)$$

From Equation (109) $x = 4.14$ in., which means that the point of maximum deflection of the real beam occurs 27.14 in. to the right of the left reaction (see Fig. 29).

Using the notation of the paper: $y_{\text{max.}} = \phi_L x - \frac{1}{2}\,I_x$, in which $x = 27.14$ in.; or, $y_{\text{max.}} = 16\,470(27.14) - \frac{1}{2}\left[(56.50)\frac{23^3}{12} + 56.50\,(23)\,(15.64^2)\right.$ $\left. - 961.2\,(4.14^2) + \frac{14.71\,(4.14^3)}{3}\right] = 447\,000 - 179\,500 \doteq 267\,500$ in. when E equals unity. When E equals 29 000 000, the maximum deflection equals $\frac{267\,500}{29\,000\,000} = 0.009224$ in.

The deflection at a point 28 in. to the right of the left reaction from the left-hand part of Equation (107), is $28(16\,470) - 193\,809 = 267\,391$ in. when E equals unity, and when E equals $29(10^6)$, the deflection equals 0.009220.

From the foregoing computations the deflection at the point of zero shear of the real beam is found to be just a little less than the maximum deflection. On comparison with the solution of this problem which is preferred by the writer[10] it does not seem that the foregoing solution of the maximum deflection by the shear-area method is the shortest.

If Fig. 29 had been loaded with uniformly distributed loads of different values, then to solve for the maximum deflection the shear-area method would have been the shortest, and as the authors state it is suggested as particularly adapted to those problems involving distributed loads.

The shaft as given in the example actually has uniformly distributed loads of different values, but for the purpose of comparison it was considered as having no weight.

J. Charles Rathbun,[11] M. Am. Soc. C. E. (by letter).—In elementary textbooks on strength of materials the development of the beam theory is given, usually starting with the authors' Equation (2) and deriving the slope and deflection curves by direct integration. It is also shown that the loading, shear, and moment curves are related in the same manner as the moment divided by EI, the slope and deflection curves. It follows at once, with the usual assumptions of the beam theory and for a constant moment of inertia, that the five curves in Fig. 30 form a series in which each succeeding curve may be obtained by direct integration.

If the method of obtaining the equation of the $n+1$-curve of this series from the n-curve is the same whether n is 1, 2, 3, or 4, one can obtain the fifth curve from the second one in the same way that he obtained the fourth from the first; or, he may obtain the fourth from the second in the same way that the third is obtained from the first. In each case the constants of integration must be taken care of by other means than those of pure mathematics. However, as shown by the authors in Equation (1), if the moment of inertia is not constant, the curves of Fig. 30(a) and Fig. 30(b) of the series do not have the same physical meaning when divided by the variable, I, as they have in the series of the previous paragraph. They must be considered as the first and second derivatives of the $\dfrac{M}{EI}$ - equation. The (d)-curve is the slope, whereas the (e)-curve is the deflection. With this

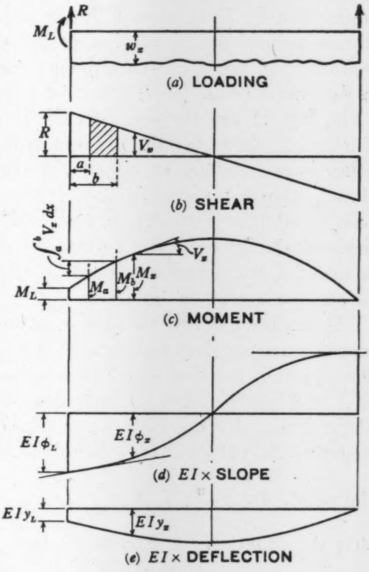

Fig. 30.

---

[11] Associate Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.

second series equations are related to each other in the same way that they are in the first.

In order to take advantage of these well-known facts, one must keep the signs consistent as well as the units. The writer feels that inconsistencies have occurred in the several basic formulas derived by the authors and he has taken the liberty to re-state Equations (6), (7), (92), (93), (94), and (95), giving the assumptions under which the re-stated formulas are derived. It is expected that some of the differences between the two sets of formulas can be explained by differences of definitions both of terms and signs. It is hoped that the authors will clarify this phase of their paper in their closing discussion and will state definitely their assumptions as to signs. The writer has used the convention of analytic geometry that a dimension is positive if measured to the right or upward from the origin, whereas a force is positive if it acts in a positive direction—that is, upward. The origin is assumed at the left end of the beam. Curves (*a*) and (*d*) of Fig. 30 differ from those of Fig. 1 in sign possibly because of these assumptions. In the case of a sudden change in the formula of the load, or in the moment of inertia, the origin can often be shifted to advantage.

In Fig. 30 the area bounded by the curve and any two ordinates is equal to the difference between the corresponding ordinates in the next lower curve. This is the result of the method of obtaining the equation of the curve, by integration. It also follows that the units used in measuring the ordinate of any curve are those of the curve from which it is derived multiplied by feet; whence, if the ordinates of the loading curve (Fig. 30(*a*)) are in pounds per foot, those of the shear curve (Fig. 30(*b*)) are in units of pounds, and those of the moment curve (Fig. 30(*c*)) are in pound-feet; the $E\,I\,\phi$-curve (Fig. 30(*d*)) are in pound-feet^2; and, those of the $E\,I\,y$-curve (Fig. 30(*e*)) are in pound-feet.^{3} If one elects to divide by $E\,I$ and so use the second series, as the y-curve ordinates must be in feet, the units for the other curves follow at once with the (*d*)-curve ordinates being non-dimensional, the (*c*)-curve in feet^{-1}, the (*b*)-curve, or mathematical curve, in feet^{-2}, and the (*a*)-curve in feet^{-3}. Each term of the corresponding equation derived should conform to one or other of these systems of units, or the reason for not doing so should be evident. In any case each equation should be self-consistent in its units.

It has been shown that the relationship between Fig. 30(*b*) and Fig. 30(*d*) is the same as that between Fig. 30(*a*) and Fig. 30(*c*). In the first series the equation for Fig. (30*c*) is obtained (from the definition of moment) from that of Fig. 30(*a*) for the moment, $M_x = R\,X$, plus the moment of the loads about Point X (the load, w, is negative and this load moment, therefore, is negative in value). If x is taken as the distance from the load, $w\,dx$, to the point, X: $M_x = R\,X + \int_0^x w\,x\,dx$. It follows, then, from Fig. 30(*b*), that the equation for Fig. 30(*d*) is:

$$E\,I\,\phi_x = E\,I\,\phi_L + \int M\,dx = E\,I\,\phi_L + I\,A\bar{x} \quad \ldots\ldots\ldots (110)$$

or $\phi_x = \phi_L + \frac{A\bar{x}}{E}$, in which $A\bar{x}$ is the first moment of the area of the shear, divided by the I-curve (or mathematical beam curve) between $x = 0$ and $x = X$ about Point X. In this case, M_L is assumed to be zero. In the example shown in Fig. 30, ϕ_L, w, and, therefore, $\int_0^x w\,x\,dx$, are all negative in value whereas $A\bar{x}$ and $R\,X$ are positive. Equation (110) the writer feels should be used instead of the authors' Equation (6). Equations (6) and (7) apply only when $E\,I$ is a constant. If it is desired to consider I as a variable, Equation (110) becomes:

$$\phi_x = \phi_L + \frac{1}{E}\int_0^x \frac{M}{I}\,dx \qquad \text{(111)}$$

or $\phi_x = \phi_L + \frac{A\bar{x}}{E}$. Integrating Equation (110) gives,

$$E\,I\,y = E\,I\,y_L + E\,I\int_0^X \phi_x\,dx = E\,I\,y_L + E\,I\,\phi_L X + I\int_0^X A\bar{x}\,dx$$

$$= E\,I\,y_L + E\,I\phi_L X + I\iint x\,dA\;dx$$

and dividing by the constant, $E\,I$,

$$y = y_L + \phi_L\,X + \frac{I_x}{2\,E} \qquad \text{(112)}$$

In Equation (112), I_x is taken as the second moment or moment of inertia of the area under the mathematical-beam curve between the ordinates, $x = 0$ and $x = X$, about the ordinate throught Point X. The value of the authors' $\int A\bar{x}\,dx = \frac{I_x}{2}$ presents an interesting and a novel idea. The proof is quite simple. Equation (112) corresponds to the authors' Equation (7) when y_L is zero. If I is a variable, $y = y_L + \phi_L X + \frac{1}{E}\iint \frac{M}{I}\,dx^2$ $= y_L + \phi_L X + \frac{I_x}{2\,E}$, as in Equation (112).

Apparently, the authors have assumed that EI is a constant in deriving Equations (92) to (95). The writer has obtained the following equations under the same assumption:

$$E\,I\,\phi_x = E\,I\,\phi_L + M_L X + \frac{R X^2}{2} + \iiint w\,dx^3$$

$$= E\,I\,\phi_L + M_L X + \frac{R X^2}{2} + \frac{1}{2}\int x^2\,(w\,dx)$$

and,

$$EI\,y = EI\,y_L + EI\,\phi_L\,X + M_L\,\frac{X^2}{2} + R\,\frac{X^3}{6}\int\!\!\int\!\!\int\!\!\int w\,dx^4$$

$$= EI\,y_L + EI\,\phi_L\,X + M_L\,\frac{X^2}{2} + \frac{R\,X^3}{6} + \frac{1}{6}\int x^3\,(w\,dx)$$

in which such terms as $\int x^2\,(w\,dx)$ and $\int x^3\,(w\,dx)$ may be interpreted as the second and third moments of the area under the load curve between $x = 0$ and $x = X$ about the ordinate through Point X. As R may be considered as a part of the load, and writing dW to represent the load whether concentrated as R, or distributed as $w\,dx$:

$$EI\,\phi_x = EI\,\phi_L + M_L\,X + \frac{1}{2}\int x^2\,dW$$

and,

$$EI\,y = EI\,y_L + EI\,\phi_L\,X + \frac{M_L\,X^2}{2} + \frac{1}{6}\int x^3\,dW$$

As dA and I_x are given definitions relative to the mathematical and shear curves and Q has not been defined by the authors these notations have not been incorporated in these equations. The subscript, L, for "left end" used by the authors is used in this discussion instead of the less definite, e, as the origin is always placed at the left end.

The writer takes issue with the authors in the case of the equations in a number of the examples particularly as to their inconsistency in units and signs. This inconsistency makes it practically necessary to re-work the examples in order to connect their application with the ordinary beam theory and through them to connect the area-moment method with this theory. It is hoped that in their closing discussion the authors will clear up these points so that their work can be followed more readily.

Harold R. Kepner,[12] Assoc. M. Am. Soc. C. E. (by letter).—Another analogy is presented in this paper, whereby structural problems involving the solution of the elastic curve equation may be simplified. Like the moment-area method and the column analogy it makes use of a dummy loading on a dummy structure, certain functions of which loading equal the desired functions of a real load on a real structure.

So far as the writer knows the analogy of the shear-area method has not been presented before, although the difficulties involved in the use of the moment area for distributed loads have indicated the desirability of some method involving the simpler shear curve.

A study of this paper has suggested a slightly different statement of the method as presented by the authors which seems more nearly to approach the "conjugate beam" method in its procedure. In spite of its limitations, the writer believes a brief presentation of this procedure may be worth while.

---

[12] Associate Prof. of Eng., Utah State Agri. Coll., Logan, Utah.

Since the advantages of this analogy over those of the conjugate beam analogy seem to disappear for beams of varying cross-section, this procedure will be presented for the case of prismatic beams only, although its use is perfectly general if not always simple of computation.

Statement.—If a dummy beam is loaded with the shear diagram from some real loading on a real (prismatic) beam, the following relations of load functions exist:

(1) The shear at a given section of the dummy beam equals the bending moment at the corresponding section of the real beam;

(2) The bending moment at a given section of the dummy beam, divided by EI (modulus of elasticity and moment of inertia of a section of the real beam, respectively), equals the slope at the corresponding section of the real beam; and

(3) The second moment of the forces on one side of a given section of the dummy beam, divided by $2EI$, equals the deflection at the corresponding section of the real beam.

That these relations are true may be seen by a study of Equations (1) to (7). By "second moment" is meant what is commonly called "moment of inertia" and is computed as follows:

(*a*) For an area, the expressions for the moment of inertia of an area are applicable, are available in handbooks and textbooks, and, for simple figures, have been memorized by most engineers;

(*b*) For a single force, it is the product of the force by the square of the perpendicular distance from the force to the point in question; and

(*c*) For a couple, it is the product of the moment of the couple by twice the distance from its point of application to the point in question. That this is true for a couple may be shown as follows: Referring to Fig. 31, the second moment of the couple, $M = F\,a$ about Point O equals,

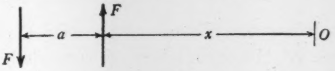

FIG. 31.

$$I_0 = F\,(a + x)^2 - F\,x^2 = F\,a^2 + 2\,F\,a\,x + F\,x^2 - F\,x^2 = F\,a\,(a + 2\,x)$$
$$= 2\,x\,F\,a = 2\,x\,M \ldots\ldots\ldots\ldots\ldots\ldots\ldots (113)$$

(Making a very small and F very large, without changing the moment, $M = F\,a$.)

The reactions at the supports of the dummy beam are either forces, couples, or a combination of forces and couples, and are determined by the conditions at the corresponding supports of the real beam. Table 1 shows how they are determined for several common types of beam. The symbols, V, M, ϕ, and y, represent the shear, bending moment, slope, and deflection at the given section of the real beam, and the primed symbols, V', M', and I', represent the shear, bending moment, and second moment, respectively, at the corresponding section of the dummy beam.

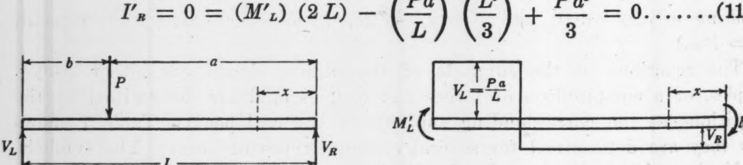
The signs used for both beams correspond to the convention in which upward forces on the left produce positive shear, and a beam bent concavely upward has positive bending moment. With a positive shear diagram taken as a downward load on the dummy beam, the sign of the second moment is the product of the sign of the bending moment by the sign of x and corresponds to a positive slope on the real beam, down to the right, and to positive deflection downward. In order to illustrate the procedure several of the cases presented by the authors will serve as examples.

TABLE 1.—Computations of Reactions for Dummy Beam

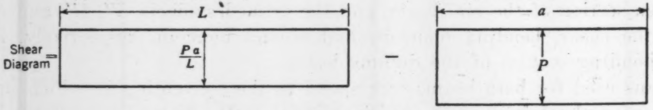
Type of Real Beam	REAL BEAM Conditions at Left End		Conditions at Right End	DUMMY BEAM Conditions at Left End		Conditions at Right End
Simple	$M_L = 0$ $\phi_L \neq 0$ $y_L = 0$		$M_R = 0$ $\phi_R \neq 0$ $y_R = 0$	$V'_L = 0$ $M'_L \neq 0$ $I'_L = 0$	 Reactions = 2 Couples	$V'_R = 0$ $M'_R \neq 0$ $I'_R = 0$
Cantilever	$M_L = 0$ $\phi_L \neq 0$ $y_L \neq 0$		$M_R \neq 0$ $\phi_R = 0$ $y_R = 0$	$V'_L = 0$ $M'_L \neq 0$ $I'_L \neq 0$	 Reactions = 1 Force, 1 Couple	$V'_R \neq 0$ $M'_R = 0$ $I'_R = 0$
Fixed	$M_L \neq 0$ $\phi_L = 0$ $y_L = 0$		$M_R \neq 0$ $\phi_R = 0$ $y_R = 0$	$V'_L \neq 0$ $M'_L = 0$ $I'_L = 0$	 Reactions = 2 Forces	$V'_R \neq 0$ $M'_R = 0$ $I'_R = 0$
Continuous. Supports Level	$M_L \neq 0$ $\phi_L \neq 0$ $y_L = 0$		$M_R \neq 0$ $\phi_R \neq 0$ $y_R = 0$	$V'_L \neq 0$ $M'_L \neq 0$ $I'_L = 0$	 Reactions = 2 Forces, 2 Couples	$V'_R \neq 0$ $M'_R \neq 0$ $I'_R = 0$

Case 3.—Simple Beam with Concentrated Load Not at Mid-Span.—Making use of the condition of zero deflection at the right support and using the equivalent rectangles of Fig. 32(c) (the moment of inertia, I, of the rectangle about its base equals $\frac{b\,h^3}{3}$):

$$I'_R = 0 = (M'_L)\,(2\,L) - \left(\frac{P\,a}{L}\right)\left(\frac{L^3}{3}\right) + \frac{P\,a^3}{3} = 0 \ldots\ldots (114)$$



(a) REAL BEAM (b) DUMMY BEAM



(c) RECTANGLES EQUIVALENT TO SHEAR DIAGRAM

Fig. 32.

$$M'_L = \left(\frac{Pa}{6\,L}\right)(L^2 - a^2) = \left(\frac{P\,a\,b}{6\,L}\right)(L + a) \ldots\ldots\ldots\ldots(115)$$

$$\phi_L = \frac{M'_L}{EI} = \left(\frac{P\,a\,b}{6\,E\,I}\right)\left(\frac{(L + a)}{L}\right) \ldots\ldots\ldots\ldots(116)$$

and,

$$\phi_R = \left(\frac{-P\,a\,b}{6\,EI}\right)\left(\frac{(L + b)}{L}\right) \ldots\ldots\ldots\ldots(117)$$

The deflection, y, at a distance, x, from the right end is given by $\frac{I'_x}{2\,EI}$, as follows (when x is measured to the left the sign is negative):

$$I'_x = -(M'_R)\,(-2\,x) - \left(\frac{P\,b}{L}\right)\left(\frac{x^3}{3}\right) = \left(\frac{2\,P\,a\,b\,x}{6\,L}\right)(L + b)$$

$$- \frac{P\,b\,x^3}{3\,L} = \left(\frac{P\,b\,x}{3\,L}\right)(L^2 - b^2 - x^2) \ldots\ldots(118)$$

and,

$$y = \frac{I'_x}{2\,EI} = \left(\frac{P\,b\,x}{6\,E\,I\,L}\right)(L^2 - b^2 - x^2) \ldots\ldots\ldots\ldots(119)$$

Since maximum deflection occurs where the slope, ϕ, is zero:

$$M'_x = 0 = -\,M'_R + \left(\frac{P\,b}{L}\right)\left(\frac{x^2}{2}\right) = 0 \ldots\ldots\ldots\ldots(120)$$

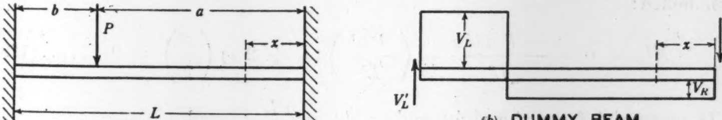
$$\left(\frac{P\,a\,b}{6\,L}\right)(L + b) = \left(\frac{P\,b}{L}\right)\left(\frac{x^2}{2}\right) \ldots\ldots\ldots\ldots(121)$$

$$x = \sqrt{\frac{a}{3}\,(L + b)} \ldots\ldots\ldots\ldots(122)$$

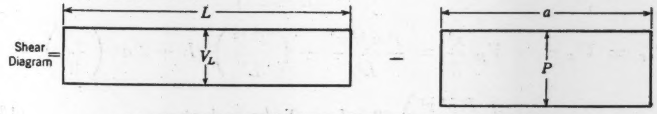
and,

$$y_m = \left(\frac{P\,a\,b}{9\,E\,I\,L}\right)\sqrt{\frac{a}{3}\,(L + b)^3} \ldots\ldots\ldots\ldots(123)$$

Case 11.—Fixed Beam with a Concentrated Load Not at the Mid-Span.—Making use of the conditions of zero slope and zero deflection at the right



(a) REAL BEAM (b) DUMMY BEAM



(c) RECTANGLES EQUIVALENT TO SHEAR DIAGRAM

Fig. 33.

support and the equivalent rectangles (see Fig. 33): When $\phi_R = 0$, $M'_R = 0$,

$$V'_L\, L - \frac{V_L\, L^2}{2} + \frac{P\, a^2}{2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots \text{(124)}$$

and, when $y'_R = 0$, $I'_R = 0$,

$$V'_L\, L^2 - \frac{V_L\, L^3}{3} + \frac{P\, a^3}{3} = 0 \ldots\ldots\ldots\ldots\ldots\ldots \text{(125)}$$

Eliminating V_L between Equations (124) and (125),

$$M_L = V'_L = \frac{P\, a^2\, b}{L^2} \ldots\ldots\ldots\ldots\ldots\ldots \text{(126)}$$

and,

$$M_R = V'_R = \frac{P\, a\, b^2}{L^2} \ldots\ldots\ldots\ldots\ldots\ldots \text{(127)}$$

Then, by substitution in Equation (124),

$$V_L = \left(\frac{P\, a^2}{L^3}\right) (L + 2\, b) \ldots\ldots\ldots\ldots\ldots\ldots \text{(128)}$$

and,

$$V_R = \left(\frac{P\, b^2}{L^3}\right) (L + 2\, a) \ldots\ldots\ldots\ldots\ldots\ldots \text{(129)}$$

Points of inflection occur where $V' = 0$; hence:

$$\frac{P\, a^2\, b}{L^2} - V_L\, x = 0 \ldots\ldots\ldots\ldots\ldots\ldots \text{(130)}$$

and,

$$\left(\frac{P\, a^2}{L^3}\right) (L + 2\, b)\, x = \frac{P\, a^2\, b}{L^2} \ldots\ldots\ldots\ldots\ldots\ldots \text{(131)}$$

If measured from the left end, $x = \dfrac{L\, b}{(L + 2\, b)}$; and, if measured from the right end, $x = \dfrac{L\, a}{(L + 2\, a)}$. Maximum deflection occurs where the slope, ϕ_x, is zero, hence:

$$M'_x = 0 = \frac{-\,P\, a\, b^2\, x}{L^2} + \left(\frac{P\, b^2}{L^3}\right) (L + 2\, a) \left(\frac{x^2}{2}\right) = 0 \ldots\ldots \text{(132)}$$

If measured from the right end, $x = \dfrac{2\, a\, L}{(L + 2\, a)}$, and,

$$I'_x = V'_R\, x^2 - V_R\, \frac{x^3}{3} = \frac{P\, a\, b^2\, x^2}{L^2} - \left(\frac{P\, b^2}{L^3}\right) (L + 2\, a) \left(\frac{x^3}{3}\right)$$

$$= \left(\frac{P\, b^2\, x^2}{3\, L^3}\right) (3\, a\, L - 3\, a\, x - b\, x) \ldots\ldots\ldots\ldots \text{(133)}$$

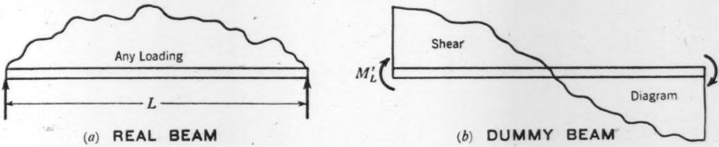
and the deflection equation, $y = \dfrac{I'_x}{2\,EI}$, becomes:

$$y = \left(\frac{P\,b^2\,x^2}{6\,EIL^3}\right)(3\,a\,L - 3\,a\,x - b\,x) \quad \text{.............. (134)}$$

Substituting the value of x for maximum deflection, the expression becomes:

$$y_m = \frac{2\,P\,a^3\,b^2}{3\,EI\,(L + 2\,a)^2} \quad \text{..................... (135)}$$

Cases 19 to 22.—Continuous Beam; Three-Moment Equation.—The right-hand side of the three-moment equation is the difference of two terms. The first equals the slope at the right end of a simple span of dimensions and loading of the left span of the continuous beam, multiplied by $6\,E$, and the second term equals the slope at the left end of a simple span of the dimensions and loading of the right span of the continuous beam, multiplied by $6\,E$. Now, for a simple beam with any loading (see Fig. 34):



(a) REAL BEAM

(b) DUMMY BEAM

FIG. 34.

$$I'_L = 0 = (-M'_R)\ (2\,L) + I'_{LS} = 0 \quad \text{............ (136)}$$

$$M'_R = \frac{I'_{LS}}{2\,L} \quad \text{........................ (137)}$$

$$\phi_R = \frac{I'_{LS}}{2\,EIL} \quad \text{........................ (138)}$$

and,

$$\phi_L = \frac{I'_{RS}}{2\,EIL} \quad \text{........................ (139)}$$

in which, I'_{RS} and I'_{LS} are the second moments of the shear diagram only, about the right and left supports, respectively.

Substituting these values for the slope, the general equation for three moments reads as follows, in terms of the second moments of the shear diagram for any loading:

$$\frac{M_1\,L_1}{I_1} + 2\,M_2\left(\frac{L_1}{I_1} + \frac{L_2}{I_2}\right) + \frac{M_3\,L_2}{I_2} = 6\,E\,\phi_{R1} - 6\,E\,\phi_{L2} = \frac{3\,I'_{L1}}{L_1\,I_1} - \frac{3\,I'_{R2}}{L_2\,I_2} \quad \text{.. (140)}$$

and for equal values of moment of inertia in both spans:

$$M_1\,L_1 + 2\,M_2\ (L_1 + L_2) + M_3\,L_2 = \frac{3\,I'_{L1}}{L_1} - \frac{3\,I'_{R2}}{L_2} \quad \text{..... (141)}$$

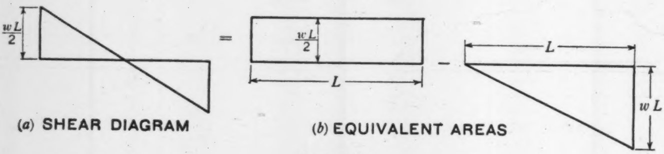
in which I'_{L1} and I'_{R2} are the second moments of the shear diagrams only, in the two spans, about the left and right outside supports, respectively.

Case 20.—Continuous Beam with Uniform Load Over Each Span.—Referring to Fig. 35 $\left(\text{the moment of inertia, } I\text{, of a triangle about its apex, is } \frac{b\,h^3}{4}\right)$:

$$I'_{LS} = \left(\frac{w\,L}{2}\right)\left(\frac{L^3}{3}\right) - (w\,L)\left(\frac{L^3}{4}\right) = -\frac{wL^4}{12} \quad \ldots\ldots\ldots(142)$$

and,

$$I'_{RS} = \frac{w\,L^4}{12} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(143)$$



(a) SHEAR DIAGRAM (b) EQUIVALENT AREAS

FIG. 35.

Equations (142) and (143) could also have been obtained by treating the shear diagram as a couple. Substituting these values for I'_{RS} *and* I'_{LS} in the three-moment equation, it becomes:

$$\frac{M_1\,L_1}{I_1} + 2\,M_2\left(\frac{L_1}{I_1} + \frac{L_2}{I_2}\right) + \frac{M_3\,L_2}{I_2} = -\frac{w_1\,L^3_1}{4\,I_1} - \frac{w_2\,L^3_2}{4\,I_2} \quad \ldots(144)$$

or,

$$M_1\,L_1 + 2\,M_2\,(L_1 + L_2) + M_3\,L_2 = -\frac{w_1\,L^3_1}{4} - \frac{w_2\,L^3_2}{4} \quad \ldots..(145)$$

It is hoped that the foregoing examples will serve to show the general procedure in applying the shear-area method in this manner and will also reveal its chief advantage, as stated by the authors; namely, the relative simplicity of calculating the second moment of shear areas composed of triangles and rectangles as compared with the first moment of parabolic segments of moment areas when uniformly distributed loads are involved. By the proper choice of equivalent areas a distributed load of any extent, or any arrangement of concentrated loads, may be handled simply. For loads of variable intensity and for beams of variable cross-section the dummy loading becomes quite as complex as that of the moment-area method. For beams of variable cross-section the loading curve is that of Equation (1) of the paper, and Statements (1), (2), and (3) of this discussion must be modified to take this into account. However, it is the writer's opinion that, for these more complicated cases, the classical methods involving integration, or approximate solutions involving the $\frac{M}{E\,I}$-diagram, might as well be used. It is worth mentioning, perhaps, that the shear-area method has the pedagogical value inherent in all such analogies in that it provides the student with excellent drill in the fundamental relations and quantities of mechanics.

FRED L. PLUMMER,[13] ASSOC. M. AM. SOC. C. E. (by letter).—Engineers, in general, are not adequately familiar with the relations existing between load, shear, moment, slope, and deflection for continuous members subjected to lateral forces. Although most engineers may have had occasion to use Equations (146) and (147), at some time, relatively few have made any use of the companion Equations (148) and (149). In these equations all the symbols for slope:

$$\frac{dy}{dx} = \phi \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (146)$$

for moment:

$$EI\,\frac{d^2y}{dx^2} = M \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (147)$$

for shear:

$$EI\,\frac{d^3y}{dx^3} = V \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (148)$$

and, for load:

$$EI\,\frac{d^4y}{dx^4} = w \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (149)$$

have their usual significance. The authors indicate these relationships graphically in Fig. 1.

The wider use of the methods of "slope deflection" and "moment distribution", together with their many modifications, has created keen interest in methods of structural analysis during the past few years. Since these methods of analysis are based on a study of distortions, it is natural that interest in methods of determining distortions and deflections should be equally stimulated. The writer has been amazed by the extent of this interest as evidenced by the attendance of designing engineers and architects in the vicinity of Cleveland, Ohio, at special classes devoted to the study of the various methods of determining stresses and deflections for statically indeterminate structures.

The authors have performed a double service to the profession, therefore, first by describing the successive relationships between load, shear, moment, slope, and deflection, and then demonstrating how these relationships may be used to develop alternates to the "moment-area" method of determining slopes and deflections. The writer has solved several problems by both the "shear-area" and the "moment-area" methods, and finds that he prefers the latter method. This decision may be due, however, to the fact that he has been familiar with this method for a much longer period.

---

[13] Assoc. Prof., Structural Eng., Case School of Applied Science, Cleveland, Ohio.

In all such "shorthand" methods of analogy, a set of rules may be established and followed blindly, thereby "grinding out" the required results with little mental effort and possibly with little appreciation of the physical significance of the process. It is quite proper that such methods be developed. The routine labor required for many similar designs may thus be lightened materially. It is also important, however, that the young engineer first familiarize himself with the physical meaning of his process so that he may use it when, and only when, it is entirely applicable.

The writer would have preferred that the authors omit several of the routine examples, substituting in their place a more complete development of the theoretical principles illustrated.

ALBIN H. BEYER,[14] M. AM. SOC. C. E. (by letter).—The claim is advanced by the authors that the shear-area method as described in their paper has the advantage over the standard moment-area method, in that it provides a simpler figure to work with, and that its use simplifies the solution for slope and deflection. This claim would be true if the authors had not introduced the computations of moments and shears in their so-called mathematical beam, loaded by the shear-area loading and supported in a hypothetical manner. The shear-area method of computation can be applied readily to any beam and loading without introducing the hypothetical beam and loading, which complicates rather than simplifies the solution.

To use any fundamental formula intelligently, the engineer must be familiar with its derivation and the meaning and sign of every symbol used. Therefore, the writer presents briefly, first the derivation of the fundamental formulas involved and, second, their application to two comparatively simple problems.

Derivation of Fundamental Formula for the General Case of a Loaded Beam.—Fig. 36(*a*) shows the beam and loading; the end restraining moments, M_A and M_B, are indicated as negative.

Fig. 36(*b*) shows the straight beam, $B\,O\,A$, deflected under the loads to the position, $B\,O'A$, where $O\,O' = y_o$, is the desired deflection of the beam at any point, O, distant x_A from A; θ_o is the slope of the beam at this point; and θ_A and θ_B are the slopes of the beam at A and B, respectively.

Select a Cartesian system of co-ordinates with the origin at O, where the deflection and slope are desired, distant x_A, a variable, from A; x is measured positive to the right of O, and y is measured positive upward. With this system of co-ordinates, the signs which apply are indicated in Fig. 37.

The differential equation of the deflected beam is given by the classical formula,

$$\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{M}{E\,I} \quad\text{..................}(150)$$

Multiplying the last two terms by $x\,dx$ gives,

$$x\,d\left(\frac{dy}{dx}\right) = \frac{M\,x\,dx}{E\,I} \quad\text{....................}(151)$$

---

[14] Prof. of Civ. Eng., Columbia Univ., New York, N. Y. Professor Beyer died on April 19, 1936.

Integrating both sides between the limits, O and A, using the method of parts for the first term:

$$\left[x \frac{dy}{dx} - y \right]_0^{x_A} = \int_0^{x_A} \frac{M\,x\,dx}{E\,I} \qquad (152)$$

or,

$$y_o = y_A - x_A\,\theta_A + \int_0^{x_A} \frac{M\,x\,dx}{E\,I} \qquad (153)$$

Equation (153) is the fundamental general formula of the moment-area method.

FIG. 37.

Referring to Fig. 36(b), $y_A = 0$ when the support at A is fixed in space; $x_A\theta_A = O\,O''$; $\int_0^{x_A} \frac{M\,x\,dx}{E\,I} = O'O''$; and $O\,O'' + O''O' = O\,O'$, the downward deflection of the beam at Point O.

The authors' contribution to this well-known theory consists in expressing M, the bending moment at any point, in terms of the shear area. In general, $M = M_A - \int_x^{x_A} V\,dx$, in which the last term is the shear area from x to x_A.

The equation for y_o expressed in terms of the shear area, O to A, then becomes,

$$y_o = y_A - x_A\theta_A + M_A \int_0^{x_A} \frac{x\,dx}{E\,I} - \int_0^{x} \left(\int_x^{x_A} \frac{V\,dx}{E\,I} \right) x\,dx \qquad (154)$$

a very much more complicated expression than Equation (153). Only when E and I are constant can Equation (154) be simplified to,

$$y_o = y_A - x_A\theta_A + \frac{M_A\,x^2_A}{2\,E\,I} - \frac{I_x}{2\,E\,I} \qquad (155)$$

in which I_x is the moment of inertia of the shear area (sign to be determined in accordance with Fig. 37) to the right of the origin of co-ordinates taken about the Y-axis through the origin. Taking the first derivative of y_o with respect to x_A (noting that $\frac{dy_o}{dx_A}$ is negative):

$$\theta_o = + \theta_A - \frac{M_A x_A}{EI} + \frac{A\bar{x}}{EI} \dots\dots\dots\dots\dots\dots (156)$$

In Equation (156) Ax is the static moment of the shear area between O and A about the Y-axis through O, using the signs for the shear area as determined by Fig. 37.

Application of Formula to Beams with Constant Moment of Inertia.—The general equations to be used are,

$$y_o = y_A - x_A\theta_A + \frac{M_A x^2_A}{2\,EI} - \frac{I_x}{2\,EI} \dots\dots\dots\dots\dots (157)$$

and,

$$\theta_o = + \theta_A - \frac{M_A x_A}{EI} + \frac{A\bar{x}}{EI} \dots\dots\dots\dots\dots\dots (158)$$

The general formulas, Equations (157) and (158), give the deflection, y_o, and the slope, θ_o at any point, O, distant x_A from A, in terms of the shear area. They can be applied directly to any beam or loading when the end shears and moments have been computed. For statically indeterminate beams, they can also be used for determining the end moments and shears. In solving these equations, the analogy of a hypothetical beam and loading is not necessary and is not recommended by the writer as the analogy does not contribute to the directness or simplicity of the solution, as can be seen from the following typical examples.

Analysis of Statically Determinate Beams (Authors' Case I).—The general formulas required are:

$$y_o = y_A - x_A\theta_A + \frac{M_A x^2_A}{2\,EI} - \frac{I_x}{2\,EI} \dots\dots\dots\dots\dots (159)$$

and,

$$\theta_o = \theta_A - \frac{M_A x_A}{EI} + \frac{A\bar{x}}{EI} \dots\dots\dots\dots\dots\dots (160)$$

In this case, y_A and M_A are each equal to zero. The value of θ_A can be computed by means of Equation (159) or Equation (160). Equation (160) is used because of its simple form; also, from symmetry, $\theta_B = - \theta_A$.

Using Equation (160) (making $x_A = L$ (see Fig. 38)):

$$- \theta_A = \frac{A\bar{x}}{2\,EI} \dots\dots\dots\dots\dots\dots\dots\dots (161)$$

In Equation (161), $A\bar{x}$ is the static moment of the shaded shear area about a vertical axis through B and is equal to $-\frac{W\,L^3}{12}$; therefore, $\theta_A = \frac{W\,L^3}{24\,E\,I}$.

From Equation (159), therefore, the elastic curve is expressed by:

$$y_o = -\,x_A\theta_A - \frac{I_x}{2\,E\,I} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (162)$$

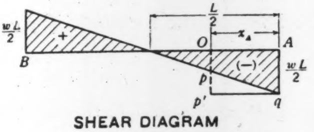

FIG. 38.

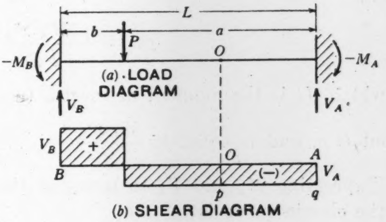

FIG. 39.

in which, I_x is the moment of inertia of the trapezodial shear area, $O\,p\,q\,A$ (Fig. 38) about $O\,p$, and is equal to the static moment of the rectangle, $O\,p'\,q\,A$, minus that of the triangle, $p\,p'\,q$, all of which is equal to $-\frac{1}{6}\,w\,L x_A^3 + \frac{w x_A^4}{12}$.

The equation of the elastic curve then becomes,

$$y_o = -\frac{w\,L^3\,x_A}{24\;E\;I} + \frac{w\,L\,x_A^3}{12\;E\;I} - \frac{w x_A^4}{24\;E\;I} \qquad \ldots\ldots\ldots\ldots (163)$$

which, for $x_A = \frac{L}{2}$, gives:

$$y_o = -\frac{5}{384}\,\frac{w\,L^4}{E\,I} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (164)$$

The slope at O can be found by differentiating y_o with respect of x_A, keeping in mind that the origin is shifted as x_A changes, which makes $\frac{dy_o}{dx_A}$ minus; thus:

$$\theta_o = +\frac{w\,L^3}{24\,E\,I} - \frac{w\,L\,x_A^2}{4\,E\,I} + \frac{w\,x_A^3}{6\,E\,I} \qquad \ldots\ldots\ldots\ldots (165)$$

The same result for θ_o can be obtained directly from Equation (160), in which $A\bar{x}$ is now the static moment of the shear area, $O\;p\;q\;A$, about $O\;p$, and is equal to $-\frac{w\,L\,x_A^2}{4} + \frac{w\,x_A^3}{6}$, which gives,

$$\theta_o = \frac{w\,L^3}{24\,EI} - \frac{w\,L\,x_A^2}{4\,EI} + \frac{w\,x_A^3}{6\,EI} \qquad \ldots\ldots\ldots\ldots (166)$$

Analysis of Statically Indeterminate Beams (Authors' Case II).—The end reactions, M_A, M_B, V_A, and V_B (Fig. 39), can be computed in the usual manner. They can also be found readily by means of Equation (159) and Equation (160), and are as follows: $M_A = -\dfrac{P\,a\,b^2}{L^2}$; $M_B = -\dfrac{P\,a^2 b}{L^2}$; and, $V_A = -\dfrac{P\,b^2}{L^3}(3a + b)$. Note that θ_A, θ_B, and y_A are each equal to zero. Then,

$$y_o = +\frac{M_A\,x^2_A}{2\,E\,I} - \frac{I_x}{2\,E\,I} \qquad \text{(167)}$$

in which, I_x is the moment of inertia (see Fig. 39), of the rectangle, $O\,p\,q\,A$, about $O\,p$, and is equal to $\dfrac{V_A\,x^3_A}{3}$.

Expressing M_A and V_A in terms of the load, P, and a and b, the equation of the elastic curve is:

$$y_o = -\frac{P\,a\,b^2\,x^2_A}{2\,E\,I\,L^2} + \frac{P\,b^2}{6\,E\,I\,L^3}(3\,a + b)\,x^3_A + \;\ldots \qquad \text{(168)}$$

in which y_o is a maximum when $\dfrac{dy_o}{dx_A} = 0$, provided a is $\geqq \dfrac{L}{2}$. This gives $x_A = \dfrac{2\,a\,L}{2\,a + L}$. The solution becomes simpler when numerical values can be substituted for M_A, V_A, I_x, and $A\bar{x}$ in Equations (159) and (160).

JOHN M. BEATTY,[15] JUN. AM. SOC. C. E. (by letter).—The "shear-area method" for the solution of the elastic functions of loaded beams as presented in this paper outlines another interesting and valuable method of analysis for both statically determinate and statically indeterminate beams. As the authors have stated it is not "the shortest method for solving slopes and deflections for all problems," but its advantages in those cases involving uniformly distributed loads become quite apparent when the method is put to the test.

The parabolic moment-curve areas involved in the solutions by the moment-area methods are always disagreeable and sometimes difficult to handle. On the other hand, the shear-curve areas for the same loadings are usually simply a combination of triangles, rectangles, and trapezoids, the properties of which are well known to every engineer and designer.

There are many cases, also, in which the shear-area method may be used to advantage in combination with some other method, such as the conjugate beam method. In the case of simply supported beams, for instance, the end slopes many times may be found much more readily by the shear-area method and then these slopes may be applied as end reactions for the "conjugate beam." The problem may then be continued to completion by the latter method if an inspection seems to indicate an easier solution by that method.

---

[15] Instr., Civ. Eng., Rensselaer Polytechnic Inst., Troy, N. Y.

For example, consider the following simple beam loaded with two patches of uniform load symmetrically placed with respect to the center of the beam (see Fig. 40(*a*)). An inspection of the shear and moment diagrams immediately suggests an easier and quicker solution of the end slopes by the shear-area method. The end slopes, which are numerically equal to each other are also equal to one-half the moment of the couple produced by the shear-area loadings. The value of the shear-area couple is equal to the value of the shear area above or below the base line, multiplied by the distance between their centers of gravity. The value of one-half this shear area couple may then be found immediately taking moments about the center line of the mathematical beam of the shear area to one side of the section. This principle may be used for all simple beams with loadings that are symmetrical with respect to the center line, providing, of course, that the beam itself is also symmetrical about the center line; thus (see Fig. 40(*b*)):

FIG. 40.—COMPARATIVE SOLUTION FOR END SLOPES

$$\phi_L = \frac{\text{Moment of Shear Area, } a\ b\ c\ d\ e\text{, About Point } O}{E\,I} \times 144$$

or,

$$\phi_L = \frac{600 \times 4 \times 12 + 0.5 \times 600 \times 6 \times 8}{E\,I} \times 144 = \frac{6\,220\,800}{E\,I}$$

To find the same end slope by the conjugate beam method involves the solution for the end reaction, R_L, of the conjugate beam. As the moment diagram is symmetrical with respect to the center line, this reaction, R_L, must equal one-half the total moment-area loading. Of this total area, $A\,C\,E\,F\,A$, that under the curved portion (that is, Area $J\,B\,C\,D\,H$, Fig. 40(*c*)), presents the greatest difficulty. This area, of course, may be found by means of the calculus by integrating the general expression for the moment area between the limits of J and H, but this introduction of the calculus is troublesome to many and is often avoided wherever possible. Another method of finding the value of Area $J\,B\,C\,D\,H$ is to divide it into the two areas, $J\,B\,D\,H\,J$ and $B\,C\,D\,B$, and then to find each area separately. The area of the trapezoid, $J\,B\,D\,H\,J$, is readily found. The area under the curve, $B\,C\,D\,B$, may be determined by finding the value of the ordinate, $C\,K$, at the mid-point between B and D and, considering this as the mid-ordinate of a parabolic curve spanning the horizontal distance, $B\,G$, the area will then be equal to two-thirds the product of $C\,K$ times $B\,G$ (see Fig. 40(*c*)). Referring to Fig. 40(*c*): $C\,K = C\,I - K\,I = 3\,750 - 3\,300 = 450$; $M_{BJ} = 600 \times 4 = 2\,400$; $M_{CI} + 600 \times 7 - 300 \times 1.5 = 3\,750$; $M_{BF} = 600 \times 14 - 600 \times 7 = 4\,200$;

and $R_L = \text{Areas } \dfrac{A\,B\,J + B\,D\,H\,J + B\,C\,D\,B + D\,E\,F\,H}{E\,I} \times 144$

$$= \frac{1}{E\,I}\left[\frac{2\,400 \times 4}{2} + \left(\frac{2\,400 \times 4\,200}{2}\right) 6 + \frac{2}{3}(450 \times 6) + 4\,200 \times 4\right] \times 144$$

$$= \frac{6\,220\,800}{E\,I}.$$

Regardless of which method is used to find the total area, $A\,C\,E\,F\,A$, it is apparent that the work involved is considerably more than that incurred in the solution of ϕ_L by the shear-area method. As the values of ϕ_L and R_L are certain to be identical, both representing the end slope of the same simple beam, the shear-area method is obviously much the easier and quicker method and, at the same time, because of its simplicity, much less liable to error than the solution by the conjugate beam method.

If the values of the moment areas are known (as they now are in this problem) there is very little to choose from between the two methods in so far as the determination of the maximum deflection at the center of the beam is concerned. Each method involves about an equal amount of numerical work, although the determination of the static moments of the moment areas in the case of the conjugate beam may be preferred by some to the solution for the moments of inertia of the shear areas in the case of the shear-area method. For example, by the shear-area method:

$$y_{\text{max.}} = \phi_L \times x - \frac{I_x}{2} = \frac{1}{E\,I}\left\{6\,220\,800 \times 14 \times 12\right.$$

$$\left. - \left[\frac{\dfrac{600 \times 4^3}{12} + 600 \times 4 \times 12^2 + \dfrac{600 \times 6^3}{36} + \dfrac{600 \times 6}{2} \times 8^2}{2}\right] 1\,728\right\}$$

$$= \frac{641\,088\,000}{E\,I}$$

and, by the conjugate beam method:

$$y_{\max.} = \frac{1}{E\,I}\left\{6\,220\,800 \times 14 \times 12 - \left[\frac{2\,400 \times 4}{2} \times \frac{34}{3} + 2\,400 \times 6 \times 7\right.\right.$$

$$\left.\left. + \frac{1\,800 \times 6}{2} \times 6 + \frac{2}{3}(450 \times 6) \times 7 + 4\,200 \times 4 \times 2\right] 1\,728\right\}$$

$$= \frac{641\ 088\ 000}{E\,I}$$

It is in the determination of the deflection at any intermediate point, such as Point X, Fig. 41, that the advantage of the shear-area principle becomes apparent.

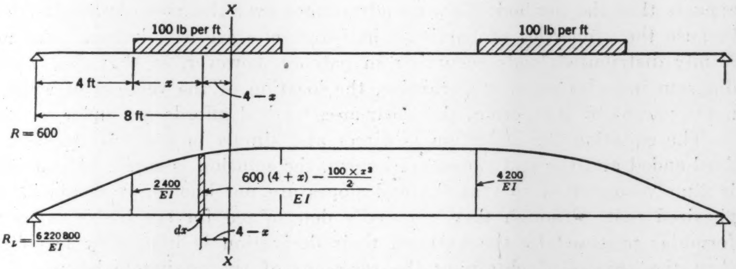

FIG. 41.—DEFLECTION AT ANY POINT BY THE CONJUGATE BEAM METHOD

In finding the static moments about Point X, of the moment areas in the conjugate beam method, recourse must again be made to the calculus for the moment of the area between Points J and X (see Fig. 40(c)). The general expression for the moment of the moment area must be integrated between the limits of J and X (see Figs. 40(c) and 41). An inspection of the following computations plainly shows the relative simplicity of the solution by the shear-area method over that by the conjugate beam method:

By the shear-area method (see Fig. 40(b)):

$$y_x = \phi_L \times x - \frac{I_x}{2};\ \phi_L = \frac{6\,220\,800}{E\,I};\ \text{and, } y_x = \frac{1}{E\,I}\left\{6\,220\,800 \times 8 \times 12\right.$$

$$\left. - \left[\frac{\dfrac{600 \times 4^3}{12} + 600 \times 4 \times 6^2 + \dfrac{200 \times 4^3}{3} + \dfrac{400 \times 4^3}{4}}{2}\right] 1\,728\right\} = \frac{510\,566\,400}{E\,I}$$

By the conjugate beam method:

$$y_x = \frac{1}{E\,I}\left\{6\ 220\ 800 \times 8 \times 12 - \left[\frac{2\ 400 \times 4}{2} \times \frac{16}{3} + \int_0^4 \left(600\ (4 + x)\right.\right.\right.$$

$$\left.\left.\left. - \frac{100\ x^2}{2}\right) d\,x\ (4 - x)\right] 1\ 728\right\} = \frac{1}{E\,I}\left\{6\ 220\ 800 \times 96\right.$$

$$\left. - \left[25\,600 + 50\left(192\ x - \frac{16\ x^3}{2} + \frac{x^4}{4}\right)_0^4\right] 1\ 728\right\} = \frac{510\ 566\ 400}{E\,I}$$

No single method of analysis can be claimed as superior to all others for the solution of all problems. Certain methods are more readily applied to certain types of problems and, therefore, are to be preferred over all others for these specific types. The shear-area method thus supplies one more possible tool which, when used judiciously, can be of real service. The authors are to be commended for bringing this method of analysis to the attention of the Engineering Profession.

R. B. PECK,[16] JUN. AM. SOC. C. E. (by letter).—The use of the shear-area method is most advantageous, as the authors state, for problems involving distributed load. Where the load is uniformly distributed over entire span lengths—that is, where the moment diagram includes a full parabola—it appears that the method offers no advantages over the moment-area methods because the properties of parabolic half-segments are well known. For uniformly distributed loads occurring in patches, however, so that the moment diagram includes parts of parabolas, the location of the vertices of which is not apparent by inspection, the shear-area method affords a simpler solution.

The equation for deflection is direct and simple in use. If the beam is fixed-ended and the end slopes are known, the solution is rapid. If the beam is simply supported so that the end slopes are not known, it should be emphasized that, although they are easily determined for specific cases by the formulas proposed by the authors, their derivation is inherently less direct than the process of obtaining the reactions of the conjugate beam. Much of the advantage of the shear-area method is lost in this case because of this difficulty in obtaining end slopes, particularly if the computer does not have the aforementioned formulas available.

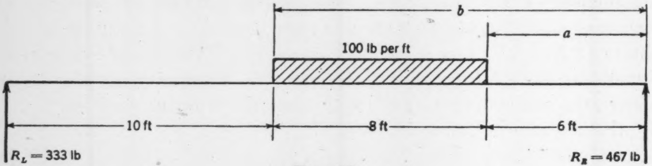

FIG. 42.

It will be noticed, however, that a very direct means of computing the end slopes for simply supported beams is found in the method, suggested by the authors, of investigating the loading directly. The deflection formula, Equation (95), will reduce to:

$$y\,E\,I = -\frac{1}{6}Q_x + \phi_x x + y_e \ldots\ldots\ldots\ldots\ldots (169)$$

for simple supports. When written for a point of support, where $y = 0$, it becomes, since $x = L$,

$$0 = -\frac{1}{6}Q + \phi_e L + y_e$$

which may be solved immediately for the end slope, ϕ_e. A numerical example is given for illustration.

---

[16] Troy, N. Y.

In order to solve for the deflection at any point in the beam shown in Fig. 42, it is necessary to know one of the end slopes, say ϕ_L. By Equation (30), $\phi_L = 25\,500$. If, however, instead of Equation (30) the loading is used directly, the expression for the deflection at the right-hand end, using Equation (169), is $0 = -\frac{1}{6} Q + \phi_L L$, in which Q is taken for the entire span and equals $\frac{R x^3}{6} - \int x^3 \, dA$. For an area, $\int x^3 \, dA = 3 x_0 I_{cg} + A x^3_0$. Then,

$$0 = \phi_L \times 24 - \frac{333}{6} \times 24^3 + \frac{3}{6} \times 10 \times \frac{100 \times 8^3}{12} + \frac{100 \times 8 \times 10^3}{6}$$

from which $\phi_L = 25\,500$.

RALPH W. STEWART,[17] M. AM. SOC. C. E. (by letter).—An interesting mathematical exercise is presented in this paper. The principle which makes the shear-area method possible is the same as that which makes the conjugate beam or elastic weight method possible, namely, in Fig. 1, each curve is the integral of the one above it. This principle is illustrated more simply by drawing the loading, shear, moment, slope, and deflection curves for a cantilever beam using the free end as the origin, thereby eliminating the effect which the reaction has on the shear curve.

In connection with these integrations, as usually performed for specific loading, it is of interest to note that the shear and moment in either the cantilever beam or the simple beam are governed by forces and distances on one side only of the point at a distance, x, from the origin. The slope and deflection, however, are affected by the length of the entire beam and by the loading on both sides of the point at a distance, x. In line with this physical condition the integrations from load to shear and shear to moment are not affected by the valuation of constants of integration, these constants being zero, but the integrations from moment to slope and from slope to deflection require the evaluation and use of constants of integration which are dependent on the entire length of the beam. The authors' treatment of Fig. 1 involves loading which is general rather than specific, thereby leading to two term expressions for the slope and the deflection with constants of integration that equal zero.

The one obvious advantage which the shear-area method offers in comparison with methods of analysis based on moment areas is that, for beams with uniformly distributed loads, the shear areas are bounded by straight lines, whereas with moment areas a parabolic boundary line is involved. To a computer with meager knowledge of geometry the straight-line figure offers an advantage. The properties of parabolic moment diagrams are so simple, however, and so easily remembered, that any one whose professional practice includes structural engineering can hold them in mind, and by their use can solve beam problems with less work than by the methods set forth in this paper.

As an illustration, the fact that the parabola cuts the rectangle in Fig. 43 into an upper and lower area equal, respectively, to two-thirds and one-third of the area of the rectangle, and that the centers of gravity of these areas are located as shown, should not tax the memory of an engineer. Even if forgotten, the integrations to obtain these areas and distances are easier than such integrations as that of Equation (10) and various subsequent integrations in the paper.

(b) TRAVERSE DIAGRAM

FIG. 44.

Using these parabolic areas and the principle that the change in direction of the tangent between two points on the elastic curve is equal to the area between the two corresponding points on the $\frac{M}{EI}$-diagram, the analysis of beams with uniformly distributed loads can be performed more rapidly and more satisfactorily than by the method set forth by the authors. For example, by the moment-area method, or by the traverse method as illustrated by Fig. 44(*b*),[18] the deflection at the center of a simple beam uniformly loaded is:

$$\frac{5}{16}\, l \left(\frac{1}{8}\, w\, l^2 \times \frac{2}{3} \times \frac{l}{2} \times \frac{1}{E\,I}\right) = \frac{5\, w\, l^4}{384\, E\, I} \quad \ldots\ldots\ldots (170)$$

This is certainly simpler treatment than the procedure indicated by the authors' Equations (10) and (11). In fact, their derivation of this maximum deflection appears more tortuous than the usual double integration of the bending-moment equation as taught in most treatises on applied mechanics.

An inherent difficulty in the general use of the shear-area method for the analysis of continuous frames is that the shear curve is one step too far removed from the curve of deflections, and the analysis of continuous frames is dependent to a great extent upon equating deflections at certain points to each other, or to zero. The slope is one step closer to the shear curve, and since the theorem of three moments is derived by equating slopes over supports, it is practicable to use the shear-area method to derive it as set forth in the paper.

As a practical tool for the analysis of structures, it appears that the prospect of the shear-area method to gain recognition is not encouraging.

C. W. JOHNSON,[19] and H. W. BIRKELAND,[20] JUNIORS, AM. SOC. C. E. (by letter).—Upon close examination and by comparison with other methods, the writers have been unable to discover any advantages in favor of the so-called "shear-area method." With a little effort it is easy to understand why the modified moment diagram was chosen as an elastic load diagram in solving for deflections. As one moves down the list of curves from the moment toward the actual load curve, the modification becomes more and more complex. For example, for the moment diagram, $\frac{M}{EI}$ is used; for the shear diagram, $\frac{V}{EI} + \frac{M}{(EI)^2} \frac{d\,(EI)}{dx}$; and, for the load diagram, $\frac{w}{EI} + \frac{M}{(EI)^2} \frac{d^2\,(EI)}{dx^2} - \frac{2M}{(EI)^3} \left[\frac{d\,(EI)}{dx}\right]^2$. If the reader doubts the increasing difficulty of using these expressions, let him try an example and be convinced.

Another misleading inference in the paper suggests that the second moment of the modified shear area is easier to find than the first moment of the moment area. This conclusion is inaccurate, of course, because in the two cases the integrations are comparable. For use with the conjugate beam method the writers have long used a simple table of areas and locations of centroids in cases where only deflections at particular points are desired. Such an expedient would be equally necessary and useful in regard to the shear-area method.

The authors have placed great emphasis upon the ease of finding the slopes by this method and the merit of having "eliminated" the moment curve. Compare the usefulness of these two curves and then decide which should be omitted. In the conjugate beam method the most used curve is employed whereas the least used curve is not used. In the shear-area method the valuable moment curve is not used and apparent emphasis is laid on the less important slope curve.

The method does not seem to be readily adaptable to any but the most simple beam problems such as statically determinate, constant section cases with uniformly distributed load. The writers have been unable to find one case in which the procedure could be applied more easily than some other one. To the practicing engineer the method offers nothing that is of sufficient value to investigate as it does not improve upon the methods now in use. However, if the paper were more complete, and included a genuine derivation of the principles, it would be of interest to students, since it calls attention to the second-moment and third-moment principles.

In Fig. 1 the authors have ostensibly set out to show the relation between beam diagrams. In doing so they start with the load diagram as a calculus curve and attempt to proceed from one curve to another by means of integration.

Since an extremely simple case was chosen, it is unfortunate that the equations were not shown mathematically complete. Some of the constants of integration are shown and others are omitted. It is necessary to show a constant of integration in each equation involving the solution of an integral, such as $y = \int f(x)\,dx$.

[19] Junior Engr., U. S. Bureau of Reclamation, Denver, Colo.

[20] Junior Engr., U. S. Bureau of Reclamation, Denver, Colo.

In deriving the equations of the shear and moment curves the origin is at the left end; this is likewise true in the first parts of Equations (6) and (7), expressing the slope and deflection. The second parts of Equations (6) and (7) are based on the first-moment and second-moment principles, respectively, and the origins are at any variable point, x. Thus, to avoid confusion, the x occurring with dA under the integral sign might well be expressed as another variable since its origin is not at the left end. Space does not permit a discussion of all the authors' examples, but the same types of omissions and inconsistencies, as mentioned in connection with Fig. 1 and Equations (4) to (7), inclusive, appear throughout.

Although it is not the chief topic of the authors' paper, the writers present a simple and consistent method of showing beam diagrams. The successive curves bear the proper mathematical relationships and the sign conventions are logical. The calculus relationships can be expressed in two simple rules: (*a*) The slope at any point on a curve is equal to the ordinate at the corresponding point in the derived curve; and, (*b*) the difference between the ordinates at any two points on a curve is equal to the area under the derived curve between the two corresponding points.

These two rules do not establish the starting point of the higher degree curve; this point is determined from the constant of integration which is fixed by physical considerations and is often referred to as the initial condition. The equations of the beam diagrams and the sign conventions are, as follows:

(1) Loading (positive when acting upward):

$$w_x = f(x) \qquad \text{.......................(171)}$$

(2) Shear (positive when acting upward on the part of the beam on the right of the cut; an imaginary cut helps to visualize internal shears):

$$V_x = R_L + \int_0^x w_x\,dx \qquad \text{....................(172)}$$

(3) Moment (positive when the lower fibers are in tension):

$$M_x = M_L + \int_0^x V_x\,dx \qquad \text{...................(173)}$$

(4) Slope (positive when deflection curve rises from left to right):

$$\theta_x = \phi_L + \int_0^x \frac{M_x}{EI}\,dx \qquad \text{...................(174)}$$

(5) Deflection (positive when upward from the original position):

$$\delta_x = \delta_L + \int_0^x \theta_x\,dx \qquad \text{....................(175)}$$

In order to keep Equations (171) to (175) general, all terms are shown positive. Therefore, algebraic signs must be included in numerical substitutions, which is the usual practice in mathematics.

FIG. 46.—CONSECUTIVE CALCULUS CURVES.

This procedure, as applied to the example of Fig. 1, is shown in Fig. 45. Fig. 45(*a*) is a sketch of the beam showing external loads and restraints. Figs. 45(*b*) to 45(*f*) show a series of beam diagrams from load curve to deflection curve, inclusive. Note that, consistent with the foregoing sign convention, the load curve, Fig. 45(*b*), is drawn below the *X*-axis, since a downward acting load is negative. The reason for such a sign convention is to show better the mathematical relationships between the load and shear curves. It is important that the sketch of the beam, showing loading and restraints, is not confused with the load curve. The Cartesian co-ordinate system, with origin at the left end throughout, is used in this method. Values are positive when measured above, and negative when measured below, the *X*-axis.

Since Equations (4) to (7), inclusive, are incomplete, and do not contain a proof of the principles involved, the writers will derive them as mathematical laws that are not limited to beams alone.

The First-Moment Principle.—A special application of the first-moment principle to beams is called Mohr's second law; conjugate beam method; and moment-area principle. Another special application to beams may be called the shear-area method, Part I. A general application, using different terms, is sometimes called the third law of derived curves. Referring to Fig. 46, let the equation of Curve No. 1 be:

$$y_1 = f(x_1) \quad \ldots\ldots (176)$$

Integrating Equation (176), the equation of Curve No. 2 is obtained; thus:

$$y_2 = y_{2A} + \int_a^{x_2} y_1 \, dx_1 \quad \ldots\ldots (177)$$

Note that instead of taking the constant of integration at the origin and starting the integration from there, the constant is taken at Point *A* (Fig. 46), and the integration starts from that point. This is done in order to remove any doubt about the universal truth of the law to be derived.

Integrating again, the equation of Curve No. 3 is obtained:

$$y_3 = y_{3A} + \int_a^{x_3} y_{2A} \, dx_2 + \int_a^{x_3} \int_a^{x_2} y_1 \, dx_1 \, dx_2 \quad \ldots\ldots (178)$$

Rewriting Equation (178) with the order of integration reversed:

$$y_3 = y_{3A} + \int_a^{x_3} y_{2A} \, dx_2 + \int_a^{x_3} \int_{x_1}^{x_3} y_1 \, dx_2 \, dx_1 \quad \ldots\ldots (179)$$

It is now possible to perform the first integration::

$$y_3 = y_{3A} + y_{2A} \, (x_3 - a) + \int_a^{x_3} y_1 \, (x_3 - x_1) \, dx_1 \quad \ldots\ldots (180)$$

Substituting b for x_3,

$$y_{3B} = y_{3A} + y_{2A} \, (b - a) + \int_a^{b} y_1 \, (b - x_1) \, dx_1 \quad \ldots\ldots (181)$$

which is the first-moment principle, so-called because the integral involves the first moment of an area. It is comparable to the second part of Equation (6).

Equation (181) may be translated into words, as follows: If there are three curves, Nos. 1, 2, and 3, that are so related that Curve No. 2 is obtained by integration of Curve No. 1, and Curve No. 3 by integration of Curve No. 2 (or *vice versa* by differentiation), then Curves Nos. 1, 2, and 3, may be treated in a manner similar to load, shear, and moment curves; that is, the ordinate at any point of Curve No. 3 may be obtained from Curve No. 1 by cutting it at that point and setting the sum of moments equal to zero. Of course, Curve No. 1 must be placed in equilibrium, consistent with known conditions in the other related curves. This is illustrated in Fig. 47. The various quantities occurring in Equation (181) should then be interpreted as follows: y_{2A} = shear at Point A; y_{3A} = moment at Point A; y_1 = load intensity at Point x_1; $y_1\,dx_1$ = differential load at Point x_1; $(b - x_1)$ = lever arm of the differential load about Point B; and y_{3B} = moment at Point B.

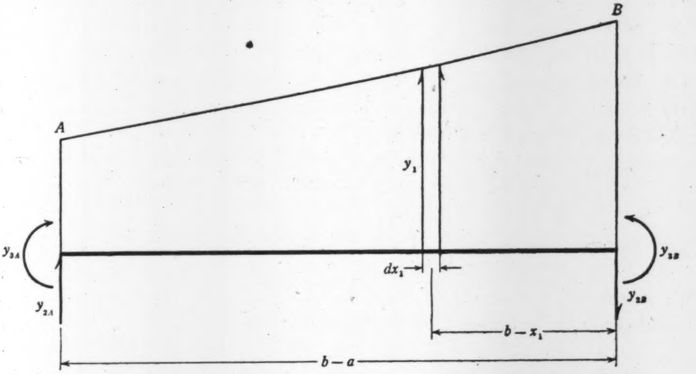

FIG. 47.—EQUILIBRIUM SKETCH FOR THE FIRST MOMENT PRINCIPLE (CONJUGATE BEAM).

The Second-Moment Principle.—A special application of the second-moment principle to beams may be called shear-area method, Part II (moment of inertia of shear diagram). Referring to Fig. 46, the equation of Curve No. 4 is obtained by integration of Equation (180):

$$y_4 = y_{4A} + \int_a^{x_4} y_{3A}\,dx_3 + \int_a^{x_4} y_{2A}\,(x_3 - a)\,dx_3 + \int_a^{x_4}\int_a^{x_3} y_1\,(x_3 - x_1)\,dx_1\,dx_3 \qquad (182)$$

Rewriting Equation (182) with the order of integration reversed:

$$y_4 = y_{4A} + \int_a^{x_4} y_{3A}\,dx_3 + \int_a^{x_4} y_{2A}\,(x_3 - a)\,dx_3 + \int_a^{x_4}\int_{x_1}^{x_4} y_1\,(x_3 - x_1)\,dx_3\,dx_1 \qquad (183)$$

It is now possible to perform the first integration; thus:

$$y_4 = y_{4A} + y_{3A}\,(x_4 - a) + \frac{1}{2}\,y_{2A}\,(x_4 - a)^2 + \frac{1}{2}\int_a^{x_4} y_1\,(x_4 - x_1)^2\,dx_1 \qquad (184)$$

Substituting b for x_4:

$$y_{4B} = y_{4A} + y_{3A}\,(b - a) + \frac{1}{2}\,y_{2A}\,(b - a)^2 + \frac{1}{2}\int_a^b y_1\,(b - x_1)^2\,dx_1 \quad (185)$$

which is the second-moment principle, so-called because the integral involves the second moment of an area. It is comparable to Equations (7), (92), and (94). It must be remembered that the four curves are consecutive.

The Third-Moment and Fourth-Moment Principles.—Continuing the derivation beyond the second-moment principle, and using the same procedure, the following equation is obtained,

$$y_{5B} = y_{5A} + y_{4A}\,(b - a) + \tfrac{1}{2}\,y_{3A}\,(b - a)^2 + \tfrac{1}{6}\,y_{2A}\,(b - a)^3 + \frac{1}{6}\int_a^b y_1\,(b - x_1)^3\,dx_1 \quad \ldots\ldots (186)$$

which is the third-moment principle, and which is comparable to Equations (93) and (95). It is understood that the five curves are consecutive. Similarly,

$$y_{6B} = y_{6A} + y_{5A}\,(b - a) + \frac{1}{2}\,y_{4A}\,(b - a)^2 + \frac{1}{6}\,y_{3A}\,(b - a)^3 + \frac{1}{24}\,y_{2A}\,(b - a)^4 + \frac{1}{24}\int_a^b y_1\,(b - x_1)^4\,dx_1 \quad \ldots\ldots (187)$$

which is the fourth-moment principle. The six curves involved must be consecutive. This procedure may be extended to obtain any desired moment principle.

Discussion of the Moment Principles.—From the first, second, third, and fourth-moment principles, represented by Equations (181), (185), (186), and (187), respectively, the following points may be noted:

(1) The first-moment principle is the only one of the group that lends itself to use in connection with an equilibrium sketch, because the numerical coefficients of all terms are unity (1.0) in this one case only; and,

(2) A problem, which in ordinary procedures would involve a multiple integration, has been reduced to one with a single integration. It is well to note that the intermediate curve or curves are not entirely eliminated since the constants of integration of all these curves are used, and, therefore, must be evaluated.

In solving a problem by beam diagrams, a choice must be made between the following procedures: (1) To apply a series of successive, straight integrations to obtain the equations of all curves; (2) to apply the first moment principle, repeatedly if necessary and desired, along with such successive integrations as are necessary to determine the constants of integration of the intermediate curves; and, (3) to apply the second or higher moment principle, along with the first-moment principle and successive integrations to determine the constants of integration of the intermediate curves.

It is futile, of course, to say that one procedure is better than the others, for one must bear in mind the possible complications accompanying the moment principles.

GARRETT B. DRUMMOND,[21] ESQ. (by letter).—There will be many who recognize in this paper another approach to the solution of beams; but it is certainly not remiss to search deeper and recognize another emphasis of the mathematical fundamentals of elasticity.

Consider the familiar expression of the calculus:

$$\int f(x)\ dx = y = F(x) \ldots\ldots\ldots\ldots\ldots\ldots (188)$$

which, with limits, becomes,

$$\int_a^b f(x)\ dx = F(b) - F(a) \ldots\ldots\ldots\ldots\ldots\ldots (189)$$

but $F(b)$ is the ordinate on the integral curve at $x = b$, and $F(a)$ is the ordinate at $x = a$; which leads to the statement which is the basis of graphical integration:

> The area under the derived curve between any two ordinates is equal numerically to the difference between the corresponding ordinates on the integral curve.

Assumptions (3), (4), and (5) of the paper are a consequence of the foregoing mathematical statement.

Papers such as this contribute to a broader viewpoint of the geometry of statics. It is not sufficient that designers be able to apply the so-called laws of mechanics without the facility of visualizing just what happens to a beam or other structure. The shear-area method provides another approach to that visualization.

Thus, the structural engineer is able to express the so-called mathematical principles in ordinary language. Shear being the sum of all the forces and the moment the sum of these forces times their distances from any given point, if the point is moved a short distance the moment will be increased by the shear times the distance. In addition, the rate of change of the shear is the unit intensity of the load.

In other words, if there are no loads on a beam, the shear across the beam is constant and the moment curve is a straight line. If all the loads on any span are in the same direction the shear in that span either has the same sign at all points or changes sign at one point in the span. Furthermore, the moment curve has a continuous slope in one direction or changes direction of slope at one point.

This geometrical conception of the action of any structure is fundamental, not only to statically determinate, but to statically indeterminate, structures. It has been stated that if a structure does not fail, it holds together. If that is true, continuity requires that there be certain geometric relations between its parts.

---

[21] Asst Prof. of Mathematics, Oklahoma Agri. and Mech. Coll., Stillwater, Okla.

These physical interpretations of mathematical statements should be stressed more and more to students. It is true that, often, a teacher of mechanics uses his integral calculus with a disregard for the true mathematical correctness of his juggling; but teachers of mathematics far too often advance mathematical laws without any effort to establish a link in the mind of the student with the more concrete evidences of their universal application. The authors have presented another demonstration of the relationship between derived curves and their integrals, and also have added to the geometrical analysis of the elastic functions of beams.

HAROLD E. WESSMAN,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Several writers of "engineering problems" texts have stated the general mathematical law of which the moment-area method and the shear-area method are special cases. In one text[23] appears the statement that:

> "In any curve, the length of the ordinate from the tangent to the curve at any point (called the first point) to any other point on the curve (called the second point) equals the algebraic sum of the moments of the areas between the ordinates of the corresponding points in the second lower curve, moments being taken about the ordinate through the second point."

Because this general law has such significance for engineers, one might expect to find it stated in some calculus text also. The writer has never seen an explicit statement of it, however, in the texts with which he is familiar. He is curious to know, simply for purposes of information, whether the authors have ever encountered it in any mathematical text. Teachers of calculus for engineers could well afford to give the general law more emphasis.

The special application of this law in the moment-area theorems of Mohr and Green is familiar to many engineers. The application *via* the shear-area concept of the authors is not so well known. That is not strange when one realizes that, in college, the embryo engineer is usually introduced to the double integration method of finding beam deflections, a method which begins by expressing the relationship between curvature and moment in the familiar equation, $\frac{d^2 y}{dx^2} = -\frac{M}{EI}$. He performs the calculus operations involved in solving this equation to find slopes and deflections. He is then, in many places, exposed to the moment-area method (often cluttered up with an imposing title) which parallels the calculus method, but which fortunately places the emphasis upon geometrical concepts.

In teaching the subject of deflections, the writer always portrays, geometrically, the five curves of load, shear, moment (or curvatures), slope, and deflection similar to those shown in Fig. 1, but he supplements these with a picture of a deformed segment of a beam. It is logical to reason geometrically from curvature of beams to deflections of beams. Since curvature at a point is expressed in terms of the moment at the same point, the moment-area method has some physical significance for the student. It does not seem quite so satisfactory to reason from the rate of change of curvature to the slope of the beam and then to deflection, even though in some cases it may be simpler to evaluate a triangular shear area rather than a curved moment area.

[22] Assoc. Prof. of Structural Eng. and Mechanics, Coll. of Eng., Univ. of Iowa, Iowa City, Iowa.

[23] "Engineering Problems Manual" by F. C. Dana and E. H. Willmarth, p. 46.

In the classroom, every teacher is confronted with the task of selecting the minimum essentials in this age of voluminous theory and with the importance of making those essentials clear to the student; hence, it is advisable, particularly in undergraduate work, to give the student the best possible tool and to make him familiar with that tool, rather than give him a nodding acquaintance with a variety of tools which have the same purpose.

This is not to be construed as a depreciation of the authors' paper. They have performed a service in presenting this special concept. Such contributions give the members of the profession an opportunity to weigh and then select that which is best suited for particular needs.

FANG-YIN TSAI,[24] ASSOC. M. AM. SOC. C. E. (by letter).—In applying the principle of moment areas to determine the slope and deflection in beams under flexure, two different methods are available. One is the so-called slope-deviation method introduced by Professor Charles E. Greene[25], of the University of Michigan, and the other is the elastic-weight or conjugate-beam method presented by H. H. Westergaard[26], M. Am. Soc. C. E., and by Professors Otto Mohr[27], and H. Müller-Breslau.[28]

In the slope-deviation method, the following two well-known theorems apply when a beam with a varying moment of inertia is subjected to bending:

1.—The angle between the tangents drawn at any two points on the elastic curve is numerically equal to the area of the $\frac{M}{EI}$-diagram between the ordinates at the two points; and,

2.—The deviation of any point from the tangent drawn at any other point on the elastic curve is numerically equal to the moment of the area of the $\frac{M}{EI}$-diagram between the ordinates at the two points about the first point.

The foregoing two theorems have proved very useful for determining the slope and deflection in beams, particularly when the point of zero slope on the elastic curve is known or easily found as in the case of a cantilever beam or a beam supported and loaded symmetrically. In the shear-area method, no such simple and elegant relationships exist between the shear-area and the slope and deflection as in the case of the moment-area method. Such relationships as these are prone to be so complicated and cumbersome as to have no practical value. The authors are to be commended for developing the shear-area method, not along the line of the slope-deviation theory, but along the line of the conjugate-beam theory (or "mathematical" beam, as named by the authors).

[26] "Deflection of Beams by the Conjugate Beam Method", *Journal*, Western Soc. of Engrs., Vol. 26 (1921), p. 369

[27] "Beitrag zur Theorie der Holz-und Eisen-Construktionen", *Zeitschrift* d. Arch. u. Ing. Vereines z. Hannover, Vol. 14 (1868), p. 19.

[28] "Beitrag zur Theorie des Fachwerks", *Zeitschrift* d. Arch. u. Ing. Vereines z. Hannover, Vol. 31 (1885), p. 418.

Although the foregoing discussion illustrates one of the disadvantages of the shear-area method as compared with the moment-area method, the use of the mathematical beam is not entirely satisfactory. In the conjugate-beam method of moment areas, the slope and deflection at any section of a given beam corresponds to (and also equals), the shear and moment, respectively, at the same section of the conjugate beam loaded with the $\frac{M}{EI}$- diagram of the given beam, provided the supporting conditions of the conjugate beam have been properly chosen in accordance with those of the given beam. For instance, if the given beam has a fixed support at a certain end, at which both the slope and deflection equal zero, the same end of the conjugate beam must be supported so as to have both the shear and moment equal to zero; that is, the end must be free. Table 2 gives the proper supporting conditions for a conjugate beam corresponding to those of the given beam. (The notation is that of the paper.) With the supporting conditions for the conjugate beam properly chosen in accordance with Table 2, the shear and bending moment curves of the conjugate beam will be identical with the slope and deflection curves, respectively, of the given beam, not only in magnitude, but also in sign if a proper sign convention has been adopted.

TABLE 2.—SUPPORTING CONDITIONS FOR THE CONJUGATE BEAM (THE MOMENT-AREA METHOD)

CASE	REAL BEAM		CONJUGATE BEAM	
1	Fixed	 $\phi = 0$ $y = 0$	 $V = 0$ $M = 0$	Free
2	Free	 $\phi \neq 0$ $y \neq 0$	 $V \neq 0$ $M \neq 0$	Fixed
3	Simple	 $\phi \neq 0$ $y = 0$	 $V \neq 0$ $M = 0$	Simple
4	Continuous	 $\phi \neq 0$ $y = 0$	 $V \neq 0$ $M = 0$	Hinge
5	Hinge	 $\phi \neq 0$ $y \neq 0$	 $V \neq 0$ $M \neq 0$	Continuous

The solution is very simple and straightforward, and the same procedure is equally applicable to beams with any supporting conditions and with the moment of inertia varying in any manner. No special devices such as the arbitrary introduction of two concentrated loads for the abrupt change in moment of inertia (Fig. 10) in the shear-area method are necessary.

In the shear-area method, the shear, bending moment, and slope at any section of the mathematical beam represent, respectively, the bending moment, slope, and deflection at the section of the real beam. As stated by the authors in Assumption (6), the supporting conditions of the mathematical beam must be determined in accordance with those of the real beam in the same manner as in the moment-area method. The writer has made a study of this phase of the problem the results of which are presented in Table 3.

TABLE 3.—SUPPORTING CONDITIONS FOR THE MATHEMATICAL BEAM (THE SHEAR-AREA METHOD)

CASE	REAL BEAM			MATHEMATICAL BEAM		
1	Fixed		$M \neq 0$ $\phi = 0$ $y = 0$	?	$V \neq 0$ $M = 0$ $\phi = 0$	?
2	Free		$M = 0$ $\phi \neq 0$ $y \neq 0$	?	$V = 0$ $M \neq 0$ $\phi \neq 0$	?
3	Simple		$M = 0$ $\phi \neq 0$ $y = 0$		$V = 0$ $M \neq 0$ $\phi = 0$	Two Rollers
4	Continuous		$M \neq 0$ $\phi \neq 0$ $y = 0$		$V \neq 0$ $M \neq 0$ $\phi = 0$	Fixed at Support
5	Hinge		$M = 0$ $\phi \neq 0$ $y \neq 0$		$V = 0$ $M \neq 0$ $\phi \neq 0$	Two Rollers

It is to be noted that the writer has failed to find the proper supporting condition for the mathematical beam (indicated by interrogation points in Table 3) to correspond with both the fixed and free ends of the real beam, since it seems impossible to devise an end-supporting condition with any physical meaning at which both the bending moment and slope will be equal to zero or not equal to zero at the same time. The authors have used a free end for the mathematical beam to correspond to the fixed end of the real beam, and *vice versa,* as shown in Figs. 8 and 9. This is incorrect. According to Assumption (5) of the paper, "the slope at any section of the mathematical beam represents the deflection at the same section of the real beam." At the free end of the mathematical beam the slope is not equal to zero; therefore, at the fixed end of the real beam, the deflection likwise must not be equal to zero, which is just opposite to the actual condition of a fixed end.

Similar inconsistencies may be cited against the authors' use of the fixed end for the mathematical beam to correspond to both the free and the simply supported end in the real beam. When the real beam has a simply supported end, at which $M = 0$, $\phi \neq 0$, and $y = 0$, the same end of the mathematical beam must be supported by two rollers in a vertical plane, as shown in Table 3, so that the corresponding values are $V = 0$, $M \neq 0$, and $\phi = 0$. Although, any value can be assigned, arbitrarily, to the shear, moment, and slope at any support of the mathematical beam, such a procedure will not only make meaningless the various types of conventional supports for the mathematical beam and the real beam, but will also cause serious confusion in the application of the method.

The conjugate-beam method of moment areas is based upon the similarity between the following two sets of well-known equations:

$$w = \frac{dV}{dx}\text{; and, } \frac{M}{EI} = \frac{d\phi}{dx}$$

and,

$$w = \frac{d^2 M}{dx^2}\text{; and, } \frac{M}{EI} = \frac{d^2 y}{dx^2}$$

Hence, if $w = \dfrac{M}{EI}$, then $V = \phi$ and $M = y$, the loading of the conjugate beam for finding the slope and deflection being the same. Similarly, the mathematical beam method of shear areas is based upon the similarity between the following three sets of well-known equations:

$$w = \frac{dV}{dx}\text{; and, } V = \frac{dM}{dx}$$

$$w = \frac{d^2 M}{dx^2}\text{; and, } \frac{V}{EI} = \frac{d^2 \phi}{dx^2}$$

and,

$$w = EI\,\frac{d^3 \phi}{dx^3}\text{; and, } V = EI\,\frac{d^3 y}{dx^3}$$

Hence, the loading of the mathematical beam for finding the bending moment and deflection is the V-diagram only, and that for finding the slope is the $\dfrac{V}{EI}$ - diagram, the loading of the mathematical beam for the three cases being thus not the same. In this connection, it may be also noted that Assumption (2) is not well founded, and that, if the V-diagram only is used as loading, the shear and slope at any section of the mathematical beam will not only "represent", but will also be numerically equal, respectively, to the bending moment and the deflection at the same section of the real beam.

Thus, despite the slight advantage in that the shear diagram is usually a somewhat simpler figure than the moment diagram for the same loading, the shear-area method has many inherent disadvantages as compared with the moment-area method.

David A. Molitor,[29] M. Am. Soc. C. E. (by letter).—In their attempt to popularize the shear-area method of analyzing beams, the authors have not presented a very convincing claim for simplicity. Although it is true that shear diagrams are more easily drawn than moment diagrams, it does not follow that the former afford any material advantages over the latter in solving structural problems. Slopes and deflections are more directly derivable from moments than from shears, for which reason the shear-area method has not received much consideration.

In the stress analysis of simple beams or frames involving redundancy, the stresses are always evaluated from the moments at the critical sections to be analyzed. Therefore, the simplest and most direct method of approach is to deal with moments first, last, and all the time. The derivation of shears from known moments is relatively easy, whereas the reverse operation is attended with more difficulty. The slope of the elastic curve can be deduced from the moment curve by the method of area moments, without resorting to shear areas, by remembering that the slope at any point of a moment curve is represented by the moment derivative for that point. This is expressed in mathematical terms by the formula,

$$\frac{dM}{dx} = \tan \beta \quad \text{..........................} (190)$$

in which M is the moment at any point, m, acting over a small increment of beam length, dx, and β is the slope angle of the moment curve; but $\frac{dM}{dx} = V$ is the shear at the point, m, where the moment is taken.

By area moments, the deflection, y_m, at the point, m, is equal to the moment of the elastic weights, $M\ dx$, about the point, m, divided by $E\,I$. Therefore, the shear of the elastic weights on one side of the point, m, divided by EI, must equal the tangent of the slope angle to the elastic curve at the point, m. It should be noted that the elastic weights for negative moment areas are likewise negative.

By the same reasoning, the tangent of the slope angle of the elastic curve at any end support, A, must equal the end shear of the moment area, or the end reaction of the elastic weights divided by EI. Hence, calling V_m the shear of the elastic weights on one side of the point, m, of any beam, and R_a, the end reaction of the elastic weights at the support, A, the tangent of the slope angle, ϕ_m, of the elastic curve at the point, m, becomes:

$$\tan \phi_m = \frac{V_m}{EI} \text{..........................} (191)$$

and the end slope at the support, A, becomes:

$$\tan \phi_a = \frac{R_a}{EI} \text{..........................} (192)$$

---

[29] Structural Engr., Procurement Div., Public Works Branch, U. S. Treasury Dept., Washington, D. C.

Equations (191) and (192) are applicable to either the graphic or the analytic methods of area moments. When the moment of inertia is variable, the elastic weights should be chosen as $\frac{M\,dx}{I}$ instead of $M\,dx$.

It is regrettable that the authors introduced the term "mathematical beam" without giving a precise definition, and also that they referred to what they term the conjugate beam method instead of simply the method of elastic weights. It seems inconsistent to attach qualifying terms to the beam itself, merely because it may be loaded either with actual loads, with moment areas, or with shear areas treated as elastic weights. More properly, the distinction should relate to the method of loading and not to the nature of the beams, which remains unchanged.

The authors have wisely limited their application of the shear-area method to beams. In dealing with rigid frames, the method could scarcely find favor when compared with the universal and elegant solution afforded by the use of Mohr's work equation.

F. Muls-Guinotte,[30] Esq. (by letter).—The well-known theorem which states that the shear diagram may be obtained by the successive derivatives of the elastic curve, is the basis of this paper. The theory of beams on elastic foundations is based on the principle that a fourth derivative of the elastic curve gives the loading diagram. The authors give the value of the successive derivatives in Fig. 1 of the paper, making the implicit assumption that the moment of inertia is constant. This assumption is not necessary. It is quite easy to obtain the elastic curve starting from the loading diagram when the rule of successive derivatives is written, as follows: $\frac{dw}{dx} = \phi_x$; $\frac{d\phi_x}{dx} = \frac{M_x}{E\,I_x}$ $\left(\text{or } M_x = E\,I_x\,\frac{d\phi_x}{dx}\right)$; $\frac{dM_x}{dx} = T_x$; and, $\frac{dT_x}{dx} = p_x$.

This suggestion for developing the p_x-diagram indicates how the equation of the elastic curve may be solved in the general case of a variable moment of inertia.

The variable loading of a tapered beam is shown in Fig. 48(*a*); the first integration yields the shear diagram (Fig. 48(*b*)); and, the second integration results in the moment diagram (Fig. 48(*c*)). If the latter curve is divided by the product, $E\,I$, at successive ordinates the resulting curve represents the M-function (Fig. 48(*d*)) which, when integrated, produces, successively, the slope curve (Fig. 48(*e*)) and the deflection curve (Fig. 48(*f*)).

It is also of interest to show the results of deriving the diagram of moments when the elastic beam is a curved one. Suppose, first, that there are no forces applied on the element, ds (Fig. 49), which is then kept in equilibrium by the forces, M, T, N, $M + d\,M$, $T + d\,T$, and $N + d\,N$. For the condition, $\Sigma M = 0$:

$$d\,M + T\,\Delta\,s\,\cos\Delta\,\theta + N\,\Delta\,s\,\sin\Delta\,\theta = 0$$

---

[30] Asst. in Univ. of Liége, Liége, Belgium.

for $\Sigma N = 0$:

$$N - (N + dN) \cos \Delta\theta - (T + dT) \sin \Delta\theta = 0$$

and, for $\Sigma T = 0$:

$$T - (T + dT) \cos \Delta\theta + (N + dN) \sin \Delta\theta = 0$$

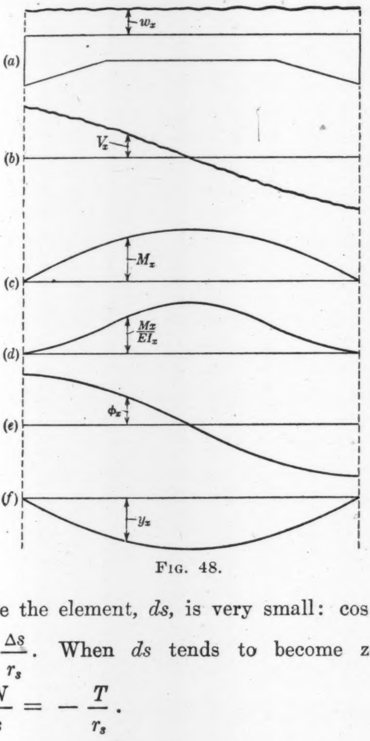

FIG. 48.

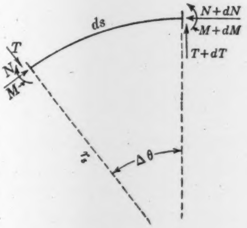

FIG. 49.

Since the element, ds, is very small: $\cos \Delta\theta = 1$; $\sin \Delta\theta = \Delta\theta$; and, $\Delta\theta = \frac{\Delta s}{r_s}$. When ds tends to become zero; $\frac{dM}{ds} = T_s$; $\frac{dT}{ds} = + \frac{N}{r_s}$; and, $\frac{dN}{ds} = - \frac{T}{r_s}$.

The coefficient, $\frac{1}{r_s}$, may be eliminated by using a derivative with respect to the variable, θ, instead of the variable, s. With this elementary change: $\frac{dN}{d\theta} = - T$; and $\frac{dT}{d\theta} = N$. Consequently, it is possible to define a rule by which the moment curve can be derived successively. Assuming that $T = \psi_s$: $\frac{dM}{ds} = \psi_s$; $\frac{d\psi_s}{d\theta} = N$; $\frac{d^2\psi_s}{d\theta^2} = - T$; $\frac{d^3\psi_s}{d\theta^3} = - N$; $\frac{d^4\psi_s}{d\theta^4} = T$; $\frac{d^5\psi_s}{d\theta^5} = N$; etc., and $\frac{d^{4n}\psi_s}{d\theta^{4n}} = T$; $\frac{d^{4n+1}\psi_s}{d\theta^{4n+1}} = N$; etc.

The foregoing properties of the successive derivatives may yield results of particular interest in the study of influence lines.

When external forces occur on the section of beam analyzed the components along the normal or the tangent appear in the equations of equilibrium. These components are easily introduced, and, in the case of radial forces, special and simple results are obtained.

HORACE B. COMPTON,[31] ASSOC. M. AM. SOC. C. E., AND CLAYTON O. DOHRENWEND,[32] JUN. AM. SOC. C. E. (by letter).—The shear-area method was presented to enlarge on the usual methods for the solution of slopes and deflections in beams. It was stated that the method was particularly adapted to those problems which involve distributed loads (when compared with solutions by the moment-area method) and still would solve other problems readily. Solutions which consider variation in the moment of inertia of the beam sections are probably obtained with a greater degree of safety by the moment-area method.

Since it appears that the engineer remembers the procedure for the solution by the conjugate beam for slopes and deflections better than by the slope-deviation method, the mathematical beam was introduced.

In most cases the tendency of the commentators has been to follow the very well known and common solutions of moment area and not to discuss the subject in question. Discussions of simple problems by the moment-area method need no further comment. However, in contrast, Professor Kepner with a few others has added materially to the subject.

The end slopes of the shaft indicated by Mr. Fischer may be solved by writing deflection equations about the ends of the shaft; thus, about the right end, $y = 0 = \phi_L\, L - \frac{1}{2}\, I_L$ by Equation (7). Therefore:

$$E\,\phi_L\, 60 - \frac{1}{2}\Big[56.5 \times \frac{23^3}{12} + 56.5 \times 23 \times 48.5^2 + 14.71 \times \frac{5^3}{12} - 961.2 \times 37^2$$

$$+ 14.71 \times 5 \times 34.5^2 - 2.27 \times \frac{12^3}{12} - 2.27 \times 12 \times 26^2 + 1\,072 \times 15^2$$

$$- 19.24 \times \frac{5^3}{12} - 19.24 \times 5 \times 17.5^2 - 90.68 \times \frac{15^3}{3}\Big] = 0$$

and $\phi_L = \dfrac{16\,474}{E}$. Mr. Fischer has indicated a similar procedure by letter. This method shortens the problem by the shear-area method considerably. The difficulty of Mr. Peck's problem can be overcome in the same manner.

The writers wish to express their appreciation for the constructive criticism offered by Professor Kepner, especially for demonstrating, by the use of Equation (7), a short method for obtaining end slopes. In correspondence submitted directly to the writers, Mr. Stewart suggested the following for the problem solved by the conjugate beam method in Mr. Beatty's discussion:

$$\phi_L = \frac{1}{E\,I}\,[2\,400 \times 12 + 1\,800 \times 8]\;144 = \frac{6\,220\,800}{E\,I}$$

---

[31] Asst.. Prof. of Mechanics, Rensselaer Polytechnic Inst., Troy, N. Y.

[32] Instr., Dept. of Civ. Eng., Rensselaer Polytechnic Inst., Troy, N. Y.

It is evident that the solution for the reaction can be given in a somewhat simpler manner than that indicated by Mr. Beatty by considering the area of *BCDGB* (Fig. 40(*c*)) as two-thirds of a rectangle with dimensions, *BG* and *GD*.

In the discussion by Messrs. Johnson and Birkeland it is inferred that there is no difference in the work necessary to solve the first moment of the moment area, or the second moment of the shear area, because in the two cases the integrations are comparable. This inference is not supportable except in deriving the two cases, since the use of the cases is not by integration directly, but by replacing the integration with equivalent expressions. The mathematical demonstrations given, showing the relations between the functions is very complete, but the following formula, due to Lejeune Dirichlet:

$$\int_a^b dx \int_{y_2}^{y_1} f(x, y)\, dy = \int_c^d dy \int_{x_1}^{x_2} f(x, y)\, dx$$

necessary in the solutions shown, is not common enough to engineers to use without some explanation. If more emphasis had been given to specific cases the following statement would have been considerably modified: "The method does not seem to be readily adaptable to any but the most simple beam problems such as statically determinate, constant section cases with uniformly distributed load."

Most of the apparent difficulties encountered by Professor Tsai will be clarified if it is recalled that the mathematical beam is hypothetical and has slope with no deflection. The loading of the mathematical beam is the shear diagram; the first moment yields the slope of the given beam only when divided by EI, and the second moment or moment of inertia gives deflection of the original beam only when divided by $2EI$. This means that for the two cases mentioned, the diagram on the beam can be considered as the shear divided by EI.

FLOOD-STAGE RECORDS OF THE RIVER NILE

By C. S. Jarvis,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Halbert P. Gillette, R. W. Davenport, H. E. Hurst, Thomas H. Means, J. W. Beardsley, J. C. Stevens, Jesse W. Shuman, Kamel Osman Ghaleb, and C. S. Jarvis.

Synopsis

The need for longer hydrographic records than are now available on American streams, as disclosed by recent investigations dealing with floods and their various characteristics, has led the writer to a study of the records of foreign rivers. The paper affords only a brief summary of outstanding records or evidences regarding stream-flow trends of European and Asiatic rivers, and then undertakes the presentation of stages of the Nile River at the Roda gauge, in Cairo, Egypt, covering a period of thirteen centuries. Additional data, such as those procured at Aswan, dealing with both stages and volumes, and various versions of divergent data, are added to make the graphic representation as nearly complete as is practicable on one continuous chart. No attempt is made at this time to evaluate the data, as they are too numerous and complex to permit ready appraisals. The main purpose is a presentation of records, or some kind of derivation from actual observations, as a preliminary to further study by the profession.

General Considerations

The study of flood frequencies and magnitudes by the United States Geological Survey in collaboration with, and under the sponsorship of, the Mississippi Valley Committee and its successor, the National Resources Board (Water Planning Committee), has advanced some interesting information relating to long-period records of river stages. These records were investigated with a view to furnishing a background for the interpretation of available hydrographic records in the United States, most of them covering relatively short periods.

Note.—Published in August, 1935, *Proceedings*.

[1] Hydr. Engr., Soil Conservation Service, Washington, D. C.

A few American flood records extend intermittently into the Colonial era —notably the Ohio River, at Pittsburgh, Pa., and the James, Roanoke, Delaware, Mississippi, and other rivers at or near tide-water. In this manner a sketchy and somewhat uncertain notion may be derived as to the comparative river stages, or the corresponding discharges, where the channel sections and controls have not changed materially; but at best a period of only about 200 yr may be thus covered in this country from written records or satisfactorily authenticated marks.

The study of drift or débris deposits, the heights of mounds distributed along the flood-plains of rivers and presumably intended as islands of refuge (as on the Lower Mississippi and in the Nile Delta), the character of trees and other vegetation along various contours, the evidences of either channel scouring or filling, and consideration of other prominent geologic and geomorphic features may add significant items of information relating to the occurrence of floods in the past, possibly within a few hundred years.

What can be said more definitely of such floods as have left their marks, and of similar contemporaneous events of equal importance that have left no physical effects or record marks clear enough for recognition and separate interpretation? Some investigators have expressed the opinion that a continuous record of stages on a large stream, over a period of 500 or 1 000 yr, for example, might indicate more definitely the trends and cyclic or other recurrent periods of stages above or below normal than several shorter records of equal or greater aggregate length. Before such long-period records of foreign streams can serve a useful purpose most effectively, account must be taken of the differences in physical factors as affecting run-off habits. This applies particularly in the present study, which concerns flood frequencies and magnitudes, to those influences that would either retard, accelerate, augment, dissipate, or otherwise change, the discharge habits of the stream or modify the discharge capacity of the channel. Thus, the regimen of a river may be affected by: (*a*) Changes in the vegetative cover of a drainage area; (*b*) erosion; (*c*) increase or decrease of natural or artificial storage either in basins or on flood-plains; (*d*) diversion to other drainage basins by either natural or artificial means; (*e*) restriction of the river channel by levees; (*f*) facilitation of flow by dredging and removal of obstructions; or (*g*) formation or abandonment of auxiliary channels and by-pass areas. Furthermore, any one of Items (*a*) to (*g*) is likely to interfere with satisfactory interpretation of records.

What is more important, available human experience is often capable of making fairly intelligent approximations of such influences, as, for example, by recognizing that one factor may be additive, another may be subtractive, and the algebraic sum may be of small amount. Thus, it has been shown for several stations on large foreign rivers, and on the Upper Mississippi River, that the dredging of bars, removal of snags and other obstructions, rectification of alignment, and improvement of the hydraulic elements of the channel, tend to lower the river surface; whereas channel encroachments and the development and protection of great areas among the natural flood-plains cause a corresponding rise of stage. The actual effect is the resulting difference of these two factors, normally lowering the stages of low water and raising the stages of high water, the net effect being to increase the range of variation in stages, except where regulation works are used to produce opposite effects.

Flood Records of Rivers in Europe

Among the rivers of Europe, the Thames, the Seine, the Rhine, the Rhône, the Loire, the Po, and the Danube seem to afford the best information. It is realized that the progressive changes which these river channels and drainage systems have undergone may vitiate, more or less, the close comparability of stages as indexes of flood magnitudes over long periods; nevertheless, the study of outstanding flood catastrophes should afford a valuable record of experience. The floods of the Rhône, the Loire, and the Seine Rivers in the years 563, 572, and 583 A. D., respectively, have been described briefly in available records. Thereafter, until about 1 000 yr later, the published fragmentary data are qualitative rather than quantitative; certain outstanding inundations, which were equal to or worse than others, are designated by date or by year of occurrence. The usual standards for comparison seem to have been based on loss of life and damage to property, and in this connection the suddenness of flood rise without warning played a prominent part; therefore, the floods at unusual or unexpected seasons would naturally be mentioned.[2]

Within the last 300 yr the quantitative or magnitude relations of floods have entered into the records of European streams. Thus, the foregoing references, together with those listed by Kuichling,[3] show that the flood in the Seine River Valley on January 28, 1910, and that of February 27, 1658, at Paris, were of approximately the same stage (8.40 m and 8.81 m, or 27.6 ft and 28.9 ft, respectively, above the zero of the Pont de Tournelle); and that the maximum estimated discharges were of a similar order (88 300 and 84 500 cu ft per sec, respectively). The greater volume and lesser gauge height thus applied to the flood crest of 1910. No other floods on the Seine during a period of nearly 300 yr approached within 15% of the maximum recorded for 1910. The catastrophic occurrences during the period, 683 to 1658, A. D., probably included several of nearly the same order, to judge from descriptive accounts of complete submergence of homes, undermining of bridges and other structures, and general devastation, including the demolition of fortification walls during the flood and the accompanying earthquake. The question naturally arises as to whether the recorded earth tremors were the cause or the effect of the structural collapse.

The year 1012 A. D., witnessed intense rainfall and the "great flood" of the Danube River at Vienna; likewise, along the River Rhine, homes were inundated, and a multitude of people and their live stock were destroyed. The margins of forests intruding into the flood-plains were wiped out during a catastrophe that was without parallel in all the preceding history of that region. Prior to 1012 A. D., as in present times, the sub-normal river stages of successive years created a false sense of security that left the people unprepared for the eventual torrent.

E., *Engineering News*, October 29, 1908, p. 467 (discusses report of Ernst Lauda, Chief of the Hydrographic Bureau of the Austrian Government (Hydrographischen Dienst in Osterreich: Beitrage Hydrographic Osterreichs, Heft 4, pp. 155–162, Wien, 1900)): "Le Seine," par E. Belgrand, Inspector General Ponts et Chaussées, 1869, (Includes a discussion of notable floods beginning with 1649): and *Engineering News*, Vol. 63, p. 327, 1910.

[3] "Flood Flows," by W. E Fuller, M. Am. Soc. C. E.: discussion by the late Emil Kuichling, M. Am. Soc. C. E, *Transactions*, Vol LXXVII (1914), p. 643.

The Danube flood of 1342 was reported to have caused the loss of 6 000 human lives. In the flood of 1501 on the Danube several marks were established on monuments and are still preserved as permanent records. Comparison of this event with another devastating flood, in 1899, at fourteen stations in the same valley, shows that the range above low-water stage was 7.24 to 16.58 m (23.8 to 54.4 ft) in 1501 and only 6.52 to 13.18 m (21.4 to 43.2 ft) in 1899, the lower stages perhaps being due in part to channel improvements in the interest of navigation.

The scattered references in early records show that flood heights above either normal or low-water stages are so nearly comparable with those of later centuries as to give support to the opinion that no radical progressive changes of intensities or frequencies of floods and droughts have taken place in historic times on any extensive river systems, except as logical consequences of regulation, diversion, utilization, or other activities of Man. On the other hand, no direct proof is available regarding the trends of climate and rainfall throughout historical periods, such evidence as exists being based on considerations other than physical measurements. On extending the period considered into geologic time, however, it is indisputably established that marked changes in both temperature and rainfall have taken place by gradual processes.

Flood Records of Rivers in Asia

Traces of irrigation, regulation, channel-training, and flood-protection works have survived from early centuries of historical epochs in various civilizations, or even from times before the earliest records now available for some countries, particularly in Asia. These remnants of a past civilization seem to supply indisputable proof of a long-continued similarity of climatic, rainfall, and run-off habits. The only possible explanation and justification for such engineering works must be found in deficient local rainfall and in reliable stream flow, even when the discharge was flashy and irregular. This combination of circumstances presumably reflects the occurrence of storms among the head-waters and intervening catchment areas, or the thawing of snow and ice accumulations.

The records of several Asiatic rivers, although enveloped in vagueness, extend back to remote periods of history. Thus, the series of irrigation canals in Mesopotamia, with combined original capacities much greater than the reliable flow of the Euphrates and Tigris during recent times, do not necessarily betoken a shrinkage of water supply since they were built. According to opinions of engineers who have studied the situation on the ground,[4] new canals were established as the irrigated tracts under the older projects became water-logged and overcharged with alkali, for want of systematic drainage, as often happens under modern practice. The important facts to note, however, are that the rainfall was deficient throughout the historical period of Babylon, Nineveh, and neighboring cities, and that the rivers were both fairly stable and reasonably tractable, to permit such bridging, navigation, and diversion for irrigation at that time. It is plain that irrigation was found necessary to raise crops and to sustain life in that country, and that the rivers were fairly reliable sources of supply. During the festival in November, about 539 B. C., Cyrus, the Persian, captured Babylon by the simple expedient of diverting the Euphrates River into the desert through one or more canals and marching his troops through the walls along the channel thus made available. This feat is quite consistent with the known habits and volume of discharge of the Euphrates as observed during the Nineteenth Century.

---

[4] "Euphrates River and Valley," by Francis Rawdon Chesney, Lond., 1868

Confirmatory evidence concerning both the variations and the stabilization of water resources lies in the rainfall records extending back more than 200 yr at a few stations, mainly in Europe, and considerably more than 100 yr at many other places. These records parallel the meager hydrographic records, and both sources furnish valuable interrelated and, therefore, mutually supporting data.

Tradition and history combine to give descriptive accounts of notable floods and droughts in India and in China. The 1930 report of the Huai River Commission, Bureau of Engineering,[5] lists the floods of 1649, 1741, 1879, and 1921 as the outstanding ones on this important northern tributary of the Yangtze River. They were measured indirectly by the extent of the inundation on populated land, the total number of "districts" inundated being reported as 5, 11, 6, and 10, respectively, whereas the usual damaging inundations affect only 3 or 4 such districts. With all available data before it, the Commission adopted the flood of 1921 as the basis for designing the Huai River regulation. Presumably, this decision was not entirely due to the high discharge rate, but also to the sustained volume, which was reported as having inundated 11 740 sq km (4 533 sq miles) to a depth of 1 to 4 m (3.3 to 13.1 ft). It is noteworthy that the expected 100-yr flood on the Huai derived from a study of rainfall, is 15 500 cu m per sec, whereas Fuller's formula gives only 11 700 cu m per sec. Reduced to English units, these rates become 548 000 and 414 000 cu ft per sec, respectively, or 8.55 and 6.46 cu ft per sec per sq mile. The maximum recorded flood discharge, which occurred in 1916, was 12 900 cu m per sec (455 000 cu ft per sec, or 7.10 cu ft per sec per sq mile), perhaps representing a 30 or 35-yr average frequency. The failure of levees during the more severe flood of 1921 prevented even approximate measurement of the maximum discharge.

THE RIVER NILE IN EGYPT

It is freely admitted that the foregoing brief references to available long-period river-stage records and to what these data seem to show, should be supplemented by further research in this inviting field perhaps in a separate paper. The presentation of fairly complete river-stage data, so far as they are now available and capable of interpretation, is limited herein to the Nile River, in Egypt. (See Fig. 1.)

---

[5] "Projects of Flood Control and Irrigation for the Huai River System," Official Tech. Rept. 1, p. 23, Huai-Yin, China, 1930.

The nilometer records are most notable with respect to antiquity, continuity, and permanence. The annual inundation of the Nile Valley in the late summer generally supplied enough moisture to the soil to insure fair crops in the fall and winter. A subnormal flood meant restricted plantings and deficient harvests; and well-sustained high water, at or above "wafa" —the stage insuring plenty—meant bounteous crops on more and more of the fertile alluvial land, as long as the stage did not overtop the protective works and islands of refuge. Thus, it happened that the most important annual event in Egypt was the Nile flood; and, therefore, records were engraved on the cliff walls in various places, notably at Semna, a section of the Second Cataract. In this locality, 179 distinct markings have been discovered dating back to about the 12th Dynasty; that is, 1 750 to 1 800 yr B. C., or earlier. Of these markings 18 on the west bank are about 8 m, or nearly 27 ft, above the flood range of recent centuries, but the difference probably reflects to a considerable degree the erosion in both channel walls and floor and does not necessarily indicate any pronounced or progressive change in discharge from century to century.

On that fragment of an ancient inscribed monument known as the "Palermo stone," because it now reposes in the Palermo Museum, in Sicily, there are notations regarding the successive ruling monarchs of the first five dynasties, dating back to between 3 000 and 3 500 yr B. C.; there are also records of such important events as military campaigns and public festivals. These notations include mention of the rise of the Nile during several consecutive years, apparently recording a range between 1 and 8 cubits (2 to 14 ft) somewhere in the Delta,[6] but with gauge readings usually about midway. Although it is difficult to tie these records to any particular section of the Nile Valley, they establish the importance of the Nile flood in making Egypt the never-failing storehouse of grain for export, especially in periods when droughts and famine prevailed in neighboring countries. Likewise, they indicate the irregular distribution of flood heights over a range quite comparable with that observed in the past century, prior to the construction of large regulative works.

Fortunately, several sections of nilometers, at various points along the stream channel, have been discovered, and their inscriptions have been deciphered and correlated. Capt. H. G. Lyons[7] states that the height above sea level of corresponding points of the ancient nilometers in Egypt and Nubia have been determined with the aid of bench-marks of the Irrigation Department, and that the zero points of the nilometer scales were found to lie in a line inclined to the north. In Nubia, according to Lyons, the line is sensibly parallel to the water slope, but north of Aswan it is considerably less inclined than the flood slope. As a consequence, a flood was indicated by a higher reading on the nilometer at Aswan than on that of Roda, at Cairo. This is offered as an explanation of the statement found in the Egyptian inscriptions and the works of the Greek and Roman authors that, in very good years, the Nile River rose 28 cubits (46.5 ft) at Elephantine, 21 cubits (36.12 ft) at

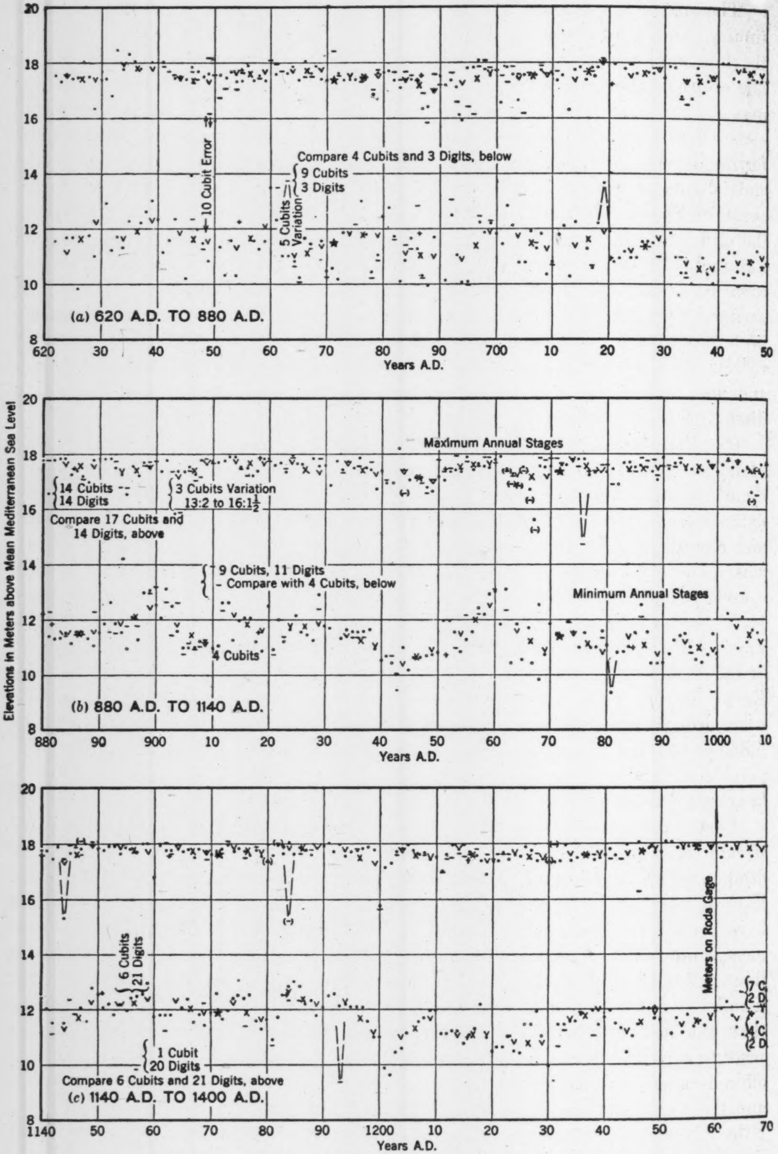

FIG. 1.—MAXIMUM AND MINIMUM STAGES OF THE

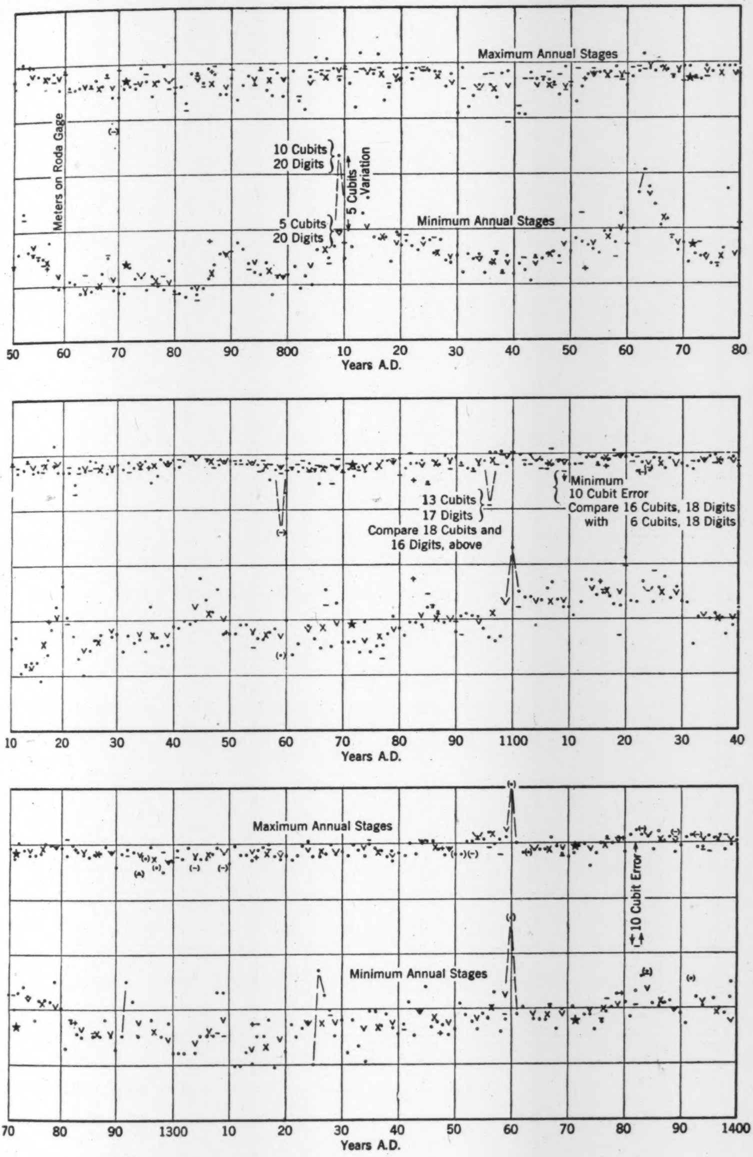

NILE RIVER IN EGYPT, FROM ALL AVAILABLE RECORDS

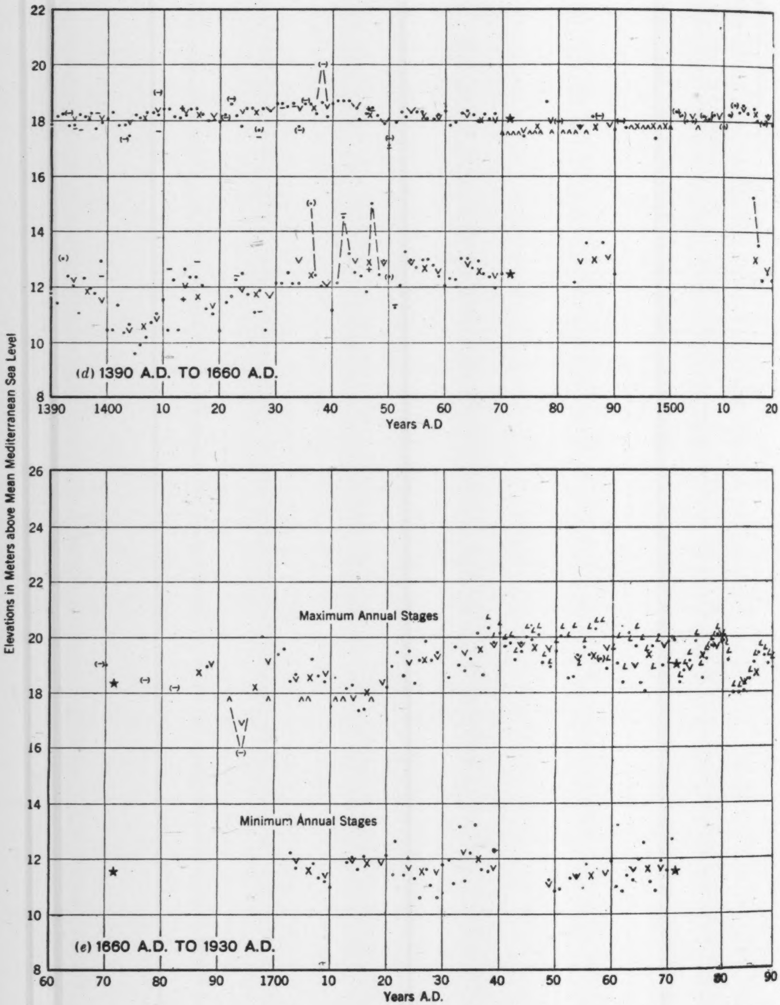

Fig. 1 (*Continued*).—Maximum and Minimum Stages of

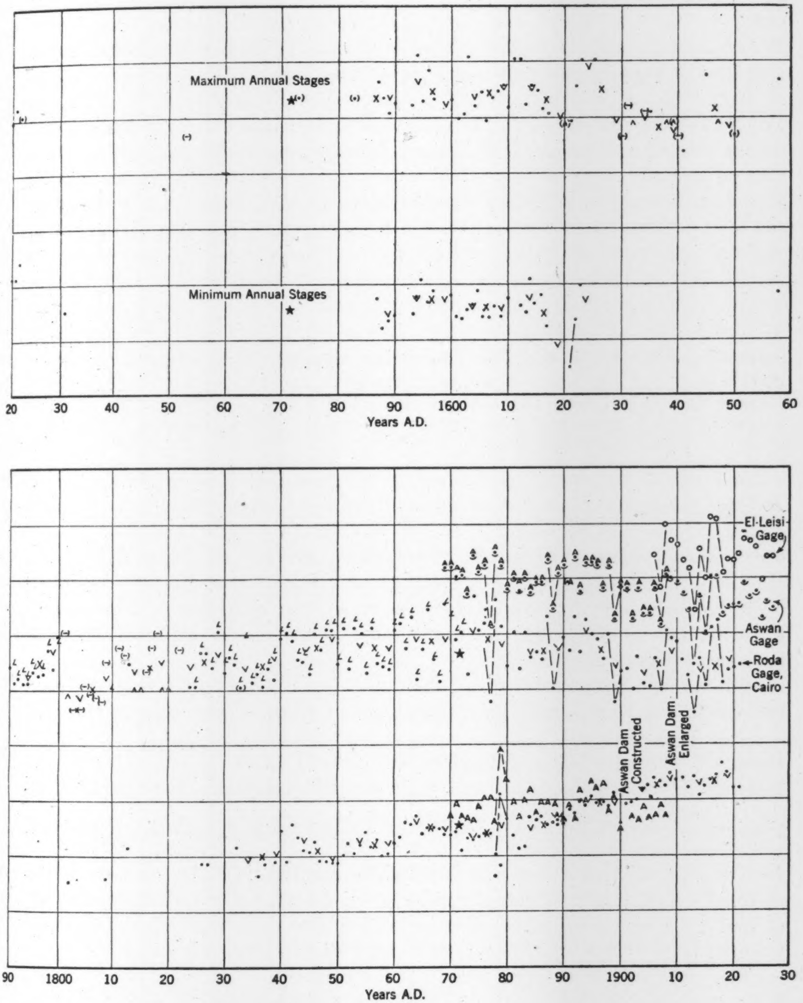

THE NILE RIVER IN EGYPT, FROM ALL AVAILABLE RECORDS

Koptos, 14 cubits (24 ft) at Roda, and 7 cubits (12 ft) in the Delta. The altitude of the zero point of the ancient nilometer at Roda may be obtained approximately from the slope of the line determined by the zero points of the remaining nilometers. After computing the secular rise of the bed one can conclude that the flood levels about 3 000 B. C. (which are recorded on the Palermo stone) and the later data concerning Nile floods given by the Greek and Roman authors agree well with those of to-day.

From the evidence he studied, Lyons was convinced that about 100 A. D. the Nile often rose to 24 cubits (41 ft) and sometimes to 25 cubits (43 ft) on the nilometer scale on Elephantine Island, at Aswan, below the First Cataract so that the high floods of that time reached the level of 91 m (299 ft) above sea level. In 1874 they reached 94 m (308 ft), or 3 m (10 ft) above the level of about 1 800 yr earlier, which corresponds to a rise of the bed of 0.17 m (6.7 in.) per century at this point. If the mean flood level of the period, 1870 to 1906, is taken, the height becomes 93 m (305 ft) and the rise, 0.11 m (4.3 in.) per century. Quoting Lyons:[7]

> "At Karnak in 1895 M. LeGrain found a series of 40 high Nile levels marked on the quay walls of the great temple. They date from about 800 B. C., and the mean altitude given by them for a high Nile is 74.25 meters [243.60 ft] above sea-level, while that of today is 74.93[8] [1906], showing a rise of the river-bed of 2.68 meters [8.8 ft] in 2 800 years, or at the rate of 0.096 meters [3.8 in.] per century."

In 1935, 76.93 m (252.3 ft) seems to be a better elevation than that reported by Lyons (74.93 m, or 245.8 ft) in 1906. If 0.15 m (5.9 in.) in a century is assumed as the average rate of rise of the Nile flood-plain, due to overflow and sedimentation, the 10-m (33-ft) average thickness of observed alluvial deposits might represent about 67 centuries of growth. Other methods of reckoning based, for example, on the maximum thickness of sediment, or the extension of the delta seaward, almost invariably indicate much longer periods of geomorphic development.

Similar conclusions regarding the rate of sedimentation follow the comparison of maximum flood height during the reign of the Roman Emperor Severus (about 200 A. D.), and the maximum flood mark noted by the French savants during the Napoleonic Invasion, in 1800 A. D., was 2.11 m (6.9 ft) higher.[9] If those two floods and their available channels were comparable, the rate of aggradation of the Delta was $\frac{2.11}{16} = 0.132$ m (5.2 in.) per 100 yr. Incidentally, that rate seems to be slightly greater than the rate of erosion at the First Cataract, about 600 miles above Cairo, derived by a comparison of maximum flood crests, on the assumption that they were of almost equal magnitude near the beginning and the end of the last 1 900 yr.

The durable outcropping ledge of Syene granite (syenite) forming the First Cataract, at Aswan, from which great obelisks and other monuments were quarried for Lower Egypt and eventual transfer to other countries, accounts for the relatively slight erosion here compared with 8 m (26 ft) in about 3 700 yr, or an average of 0.22 m (8.7 in.) per century, at Semna, on the Second Cataract, where the outcropping stone is not so durable and where sandstone or other sedimentary formations predominate along the canyon walls.

---

[8] 74.25 + 2.68 = 76.93 m which presumably was intended.

[9] "The Nile in 1904," by Sir William Wilcocks, p. 48.

The only long-period continuous records now available for the Nile relate to the Roda gauge, at Cairo. There is fair assurance that the gauge datum has been maintained throughout the thirteen centuries of record without change, unless the Temple of Roda, in which the nilometer column is located, has settled into the alluvium. The depth of the temple foundation, and the tradition that the gauge which was used throughout most of the Arabian epoch and thereafter, was referred to the datum and site of a much older structure, are items of evidence tending to insure the stability of the foundation.

Incidentally, the graduation of the masonry column into plainly marked cubits, with the zero of the scale somewhat lower than was ever attained (according to the available records) in the 1 300 yr following 622 A. D., is indirect evidence of its antiquity, if the zero represented the lowest previously observed and recorded stage. During the first 1 000 yr of this record the lowest annual stages approached within about 2 ft of the zero only five or six times, depending on which tabulation is adopted; but in 1531 and in 1621 the recorded low stage was only 9 digits, or 8 in., above the zero. Moreover, the graduations between the sixteenth and twenty-second cubit marks on the column are half cubits, whereas above 22 cubits (38 ft) they resume the full measure. This is explained by Lyons on the ground that the canals were opened at 16 cubits (27.5 ft), as was customary at the beginning of the Arabic epoch, about 641 A. D., and a half-unit rise at Roda meant a full-unit rise above the canal diversions; but at 22 cubits, the irrigation basins were ordinarily full, and no further diversion was necessary. As a further assistance in visualizing the units of the paper, roughly, in terms of their English equivalents, Fig. 2 includes three general conversion scales.

It is understood that most of the records had a common origin, but the originals are not known to exist at the present time. There are various versions of parts of the records, transcribed by different authors either from the original documents or from other transcriptions. Volumes 4 and 9 of the *Memoirs* of the Institute of Egypt (published in French by Prince Omar Toussoun during the period, 1923 to 1925) afford three different sources of data, all more or less interrelated, yet not identical. Ibn Iyas and others have compiled voluminous textual notes, which appear in part in Volume 9 of the *Memoirs* and from which many data may be derived for various years from 769 to 1878 A. D. Some of these data confirm similar figures in tabulated form; others differ; and still other significant notes make cross-references that agree with previous records and supply data for many years which are omitted in the tabulations.

The record of Aboul Mehasin in Volume 4 of the *Memoirs* extends from the year 20 to 855 of the Hegira, or 641 to 1451 A. D., but all according to Mohammedan years of 12 lunar months, which are thus 11 days shorter than the solar years. Therefore, there are 103 yr per century of the present-day mode of reckoning. The longer tabulation published in Volume 9, in

1925, or two years later than that of Aboul Mehasin, gives 1 108 maximum annual stages and 1 025 corresponding annual minima during the 1 300-yr period from 622 to 1921 A. D.

There would be definite advantages in publishing these tabular data, in pics and kirats, coudees and doights, or cubits and digits, according to the various transcriptions, with their equivalents, in meters, above mean sea level; but they are too voluminous to present in this manner, especially for all three main sources of data mentioned herein. The use of a chart on which all the data could be shown, and their trends compared, century by century, by connecting successive century or other averages of maximum or minimum stages, has seemed to be a more acceptable method of presentation. Naturally, the longer tabulation, representing the latest and most nearly complete version of available data regarding Nile River stages, was adopted as the one to be given preference.

In Fig. 1, the various plotted points may be identified as follows:

Applying to All the Records:

v = five-year average for the data shown by dots, supplemented by – or (–) when the location of the dot is not given;
× = ten-year average for data shown by dots, supplemented by – or (–) when the location of the dot is not given; and,
★ = one hundred-year average.

Applying to the Roda gauge, at Cairo:

• = records compiled by Omar Toussoun[10] covering the 1 300-yr period from 622 to 1921 A. D.;
(•) = confirmation from textual notes for the records compiled by Omar Toussoun; when – is lacking an agreement is indicated between all three sources;
_ = records compiled by Aboul Mehasin,[11] covering the period, 20 to 855 of the Hegira, or 641 to 1451 A. D., a total of 811 years. A small + indicates extra data, representing 25 surplus years of Mohammedan reckoning;
(–) = records from notes compiled by Ibn Iyas and others,[12] for the period 769 to 1878 A. D.
∠ = records by Lyons;[13] and,
∧ = records indicating "wafa," or the stage that assures plenty, at which the canals were opened to supply the basins; the maximum flood stage, ordinarily, was somewhat higher.

Applying to the gauge down stream from Aswan Dam:

A = maximum annual river stages at the Aswan gauge above the assumed datum, 71.0 m, or 232.9 ft, above mean Mediterranean Sea level;
◡̇ = maximum ten-day, average gauge heights, and, therefore, somewhat below the actual maximum.

Applying to the El-Leisi gauge, 37 miles up stream from Cairo:

○ = maximum ten-day average gauge heights, and, therefore, somewhat below the actual minimum.

FIG. 2.—CONVERSION SCALES

Fig. 1 probably includes many items that represent river stages at the time of the festival attending the opening of canal gates, after which the flood ordinarily continued to rise to varying heights. According to tradition and historical references, furthermore, some of the flood heights were increased falsely in the records for the purpose of adding to the revenues from land taxation. There appear to be good reasons for expecting fully as wide ranges of variation for the maximum annual gauge heights as for the minima, except as the former may be affected by valley storage and flood-plain discharge.

The data from Aboul Mehasin's tabulation that differed by measurable amounts (say, 3 in., or more, on the adopted scale) are shown as short dashes crossing the grid lines; and those derived from or confirmed by textual notes are shown within parentheses. In this manner, it was found possible to supply about 65 additional maxima, so that a total of 1 173 out of a possible 1 300 are plotted, some with more than one value owing to the unexplained discrepancies among the records. These differences may reach 3, 4, 5, or even 10 cubits, but usually are less than 1 cubit. The data for the extra 25 yr of Mohammedan reckoning are shown as short dashes between grid lines.

For the 811 yr of concurrent record covered by the aforementioned two tabulations, about one-fourth the maxima and one-half the minima coincide, but if those in practical agreement or those differing by only a few inches are included, the proportions increase to about one-half and three-fourths, respectively. The textual notes of Ibn Iyas, El Gabarti, and others provide several coincidences of both maxima and minima, as well as at least an equal number of measurable divergences. Furthermore, they supply the sixty-five yearly maxima not found in either of the long tabulations. All these new data are shown in Fig. 1 as short dashes enclosed in parentheses. Agreement of textual notes with the data from the longer tabulation is indicated by parentheses around the individual dots or small groups of dots. Such a symbol for any year between 641 and 1451 A. D., without a dash, indicates agreement of all three sources, as explained in the foregoing list of symbols.

It seems to be fairly well established, by tradition as well as by historic references, that the records of some of the sub-normal Nile flood stages were increased arbitrarily by order of unscrupulous rulers whose prospects of land revenues had been adversely affected by the drought. In years of assured plenty, or abundant water supply, such sordid motives for falsification of records would seem to be lacking. However, there is considerable evidence that a record was sometimes made of the stage at which the canal gates were opened, upon the assurance of a satisfactory water supply, after which the river may have continued its rise in varying unrecorded amounts. Furthermore, a sudden or early recession of the flood from what was at first considered to be a stage assuring plenty, or "wafa," was occasionally followed by a partial famine, due to the brief duration of high flood. Obviously, any neglected maximum stages would tend to counterbalance the artificial increase of sub-normal stages as expressed in trends.

With full recognition of the obvious discrepancies in the records and the likelihood that many other errors and inaccuracies were incorporated which may never be detected (or at least are not detectable at this time) it is truly remarkable, nevertheless, how nearly the computed trends of rise apparently ascribable to sedimentation, ranging from 0.10 to 0.15 m (3.9 to 5.9 in.) per century, are reflected in Table 1.

TABLE 1.—Computed Trend of Rise, Flood Stages of the Nile, Ascribable to Sedimentation

Years of Record (A. D.):		Cumulative interval, in years	Average Annual Low-Water and Flood Stages				Average Rise for the Cumulative Interval			
			In Meters Above: Mean Mediterranean Sea Level at Alexandria, Egypt		In Feet Above: Mean Mediterranean Sea Level at Alexandria, Egypt		In Meters per Century		In Inches per Century	
From (1)	To (2)	(3)	Minimum (4)	Maximum (5)	Minimum (6)	Maximum (7)	Minimum (8)	Maximum (9)	Minimum (10)	Maximum (11)
622	721	100	11.51	17.50	37.8	57.4	......	......	......	......
1 422	1 521	900	12.52	18.21	41.1	59.7	0.13	0.09	5.12	3.54
1 522	1 621	1 000	11.09	18.71	36.4	61.3	—0.05	0.13	—1.97	5.12
1 522	1 721	1 100	11.66	18.34	38.3	60.2	0.015	0.084	0.59	3.23
1 722	1 821	1 200	11.66	19.06	38.3	62.5	0.014	0.14	0.55	5.51
1 822	1 921	1 300	13.19	19.33	43.3	63.4	0.14	0.15	5.51	5.91

The year 1834 marks the construction of a main barrage below Cairo and the beginning of perennial irrigation in Egypt. The effect of this development soon after the severe drought that culminated in 1833, is more marked in the trend of minima than in that of maxima. The barrages raised the river bed, the release of storage water from large reservoirs far up stream augmented the minimum flow, and the storage of a portion of the flood flow in these distant reservoirs tended to decrease the peak stages. A study of the trends on the graphic composite record covering

1 300 yr, especially between successive century averages (marked * in Fig. 1), shows unmistakably why the flood stages that indicated an assurance of plenty progressed gradually from 16 to 20 cubits (28 to 35 ft) on the Roda gauge and then, during the final century of record, increased nearly another 6 cubits (10.3 ft), owing to increased usage of water and to the construction of the main barrage or diversion dam about 15 miles below. This was designed to raise the low-water surface about 3.2 m, or 10.5 ft, or 6 cubits (10.3 ft), and it actually raised the flood crests about 0.75 m (29.5 in.) at the barrage, even with all gateways open; or 0.25 to 0.75 m (9.8 to 29.5 in.) at the Roda gauge.[14]

The first notable effort toward providing a reliable perennial irrigation supply for Egypt was evidently the Lake Moeris Reservoir project, described by Herodotus after his personal visit to Egypt about 450 B. C. The site has been identified definitely as the fertile Fayum Basin of the present day, with its saline lake occupying the lowest part of the valley, 140 ft below sea level, in a manner similar to the Salton Sea in Imperial Valley, California. The width of the canal supplying the reservoir was given as the equivalent of about 300 ft. With an average depth of 25 ft during high flood and a mean velocity of 4 ft per sec, the discharge would have been 30 000 cu ft per sec, or 60 000 acre-ft per day, thus requiring approximately 17 days of continuous flow to deliver 1 000 000 acre-ft. It is plain that both the diversion and the storage quantities might have been considerably greater or less than these values, but they afford at least an idea of the possibilities in the light of modern practice.

Sir R. Hanbury Brown[15] derived the available storage depths and capacities for Lake Moeris which are used in the following comments: Taking into account the present contours of the Fayum Basin, enclosing an area of fully 630 sq miles under the level of ancient lake shells, or 22.5 m (74 ft) above mean sea level, and assuming the depth of usable storage for return to the Nile to augment the low flow, as 10 ft, intermediate between the high-water and low-water stages of the adjacent Nile channel, the net available volume is found to have been about 3 000 000 acre-ft, or nearly the usable capacity of the Aswan Reservoir from 1912 to 1930, after the first enlargement and before the recent one. The storage and release of this water, therefore, must have modified the Nile discharge at Cairo, about 80 miles below the diversion canal leading to the Fayum Basin; but it appears that before 622 A. D., the beginning of the nilometer record herein presented, Lake Moeris had been abandoned as a storage project, and the rich alluvial lands of its bed had been devoted to agricultural use, such as prevails to this day. In addition to this storage, the chains of natural lakes were doubtless operating as effectively in those ancient times as at the present, if not more so. Presumably, the natural processes of erosion and sedimentation would have tended to enlarge the lake outlets and to convert the shallower lakes or portions of them into marsh land, such as now prevails on the White Nile above Khartoum.

[14] "The Delta Barrage," by Sir R. Hanbury Brown, Cairo, 1902.

[15] "The Fayum and Lake Moeris," by Sir R. Hanbury Brown, Lond., 1892, p. 80.

From what seems to be the best information and opinions thus far published and discovered in the present research, it appears that the storage and regulative features of the Nile were not greatly changed during the first 1 200 yr of the record plotted herewith; but that the developments during the final century of this record at least restored the quantity of storage and regulation provided by Lake Moeris for possibly sixteen centuries before, and more than a century after, the visit of Herodotus, about 450 B. C.

In spite of all the changing, uncertain, and erroneous factors that must be considered in connection with the records of stages of the Nile River, it is believed that they disclose some important information; and there is a fair prospect that they may yield more data with further study and the cumulation of ideas of various students.

It is readily apparent that the use of records covering only a single early century might yield an unreliable estimate of the frequency characteristics of the maximum stages for the total period. On the other hand, it is believed that, after eliminating the obvious errors in Fig. 1, such as 3, 5, or 10 cubits (5, 8.5, or 17 ft), and some lesser ones, and then applying an average rate of rise per century to indicate the increase of sedimentation on the flood-plains and the resultant rise of flood stages, any one of the first twelve centuries of record may be found to qualify as a rough indicator of what should be expected during a longer period, such as 500 or 1 000 yr. Furthermore, the comparison of the Toussoun data (plotted as dots in Fig. 1) and the Lyons data (marked ∠ in Fig. 1) for the two centuries ending in 1902, shows several measurable differences, some of them systematic and nearly constant, and others of irregular amounts and sign; that is, alternating as positive and negative variations. In view of such discrepancies, of the ease with which a "3" may be read as an "8," or a single unit changed in the 10's column in Arabic numerals, and of the chance of other errors of transcription, it is not surprising that about 5 or 10 digits or cubits or other differences exist in the two tabulations covering 811 yr concurrently. The greater occasion for surprise seems to lie in the possibility of synchronizing the two time scales (Mohammedan and solar years), which has been done in such a way that a majority of the items are in actual or substantial agreement, for both maximum and minimum annual stages.

This presentation of what purport to be records or data derived in some way from actual records, is made with the hope that others may be spared the tedious work of computation, co-ordination, and plotting of the various items. Perhaps it may serve as a kind of groundwork on which comparison may be made between segments of this record, or between these data and others for rivers in the United States, proper account being taken, of course, of differences in drainage-basin characteristics and river regimen.

It seems important to observe that the site of the Roda gauge, at Cairo, is virtually at the apex of the Nile Delta cone and that the opportunity of the stream to spread through a wide angle resulted in various conditions regarding the number of outlet channels. Thus, some of the early maps outline six distinct outlet branches; others show three or four; and now there are only two well-established natural channels. Perhaps the combined capacities of the various canals in Lower Egypt, or even those restricted to the Delta itself, would account for the equivalent of one or more of the abandoned channels. It is quite probable that under such conditions as are known to have existed some of the annual flood heights were affected more by channel changes than by variations in rates of flow. For example, a devastating flood may have lowered the river heights temporarily as a result of scouring, or an obstruction may have increased them. The transfer of the main gauging operations, about 1870, to the Aswan site, below the First Cataract, avoided some of the disturbances that have been felt at Cairo from new irrigation developments since the British occupation. These Aswan gauge heights, above an assumed datum, are superimposed on Fig. 1 with Roda gauge readings.

Attention is also invited in Fig. 3 to the plotted records of both annual volumes and 4-month flood volumes at Aswan, beginning with 1870, as determined from the records of the Ministry of Public Works, of Egypt.[16] These values may be read from the various scales in almost any desired unit of measure in common use. The decrease from the first to the latest decade of record seems to be due, in part, to climatic trends over the period of record, but perhaps it may reflect also the increased use of water in Upper Egypt and the increased losses in storage or in transit due to recent works.

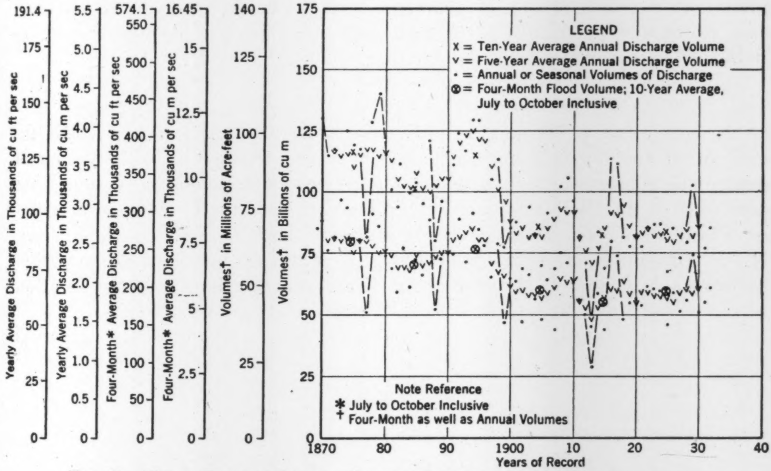

FIG. 3.—FLOOD DISCHARGE AND VOLUMES OF THE NILE RIVER AT ASWAN

Probably the most authoritative appraisal is that of the Physical Department, Egyptian Ministry of Public Works, as expressed[17] by H. E. Hurst, Director General, and P. Phillips, Director of the Hydrological Service:

"One series of maxima and minima at Cairo extending from 641 A. D. to 1450 A. D. is fairly complete. The outstanding feature of these is that over considerable periods, sometimes as long as 50 years, floods are above the average, while over other periods they are below the average. It is also the case that very low floods may occur amongst a high series and *vice versa.* These records have been analyzed for periodicities, and periods of small amplitude have been found. They are, however, so masked by irregularities as to be useless for forecasting purposes."

[16] Physical Dept. Papers, Nos. 29 and 31; also "The Nile Basin," Vol. III and IV (Supplement).

[17] "The Nile Basin," Vol. 1, p. 20, 1931.

Despite the obscuring effects of errors, uncertainties, and difficulties attending these records of Nile River stages, it seems probable that the concentrated attention of members of the Engineering Profession who are so inclined may yet bring into view many facts and relationships to build up a better background of experience and to afford perspective covering long-time trends of river behavior. Throughout the notable long-period records recently investigated on both American and foreign rivers, aggregating thousands of years in length, it appears that no single flood event is completely at variance or out of character with what appear to be the natural and reasonable potentialities of that particular basin or river system, as indicated by other similarly outstanding events of record.

ACKNOWLEDGMENTS

A wide circle of associates and advisers have been most helpful in the conception and development of the plan for this paper, and in reviewing or contributing ideas to be included. Especial mention should be made of the personnel of the U. S. Geological Survey and that of the Society's Committee on Flood Protection Data; and, particularly, to N. C. Grover, H. T. Cory, R. W. Davenport, J. C. Hoyt, Gerard H. Matthes, and Thorndike Saville, Members, Am. Soc. C. E., for their direct contributions and co-operation.

DISCUSSION

HALBERT P. GILLETTE,[18] M. AM. SOC. C. E. (by letter).—In a paper on "The Cycles That Cause the Present Drought"[19] the writer has compared curves of mean flood levels of the Nile River from 1735 to 1919 with those of mean annual rainfall at or near Boston, Mass., from 1750 to 1934. The two curves are quite similar, each having a minimum for the 5-yr. period, 1790–94, and a maximum at or near the period, 1865–69.

Another diagram[20] gives the mean thickness of annual tree rings by decades, for Arizona pines, from 1390 to 1909, indicating three cycles of about 152 yr. Each cycle has less amplitude than the one preceding because tree rings vary less in thickness as the roots attain greater depth. The California sequoias also show the 152-yr cycle clearly, particularly when they are young. The first great valley in the curve of their annual rings shows a maximum drought about 1255 B. C.

The annual silt layers, or varves, in the ancient glacial lakes of New England and Canada show the 152-yr cycle; but the most impressive evidence of this "grand cycle" is found in the recessional moraines left by the retreating ice sheet, and in the ancient beaches around the Great Lakes and Lake Winnipeg.

From the foregoing evidence the writer has concluded that the exact length of the cycle is one month longer than 152 yr and that its amplitude is cyclic, reaching a maximum every 1 825 yr. T. W. Keele, an Australian civil engineer, was the first to discern any evidence of the existence of the cycle[21] and he found it in the Nile flood-level records subsequent to 1736, as well as in the records of Australian rainfall. Unfortunately, he erred 12% in determining its length.

By means of tree rings the writer estimates that the year of maximum drought due to this cycle will be 1939; but since there are a dozen other cycles longer than 2 yr, not to mention several shorter than that, there may be years even dryer than 1939, in the near future. This is illustrated by reference to Table 2,[22] in which the mean amplitude (Column (2)) is the percentage departure of the cyclograph peak or valley from the mean. The cyclographs were those derived from Arizona pines (1391–1910) except for the 100⅔-yr cycle, for which early sequoias were used. The sequoias usually have amplitudes about two-thirds as great as Arizona pines; therefore, the 13% in Column (2), Table 2, should be increased about one-half. The amplitude varies periodically through the cycle in Column (3), Table 2; and Column (4) gives a year in which a peak of the basic cyclograph had its greatest amplitude, which is to be used as an epoch date.

Four principles seem to be indicated by Table 2, in its relation to the paper by Mr. Jarvis, namely, (1) the amplitude of a rainfall cycle tends to increase with the length of the cycle; (2) the amplitude itself is cyclic; (3) cycle lengths approximate a geometrical progression series, with a ratio equal to $\sqrt{2}$; and (4) cycle lengths are either an integral number of months, or of two-thirds of a month.

TABLE 2.—THIRTEEN RAINFALL CYCLES

Basic cycle, in years (1)	AMPLITUDE		Year (A. D.) of maximum rainfall (4)	Basic cycle, in years (1)	AMPLITUDE		Year (A. D.) of maximum rainfall (4)	Basic cycle, in years (1)	AMPLITUDE		Year (A. D.) of maximum rainfall (4)
	Mean (percentage) (2)	Cycle, in years (3)			Mean (percentage) (2)	Cycle, in years (3)			Mean (percentage) (2)	Cycle, in years (3)	
$1\frac{17}{18}$	4	35	1911	$13\frac{11}{12}$	8	167	1816	$48\frac{5}{6}$	12	293	1756
$3\frac{1}{6}$	6	19	1900	$18\frac{5}{6}$	11	113	1889	$69\frac{2}{3}$	15	209	1760
$4\frac{1}{9}$	7	37	1922	$23\frac{5}{6}$	12	143	1859	$100\frac{2}{3}$	13	302	1912
$5\frac{13}{18}$	6	103	1919	$39\frac{2}{3}$	10	119	1921	$152\frac{1}{12}$	25	1 825	1711
$7\frac{5}{9}$	6	68	1921	.....	.....	.....	......	.....	.....	.....	......

Since sequoia tree rings have been measured spanning 3 200 consecutive years, it follows that they supply a means of determining lengths of cycles with great precision. A total of one hundred and thirty-three 24-yr cycles can be traced by the sequoia data. Therefore, if the peak of the cycle is determined near the beginning and near the end of the 3 200 yr, the error in the length of the cycle cannot exceed $\frac{1}{130}$ yr.

For the foregoing reasons the writer finds that tree rings are preferable to level records of the River Nile in deriving the lengths of cycles. Furthermore, the low-water levels of this river are more variable than the flood-stage records cited by Mr. Jarvis and, therefore, are preferable for cycle analysis. A simple method of cycle analysis has been recommended by the writer[23] which is similar to that devised by Balfour Stewart.[24] It should be noted that this method or Schuster's[25] harmonic analysis modification of it will yield pseudo-cycles of two-thirds, one-half, one-third, or one-fourth the length of the true cycle. No writer has previously called attention to this fact. It arises from the shape of the rainfall curve of a cycle; and, consequently, meteorological literature abounds in pseudo-cycles.

Except for the records of the River Nile, man-kept records by weather cover such few years that they are of little value in determining cycles longer than about 6 yr. It often requires data covering more than 30 cycles to establish the existence of a cycle with a high degree of probability, because there are so many cycles that they tend to hide each other. Two rainfall cycles (approximately 152 yr and 101 yr) often are very clearly evident in spite of the other obscuring cycles. Occasionally, at intervals of 35 yr, the cycle of approximately 2 yr is well defined in winter temperatures and in laminated silt or varves.[26]

R. W. DAVENPORT,[27] M. AM. SOC. C. E. (by letter).—The occurrence of a flood is determined by the conjunctive operation of a variety of meteorologic, hydrologic, topographic, and other factors and conditions in a manner favorable to the production of abnormally excessive flows. As knowledge of these fundamental factors and conditions has become more plentiful through the collection of records at rainfall and river measurement stations, topographic surveys, etc., it has been possible to introduce more science into the analysis of flood occurrence and thereby to advance somewhat in relating floods to their constituent elements. Notable advances of this kind have been made in recent years by different individuals and organizations along more or less closely related lines, with resulting improvement in the technique of flood study and the promise of further improvement as the supply of essential base data increases and the knowledge of practical and theoretical hydrology progresses.

The flood record of the Nile River, as presented in the paper by Mr. Jarvis, is the result of a thorough and painstaking endeavor to reconcile conflicting evidence of Nile flood heights as derived from various sources and to convert the information into a form that can be readily understood and discussed. Future students of the long Nile record may have the advantage of starting from the advance point to which Mr. Jarvis has progressed in his researches. Although numerous uncertainties and difficulties tend to place the record somewhat in a cloud of doubt as regards its reliability of detail, full knowledge of the facts as developed will be of great value to future investigators. The writer believes with Mr. Jarvis that despite these unfortunate defects of the record the Engineering Profession may be able to derive from it valuable knowledge in regard to long-time characteristics of river behavior, and particularly in regard to the changes in behavior with respect to floods within the centuries covered by the record.

The proposition that the characteristics of flood behavior of a stream may be best understood and dealt with by analyzing them in relation to their fundamental constituent elements has the direct corollary that such an analysis of these characteristics for a certain stream may also best contribute to knowledge of corresponding characteristics for other streams, neighboring or distant. Obviously, therefore, if the flood characteristics of the Nile and other foreign rivers, as displayed by long records, are to be made rationally applicable to streams elsewhere in the world they require to be analyzed and translated, so far as practicable, into common fundamental terms. In undertaking to determine, in a superficial way at least, something of the significance of the

[27] Hydr. Engr., U. S. Geological Survey, Washington, D. C.

Nile record in relation to other streams, the writer has been interested to review some of the outstanding features of the Nile floods.

The Nile drainage basin has an area of 1 119 737 sq miles, and the river has a waterway length of 3 728 miles.[28] The corresponding values for the Mississippi-Missouri System are 1 240 000 sq miles and about 4 200 miles.

The main Nile is formed by the junction of the White Nile and the Blue Nile at Khartoum, 1 913 miles above the mouth. Through this 1 913-mile reach below the junction the river flows through a very arid country and except for the River Atbara, which enters from the east, 159 miles below the junction, the tributary area is small and the inflow practically negligible. The flow is subject to substantial diminution by evaporation and seepage; moreover, for thousands of years each flood has supplied substantial volumes of water, largely from the lower part of this reach, for the irrigation of the fertile Nile Valley. The flow of the river is derived from two main sources: (1) The lakes and great swamp areas of Central Africa drained by the White Nile and its tributaries, with a heavy tropical rainfall distributed through the greater part of the year; and (2) the highlands of Ethiopia, drained by the River Sobat, tributary to the White Nile from the East, the Blue Nile, and the River Atbara—a region marked by an extraordinary concentration of rainfall and run-off in the period from July to September. Thus "reduced to its simplest expression, the Nile system may be said to consist of a great steady-flowing river fed by the rains of the tropics, controlled by the existence of a vast head reservoir, and annually flooded by the accession of a great body of water with which its eastern tributaries are flushed."[29]

TABLE 3.—DRAINAGE AREAS OF ETHIOPIAN EFFLUENTS

River	Drainage area, in square miles	Distance of junction from mouth of the Nile, in miles
Sobat	94 560	2 429
Blue Nile	127 998	1 913
Atbara	85 216	1 754
Total	307 774	......

Table 3 shows, in down-stream order, the drainage areas of the Ethiopian effluents that are the sources of the annual Nile flood and the relative locations of their junctions with the main river. The Blue Nile rises above Lake Tsana, about 2 800 miles from the mouth of the Nile.

Some understanding of the seasonal distribution of the rainfall that is the source of the Nile floods may be obtained from Table 4, which gives the mean monthly rainfall at Addis Ababa for a period of 13 yr and 2 months.[30]

---

[28] These and other statistical data of the Nile presented herein are obtained from "The Physiography of the River Nile and Its Basin", by Capt. H. G. Lyons, Director Gen., Survey Dept., Finance Ministry, Egypt, Cairo, National Printing Dept., 1906.

[29] "Encyclopædia Britannica, 14th Edition, Vol. 16, p. 454.

[30] "The Rains of the Nile Basin and the Nile Flood of 1912", by J. I. Craig, Director, Meteorological Service, Survey Dept., *Survey Department Paper 32*, Ministry of Finance, Egypt.

The hydrographs of flow at stations in the upper reaches of the tributaries[31] show a most pronounced flood rise extending from July to the late autumn and culminating in a maximum stage in August or September (averaging about September 1). The hydrographs at the upper stations follow an irregular saw-tooth line, thus displaying direct sensitiveness to the variations of rainfall distribution over the upper part of the drainage basin.

TABLE 4.—Mean Monthly Rainfall at Addis Ababa, Ethiopia

Units	January	February	March	April	May	June	July	August	September	October	November	December	Total
Millimeters.....	15	39	70	82	64	142	283	302	163	16	19	3	1 198
Inches.........	0.59	1.54	2.76	3.23	2.52	5.60	11.13	11.90	6.42	0.63	0.75	0.12	47.19

The flow of the White Nile above the mouth of the Sobat is extraordinarily regular. The influx of the Sobat tends to swell the flow materially, beginning with June, but apparently the river continues to be characterized by unusual regularity until it approaches the mouth of the Blue Nile, where it shows greater domination by the influences that create the Nile floods. Below the junction of the Blue Nile, the flow assumes the definite pattern of the Nile floods.

Farther down the main river the hydrographs become continuously more smooth, until at the Roda gauge, at Cairo, where the long record has been kept, the incisions in the hydrograph that are due to natural causes are undoubtedly very small. Moreover, under natural conditions, the time of maximum stage at Cairo is about October 1 on the average, or about a month later than on the upper reaches of the tributaries.

From the available information it is apparent that:

(1) The rainfall that creates the Nile floods is concentrated largely in a 90-day period;

(2) The collecting system of the flood waters integrates the variable flows originating from the heavy rainfall over a wide area in a peculiarly effective manner, so that the flood at the place where it enters upon its long course to the sea through the main Nile channel is characterized by a remarkable uniformity of pattern from year to year; and,

(3) The passage through about 1 900 miles of capacious flood channel, with the resultant regulating influence of a great volume of channel storage, still further smooths the hydrograph of flow, except as artificial regulation and diversion have produced irregularities, usually of minor character.

The only drainage basin in the United States that is comparable in area and length to that of the Nile is the Mississippi Basin, but its hydrologic characteristics are quite dissimilar. The Colorado Basin is similar to the Nile Basin in respect to the fact that its flood is peculiarly seasonal in its occurrence, but it is much smaller and quite unlike the Nile Basin in various other ways. It is evident, therefore, that the application of the Nile experience to the rivers of this country is not direct and easy, but requires an appropriate analytical treatment of fundamental factors.

---

[31] As pub. in the *Survey Department Papers* of the Ministry of Finance, Egypt.

In reviewing the evidence of past centuries, therefore, it appears that the annual maximum stage at the Roda gauge represents the culminating height attained by a flood rise of large volume and unusual regularity of pattern. Outstanding features of the flood are its regular seasonal recurrence and its obscuring of erratic tendencies, both in distribution of rainfall and in the characteristics of drainage basins in shedding flood waters. Any application of the facts disclosed by the Nile record to streams elsewhere, of course, should take these and other essential characteristics appropriately into account.

H. E. HURST,[82] ESQ. (by letter).—The Roda nilometer situated in Cairo is said to be the oldest existing Arab monument in Egypt, and consists of a well of about 5 m (16.4 ft) square communicating by tunnels with the river and having a vertical column at its center on which the scale is cut. The column is held at the top by a cross-piece of masonry spanning the well, and the water levels were read from a staircase that winds around the outer edge. Its records dating back to A. D. 622, although not complete, form perhaps the longest written record of any meteorological phenomenon.

The originals as far as known do not exist at present, and the form in which the records were kept is also unknown. Colonel Sir Henry Lyons who came to Egypt in the Nineties was told that the original records were written in Coptic and existed in the Ministry of Public Works in the time of Aly Pasha Mobarak, a few years before his arrival in the country, but he was never able to trace them. The writer has never heard of a record with any claims to antiquity, and if any such existed in Egypt, H. H. Prince Omar Toussoun who has collected so much old material about the Nile would probably have discovered it.

In assessing the value of these records many points need consideration (some of which will be mentioned subsequently), and the investigator must divest himself of the idea that they are comparable in accuracy with present-day records. The scientific spirit of recording exactly what is observed, without personal bias and with every effort to eliminate sources of error, is a recent growth and is not to be expected in records the most complete portion of which is from 600 to 1400 A. D.

The Roda nilometer has been repaired on various occasions recorded by historians, in some of which the repairs have been so extensive as to leave a doubt as to whether it was not entirely reconstructed. There is little doubt that the list of repairs is incomplete and in no case is there any account of what steps, if any, were taken to preserve the datum level during the repairs.

Apart from changes of datum of an accidental nature one must consider the effects of changing topography and varying regime of the river such as have occurred in historical times. An example of this mentioned in the paper is the varying number and position of channels through the Delta, and a further example is that the position of the western bank of the river near Cairo has changed by nearly 1 km (0.6 mile) since Napoleon's time.

---

[82] Director-General, Physical Dept., Ministry of Public Works, Cairo, Egypt.

A point that may be mentioned is the effect of the basin system of irrigation on the river levels at Cairo. In this system, which was the only one practised in Egypt until the Nineteenth Century, the country is divided into sections by banks transverse to the course of the river, and the flood waters of the Nile are admitted to these sections or basins by means of short canals. After a period of forty days or more the water is allowed to escape back to the river and the basins are planted with crops. In recent times, basin irrigation has been well controlled by means of masonry regulators on the canals and escapes, and the water is admitted to and escaped from the basins according to a program. The effect of this is to alter the natural flow of the river at Cairo very considerably, lowering the natural peak and the succeeding levels to raise them again when water begins to escape. In some cases the second peak has been higher than the first one and, in others, it has not been noticeable, the actual regime depending largely on the nature of the flood. Since 1900, the basin area of Upper Egypt has been diminishing gradually, owing to the conversion of the basins to the perennial system.

Previous to the Nineteenth Century basin irrigation must have been a much more haphazard process, as lack of communications would prevent its regulation on an organized plan directed from headquarters. Moreover, there would be no masonry regulators; the only control of entrance to, and escape from, basins would be by earthen banks; and after these were once cut the water would take its course. Possibly the water merely flowed through breaches in the river bank as the flood rose, and back through the same breeches as the river fell, making the process more or less a natural one, which would be modified occasionally by the bursting of cross-banks. In very early times the cross-banks probably did not exist, and the annual inundation of Upper Egypt was a still simpler phenomenon.

Unfortunately, no details of the form of the Roda gauge curve previous to the Nineteenth Century have been handed down, and only readings purporting to be the maximum and minimum, are available. The minimum readings would be much more likely to be affected by changes of topography, such, for example, as the closing of a main channel near Cairo by a silt bar or an earthen bank (as must frequently have happened), or by the gauge itself being shut off from the main stream.

The possible exaggeration of low floods for revenue purposes has been mentioned in the paper. Another source of error is that the gauge pillar must always have been difficult to read as the observer cannot approach it closely; furthermore, the scales became worn and often no doubt were incrusted with mud. This led to a practice which was followed by some of the gauge readers of recent times and was referred to by Col. J. C. Ardagh in 1889,[33] of reading not on the gauge, but on private marks either on the wall of the gauge-well or on a flight of steps outside, leading down to the Nile.

---

[33] "Nilometers", by Col. J. C. Ardagh, *Proceedings*, Royal Geographical Soc., Vol. XI, No. 1, January, 1889.

Some of the sources of error that affect the records are of an accidental nature and will be largely eliminated by the number of observations, which is approximately 1 100 both of flood stage and of low stage.

Systematic changes such as the gradual rise of the river bed can be eliminated for some purposes by dividing the observations into groups of, say, 100 yr and dealing with the departures from the mean of the century. This procedure helps also to eliminate the effects of topographical changes. Deliberate exaggeration of low floods cannot be eliminated, but it is quite likely that it is a practice which was only used for a time and does not affect all the records, and, therefore, its effect is minimized when the entire mass of material is discussed.

As a whole, these records represent observations extending over a very long period of the rise and fall of the Nile. They have not the precision of modern observations, but are probably as reliable as many of the statistics collected at the present day about less well-defined phenomena, such as the health and social conditions of mankind.

Two uses to which these records have been put in recent times are: (1) Analysis to discover the existence of periodicities; and (2) construction of a curve giving the frequency of floods of different heights.

The old records of the Roda gauge given by various authors were scrutinized by Mr. J. I. Craig, of the Egyptian Ministry of Finance, and converted to a metric scale, and it is this collection, with certain minor changes, that has been used in the Physical Department, Egypt, or communicated by the Department to inquirers.

Periodic analyses have been made by the late Professor H. H. Turner[34], and by Messrs. J. I. Craig, and C. E. P. Brooks[35], and periods varying from 2 to 240 yr have been found. The period of greatest amplitude so far is one found by Professor Turner of 240 yr, with an amplitude of 15 cm (6 in.) for the maxima and 46 cm (18 in.) for the minima.

The analysis by Dr. Brooks does not extend beyond a period of 76.8 yr, but he finds a number of periods of average amplitudes of the order of 10 cm (4 in.). His best defined periodicity is the one of 76.8 yr, with a mean amplitude of 17 cm (6⅝ in.). The average standard deviation of the flood levels is 56 cm (22 in.); this makes apparent the relative smallness of any periodic effects, which although of theoretical interest, are of no use to the forecaster. A glance at the records when plotted on a fairly large scale shows that there is no period which is directly evident to the eye, and that the principal features are the existence of fairly long terms of years when, on the whole, the floods have been high and others when floods have been low. This fact is well illustrated by the Aswan gauge records for the period, 1869–1933. By dividing this period into two parts, 1869–1898 and 1899–1933, an example is afforded of a high term of 30 yr followed by a low term of 35 yr, with the results indicated by Table 5.

---

[34] "On a Long Period (240 Years) in Chinese Earthquake Records", by H. H. Turner, Monthly Notices, Royal Astronomical Soc., May, 1919, Vol. LXXIX.

[35] "Periodicities in Nile Floods", by C. E. P. Brooks, *Memoirs*, Royal Meteorological Soc., Vol. II, No. 12.

The most striking feature of Table 5 is that in the high term, one year in every two was higher than the highest flood of the following low term. No regularity in the occurrence of these high and low terms has been discovered so far; nor are floods uniformly high in a high term or low in a low term.

TABLE 5.—RECORDS OF ASWAN GAUGE DIVIDED INTO TWO PERIODS

Description	1869–1898			1899–1933		
	In meters	In feet	Year	In meters	In feet	Year
Maximum gauge reading of highest flood	94.15	308.9	1878	93.30	306.1	1908
Maximum gauge reading of lowest flood	91.40	300.9	1877	90.11	295.6	1913
Mean flood maximum for the period	93.26	306.0	....	92.39	303.1	....
Number of years with maxima greater than 93.30 m.	15		....	0		....
Number of years with maxima less than 91.40 m.	0		....	2		....

A frequency curve was constructed by the writer from all available Roda gauge maxima. This curve was used to estimate the frequency of occurrence of very low floods such as that of 1913.[36]

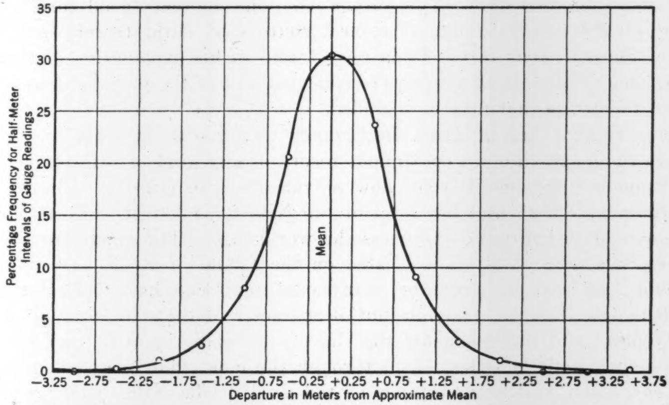

FIG. 4.—FREQUENCY CURVE, MAXIMUM READINGS, RODA GAUGE, CAIRO, EGYPT.

In Fig. 4 the effect of progressive change and discontinuities has been eliminated to some extent. The ordinates give the percentage of cases in which the reading falls within the half-meter indicated by the abscissa and, therefore, an ordinate is a measure of the probability of occurrence. The plotted points are derived from observations from 640 to 1451 A. D., together with observations from 1737 to 1917 A. D., making a total of 961 observations. It will be seen that the frequency distribution of Nile floods approximates closely that given by the Gaussian law of errors, and the regularity of the curve tends to show that systematic misrepresentation of the records of low floods did not occur to any great extent, and that perturbing effects act mainly in an accidental manner.

---

[36] "Nile Control", by Sir M. MacDonald, Cairo, Govt. Press, 1921.

In the paragraph following Table 1 of the paper there seems to be a misconception of the effect of the Delta Barrage below Cairo. The function of this structure is purely to raise the river level so that the three main canals taking off at the Barrage can be fed at all times of the year. The storage behind the Barrage is negligible and, therefore, so is its effect in lowering the flood-peak or augmenting the minimum flow.

In recent years considerable archæological research has been done with regard to Lake Moeris and the Fayum Basin and the results have been published.[37] A few references to old records of the Nile are: (1) "Nile Gauge at Roda", by Mohammed Kasim[38]; (2) "The Nilometer at Cairo", by Dr. Reiss[39]; and (3) sundry items of correspondence on nilometers.[40]

Thomas H. Means,[41] M. Am. Soc. C. E. (by letter).—Attention is drawn, in this paper, to the long record of the Nile. Many references have been made to such records and there have been a number of summaries and brief discussions of the data, but the records themselves have not been available to many engineers in America. Mr. Jarvis has presented in pictorial form about as much as most engineers will want to see, while the specialist can go back to the more detailed data. The author has done another "good turn" in his studies of the reconciliation of several sources of data, thereby supplying some of the omissions in the Roda record, and in his explanation of the conditions under which the records were collected and of the probable reasons for some of the errors that may be included.

These records are of great importance because, aside from tree rings, they are the longest known continuous record of any kind of information that bears upon the changes in river flow or variations in climate. Briefly, they show the yearly high and low level of the Nile for 1 300 yr—information of great interest to hydraulic engineers the world over. The gauge from which these records were obtained is located on the Island of Roda, at Cairo, and no doubt has been inspected by many engineers who have been fortunate enough to visit Egypt. The substantial character of the structure and of the many repairs and improvements that have been made upon it, and the care with which records have been kept through the more than thirteen centuries, speak eloquently of the importance of the level of the Nile to the people of Egypt. No nation has been so dependent upon one source of water and in no other place in the world is there so much interesting material for profitable study by the engineer.

The recent series of dry and hot summers in many parts of the United States has attracted more than usual attention to matters of weather. In parts of the Pacific Coast there have been seventeen years with precipitation below the average—below the normal. The question is, "Do we know what is normal?" "Is this dry period normal or were the earlier years of relatively high precipitation more nearly normal?" News items have told of railroads hauling drinking water for stock in Imperial Valley. Cities and towns in the Mississippi Valley have placed restrictions on the use of water, and thousands of fertile acres are suffering from lack of rain. An "unprecedented drought" is the explanation. Such disasters occurred not only in 1934, but for several preceding years. Are they "unprecedented"? Are they likely to occur soon again? The climate is changing, say some.

[41] Cons. Engr., San Francisco, Calif.

The belief that the climate is changing has been adopted as probable by many people and sensational broadcasts have told of the necessity of abandoning large areas of the great plains. The people are told that they have over-developed their water resources and must now take a backward step, consolidating their dwindling resources to fit the true conception of the water supply or rainfall.

The memory of human beings is notoriously unreliable as to weather. The deep snows of the past generation, the freedom from floods, or greater floods, the "big freeze", or the "big wind" are phenomena which, to human recollection, no longer occur. Examinations of records of weather, when they are available, seldom support these beliefs. Actual records seldom show any progressive change within historic times. Long-term records, such as these from the Nile, enable the student to carry facts a little further back, to compare with beliefs and theories.

When one reads of abandoned cities in now desert places, or sees wave-cut shore lines made by prehistoric lakes now long evaporated and either gone or greatly reduced in size; when one sees in the abandoned trails of glaciers proof of changed climate, one wonders, if such changes are going on to-day.

There are no weather records in America of any high degree of accuracy extending over 200 yr; in Europe, of not more than 400 yr, which is a very short time when compared with the 4 000 or 5 000 yr in which Man has gathered some historical facts, and insignificantly small when compared with the length of the most recent geological period. Estimating the length of geological time in years is by no means accurate, but from all the evidence available it appears that the time since the last glacial period is from 25 000 to 100 000 yr. The longest rainfall record, therefore, is in the order of one-twenty-fifth of the historical period, or one-five-hundredths of the most recent geologic period. If the rainfall in the eastern part of the United States was reduced one-half in quantity since the last glacial epoch the rate of reduction would be about 0.1 in. per century. There is no way of ascertaining with certainty any such small average change in rainfall. So far as local records alone show, this country may be in an increasing or decreasing cycle—no man knows which. The records of the Nile, therefore, are of great interest in extending the period of observation. Perhaps if it were 4 000 or 5 000 yr long, the trend could be predicted.

The height of the Nile at flood time, in a general way, is dependent upon rains in the Abyssinian highlands; the low flow depends on rains in Central

Africa which reach the main stream through the White Nile. There are many factors other than rain that may effect both these flows but, on the whole, rain is the most important single influence, and in a long period, such as this, its effects must have over-shadowed all other factors.

The Nile is an unusual stream. It flows out of a tropical region including in its water-shed humid, semi-arid, and desert areas of great size. The total area of water-shed approximates 1 200 000 sq miles, or nearly one-half the area of the United States. Its yearly flow in volume approximates 75 000 000 acre-ft, or about as much as all streams in California combined, or one-half of the Columbia River at The Dalles, Ore. The flow in Egypt, ordinarily, is at a minimum in May when it begins to rise from rains in Ethiopia; first the Atbara, then the Blue Nile rise in flood. The flood increases, reaching a maximum in September or October to fall as the Ethiopian summer rains diminish. The White Nile maintains the flow during the winter until the summer rains come again. In round numbers, two-thirds of the flow comes from the Blue Nile, one-fourth from the White Nile, and one-eighth from the Atbara.

In this manner the Nile has been rising and falling each year for several thousand years. In ancient times the cause of this regular procedure was a mystery satisfactorily explained only by introducing the supernatural. Then, nearly the entire irrigated area in Egypt was flooded in basins, under more or less control, as the river rose. In years of very high floods the control was ineffective, and disaster and famine followed; in years of low flood, the supply became inadequate and equally great disaster resulted. The reports accompanying the records published in the *Memoirs* of the Institute of Egypt give the harrowing story of these periods. On the whole, however, the rise and fall of the stream were so regular and dependable that Egypt became one of the richest countries in the world and was the storehouse of food from which neighboring countries were supplied in time of drought and famine.

It was the custom of the rulers to announce each year the time when the river had reached the proper level for the dikes to be opened and the basins flooded. This "wafa" was the occasion of rejoicing and feasting, the important period of the year, for on it depended the prosperity of the country and the amount of taxes which could be collected.

The records of flood level—presumably the highest level on the Roda gauge—and the low-water stage at the same place then became one of the most important records in Egypt and probably epitomizes the economic history of the country. It is no wonder such care was taken in their preservation.

The Roda gauge was in its present location as early as the Seventh Century although there is reason to believe that earlier gauges existed either here, or at Memphis, a few miles up stream. The gauge was built in a temple, or mosque, and the collection and preservation of records was the duty of the priest or sheikh of the temple. The record now existing begins in 622 A. D.

A summary of the thirteen centuries of record is given in Fig. 5. This includes only the Roda gauge readings and not the additional data recorded in Mr. Jarvis' charts. This record of two readings of river level—the highest and the lowest— in each year does not give information from which the yearly flow may be computed but, in a stream like the Nile which goes through a regular cycle, such figures are very significant and should indicate any progressive change that may be taking place.

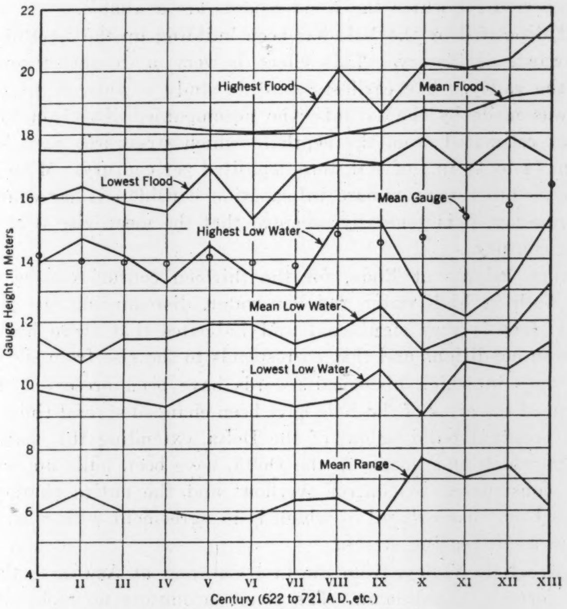

Fig. 5.—River Nile at Roda Gauge, Cairo, Egypt.

Little information is available concerning changes in the size of the channel, but such as there is indicates that there has been no notable variation in the width of the waterway. From Aswan to the head of the Delta near Cairo the stream seems to have occupied much the same channel since the Egyptians began to build dikes and cities and temples. The location of prominent objects and many historical references all indicate no great change in channel width.

The river levels at Cairo might have been effected by changes in the irrigated area in Upper Egypt, but so far as is known from historical records there was no important change in either area or method of irrigation in the thirteen centuries, until 1833, when Mehemet Ali began the construction of barrages at the head of the two branches of the Nile a few miles below Cairo. This structure effected the levels at Roda by back-water. Prior to 1833, the stream flowed past Cairo substantially as it has done for many centuries. In ancient times Lake Moeris, one of the "seven wonders of the world", may have effected the levels. This lake, which occupied what is now known as the Fayum Basin, a depression in the Lybian plateau west of the Nile Valley, was filled at high water and drained as the flood receded, thus affording both flood protection and water supply to the valley below. It is believed that this lake was not used after 300 A. D. Certainly, it has not influenced the river during the period for which the Roda records are available.

The silt deposited by the Nile has been building up the level of the valley since the dawn of history. This effect is very noticeable throughout the length of the valley. The earliest scientific study of this, of which there is a record, was made by the savants who accompanied Napoleon to Egypt in 1798. They estimated from the depth to which structures were buried that 10 to 12 cm (4 to 4¾ in.) of soil were deposited per century. More exhaustive research, with other approximate information considered, has confirmed this figure and, to-day, it is generally accepted that the mean rise is about 13 cm, or 5 in. per century.

The gauge heights at Roda, for the thirteen centuries show nearly the same rise, both in high water and low water, disregarding the period since 1833. This fact is very significant and indicates that there has been only one change in conditions and that corresponds to the rise from silt deposition.

In the ages in which historical records have been preserved the number and location of the arms of the Nile have been changed several times, and there has been a constant building out of the Delta, extending the channel length. The swamps which once made up the Delta, have been built up by silt, dikes have been constructed to control overflow, and the entire character of the country has been changed; all of which is in agreement with what one would expect from a silt-bearing stream.

The entire Nile Valley, from the first Cataract at Aswan to the Mediterranean, is formed of sediment. The river encounters no rock after leaving the granite at Aswan. The slope of the water surface as far as Cairo is remarkably uniform both at low flow and in flood; it is about 1 on 13 000, or a little less than 7 in. per mile. The cross-section of the stream bed is also very uniform, increasing slightly down stream. On the whole, the result is what might be expected from a silt-bearing stream flowing through a channel of its own deposition. As the valley level rose through deposition, the stream has maintained its channel in depth, width, and slope.

Since the change in average levels on the Roda gauge corresponds so closely to the general average change in valley levels there is no reason to believe that there has been any progressive change in volume of flow.

These records from the Roda gauge indicate the following conclusions:

(1) There has been a fairly constant rise in levels, which may be attributed to the sediment building up the valley lands and the river bed at the same rate. Disregarding the last century of records (which since 1833 has been effected to some extent by work on the barrage at the head of the Delta),

there has been an average in flood levels of about 14 cm, or 5½ in. per century, in the 1 200 yr.

(2) The mean flood, taken as the average of high flood and low flood, has increased at about the same rate.

(3) The mean height of low water has apparently increased at a smaller rate, although the greater variation in low flow renders determination of the change uncertain. This may have been caused by the regulating effect on low flow by diversions, or by the dams from vegetation in the Sudd or swamp region on the White Nile.

(4) The mean of all records, averaging mean flood and mean low water, has changed about as the mean flood level, an increase of about 5½ in. per century. The change in the first seven centuries was less than in the latter five centuries.

(5) The mean range showed little change for nine centuries; then it increased about a meter for three centuries, but on the whole, it changed little in the 1 300 yr. This seems to indicate little change in the rise and fall of the river as a whole and points to a comparatively uniform channel during that period.

(6) There is nothing in this 1 300-yr record that shows any progressive change which may be attributable to change in climate.

J. W. Beardsley,[42] M. Am. Soc. C. E. (by letter).—Based on extensive records, this paper is complicated by the need of changing units and the interpretation of various languages. The Italian, Lombardini, stated in 1865 that "no river in the world lends itself to hydrological studies on so majestic a scale as the Nile." The Nile is Egypt. British engineers have estimated that it built up the Delta at the rate of about 6 cm per century (see Fig. 6 (*a*)). It furnishes ample water for fertile lands in a region practically rainless. In 1908, Sir William Willcocks, referring to the old basin irrigation, wrote:

> "It will be an evil day for Egypt if she forgets that, though basin irrigation with its harvest of corn has given way to perennial irrigation with its cotton fields, the lessons which basin irrigation has taught for 7 000 years can be unlearned with impunity. The rich muddy water of the Nile flood has been the mainstay of Egypt for many generations, and it can no more be dispensed with today than it could be in the past. * * * The basin irrigation of the ancient Egyptians may well be likened to the path of the eagle in its boldest flight, while the perennial irrigation of our day finds its true simile in the laborious task of the working bee."

Exclusive of Fayum and a few square miles of irrigable patches along the Nile between Aswan and Cairo, the productive area of Egypt is an equilateral triangle with sides about 240 km (see Fig. 6 (*b*)) long and with its apex at Cairo, approximately one-fifth of the area of New York State.

The White Nile rises in Lake Victoria under the equator, about 5 600 km from the sea, flows through long stretches of the Sudd with its papyrus, its swamps, and marshes, and delivers clear water into the Nile at its junction with the Blue Nile at Khartoum, 3 036 km from the sea. The Atbara joins the Nile about 320 km below Khartoum, and these two tributaries are the only ones between Khartoum and the Mediterranean Sea—a solitary course of 2 768 km to the sea.

---

[42] Cons. Engr., Syracuse, N. Y.

The total drainage area of the Nile is about 2 867 600 sq km (501 000 sq miles), of which the White Nile drains about 60%, the Blue Nile and the Atbara about 10% each, and these last two rivers bring down the floods of muddy waters during August and September; otherwise, their discharge is nominal. A table of monthly discharges prepared by Mr. E. M. Dawson[43] covers the years 1890 to, and including, 1908, the discharges being taken at Sarras 390 km south of Aswan. The mean low flow for May, the lowest month, was 800 cu m (see Fig. 6 (*c*)) per sec, ranging from 540 cu m in 1907 to 1 410 cu m in 1894. The high stage of September, the highest month, averaged 10 470 cu m, varying from 6 870 cu m in 1900 to 14 590 cu m in 1893.

FIG. 6.—CONVERSION SCALES.

An inspection of Fig. 1, covering maximum and minimum stages for 1 310 yr, suggests that equatorial cycles of rainfall may be shown by a study of minimum stages, the clear waters of which are derived almost entirely from the White Nile. A casual examination indicates cycles between 30 and 40 yr, or multiples thereof. Such an opinion needs verification based on original records. An expression of opinion by Mr. Jarvis regarding such verification would be of considerable interest.

The writer's notes are based on investigations made during the spring of 1909, when the height of the Aswan Dam was increased by 5 m. At that time a photograph was taken of the nilometer on Roda Island, near Cairo (see Fig. 7). This old gauge of Nile floods, a granite-like column with an ornamental capital, is located in a well about 16 ft square. It is said that when waters flooded the capital, benefits were a maximum and so were taxes. When flood waters did not reach the ornamental capital, or when they covered it entirely, taxes were reduced proportionately. Insufficient water reduced the normal crops. The excessive flood waters were harmful and taxes were reduced accordingly. The diameter of the gauge column is now (1935) estimated to be from 18 to 20 in. This gloomy well in a neglected garden, covered with a crude roof of galvanized iron supported by four posts, with its narrow steps growing slimy opposite the beautifully carved capital of the gauge column, and with a black bottom of unknown depth, was not specially inviting, but the view obtained was well worth the trouble. The date of the construction of this gauge was not determined. It was said that when floods reached the capital, agricultural conditions were perfect. Higher floods caused damage and lower floods were deficient. Land taxes were levied proportional to the stages above or below the capital, and if such stages were excessive, no taxes were levied. A maximum tax was due when the flood-stage was on the capital, a range of about 0.75 m. The low stages of May, and the rapidly increasing floods during July and August, and the September peak[44], are clearly shown on Fig. 8.

[43] *Cairo Scientific Journal*, October, 1908.

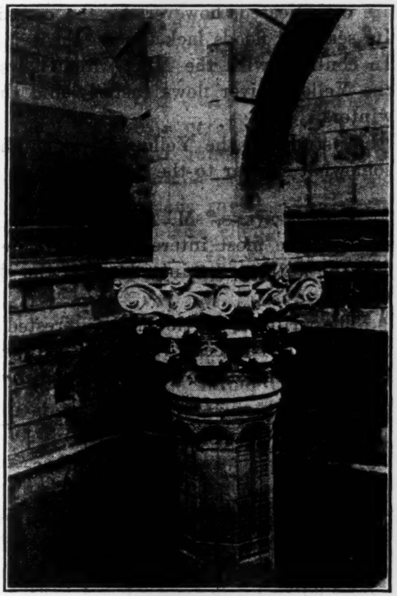

FIG. 7.—THE NILOMETER ON RODA ISLAND, NEAR CAIRO, EGYPT.

Possibly, the Yellow River of China has as many features in common with the Nile as any other river in the world. It flows through a fertile delta built up during past centuries by its load of silt. It flows through a region of scant precipitation insufficient for sprouting spring plantings, and the dense

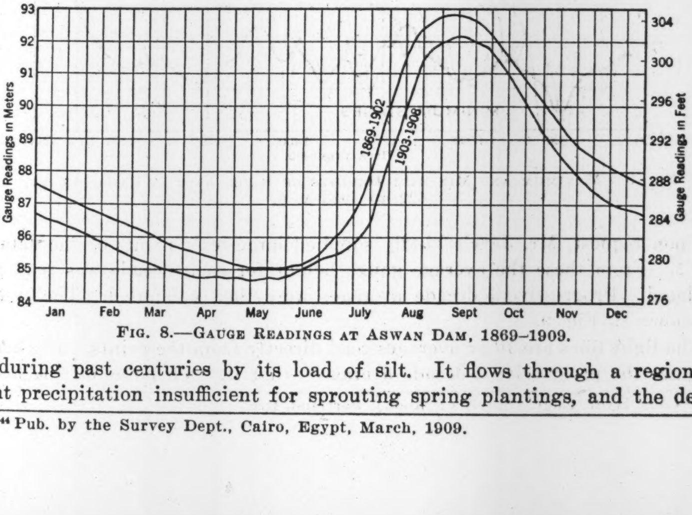

FIG. 8.—GAUGE READINGS AT ASWAN DAM, 1869–1909.

---

[44] Pub. by the Survey Dept., Cairo, Egypt, March, 1909.

population is dependent upon irrigation. Its tributaries are small and few throughout its 900-mile course through its deltaic area from its western mountain barriers to the sea. It also has long-time records of floods, which are complicated, however, by the occasional destruction of controlling dikes. Its seasonal floods lack the regularity in time and volume of the Nile floods. In contrast with the Nile, which flows north and is entirely free from ice, the Yellow River flows easterly and through some regions of intensely cold winters.

A study of the Yellow River might develop hydrological facts of value somewhat similar to the author's study of the Nile.

J. C. STEVENS,[45] M. AM. SOC. C. E. (by letter).—These records constitute some of the most interesting long-time river data that have been published, and the author certainly deserves the thanks of the profession for presenting them.

The writer is particularly interested in the rate at which the Lower Valley of the Nile has been raised by sedimentation as disclosed by these records. He is also curious to know whether any cyclic variations are in evidence.

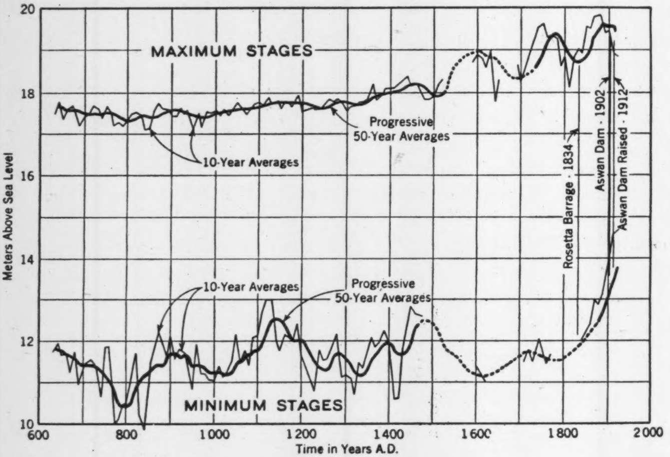

FIG. 9.—MAXIMUM AND MINIMUM HEIGHTS OF RIVER NILE AT CAIRO, EGYPT, 622 TO 1933 A. D.

Upon request, Mr. Jarvis kindly supplied large-scale prints of the data in Fig. 1. From these the average gauge height for each decade was read and tabulated. Progressive 5-decade averages were then computed. The results are shown in Fig. 9.

The light lines are 10-yr averages read directly from the prints. The heavy lines are the progressive 5-decade averages—that is, each point on the heavy line is an average of the preceding five decades. The upward slope of the heavy lines may be taken to be an index of the rate at which the Lower Valley of the Nile is being raised by sedimentation. Neglecting the increased stages caused by the construction of the Rosetta Barrage and Aswan Dam the average rate of rise is practically 4 in. per century for both the maximum and minimum stages.

---

[45] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

The highs and lows are prominent in the minimum stages and are nicely demonstrated by the progressive 5-decade line. No periodic cycle is in evidence, but high cycles alternate with low cycles of irregular duration.

Another significant point is that as evidenced by this nearly continuous record and from the sporadic records of isolated periods running back over 5 000 yr, there appears to have been little or no climatic changes that can be detected. In other words, it appears that the regimen of the Nile at present is very much as it was about 5 000 yr ago.

JESSE W. SHUMAN,[46] M. AM. SOC. C. E. (by letter).—The labor and patience involved in preparing a paper of this kind, are generally appreciated only by those who have made similar attempts, and the author deserves the thanks of the entire profession for his industry. As stated in the paper, the discharge records of rivers in the United States and in most other places extend back relatively only a few years. Although the Mississippi River, in length, is on a par with the Nile, the continuous discharge records run back only to about 1885; the records for the Tennessee River extend back about fifteen years more; so that if one wishes to study the behavior of a river, its mean, minimum, and flood flows, the available data upon which to base performance are really quite meager. In some cases the analyst finds that rainfall records over the drainage area of a river run back considerably farther than the discharge records, and through correlation between rainfall and run-off, he can "piece out" flows somewhat, and thus lengthen the record for statistical analysis. Although one might not believe in the theory of probability as applied to the study of river discharge, the longer the period embraced by the observations, the nearer to truth the results derived from them should be.

The Nile, alone, stands out as one river in the world on which flow data have been recorded for centuries. The author cites the various sources from which he has gathered the data depicted graphically in his paper. Doubtlessly, there are errors in the data—departures from the absolutely true data; but considering the nature of recording and bringing together these data in the first place, attended by the plus and negative errors of personal observation, it is quite likely that these, as well as the errors arising from copying and translation, would tend to neutralize one another, and thus leave an array of data that was fairly homogeneous, and suitable for any type of analysis. The Nile records, therefore, extend from the present back to about 620 A. D., with gaps here and there, but fairly continuously from 620 to 1521, and from 1700 to date, for the maximum stage of the river.

---

[46] Secy.-Treas., Power Eng. Co., Minneapolis, Minn.

Except for a casual glancing over of the graphs of dots and various check marks, and drawing from them only general conclusions, no type of analysis can be applied to the data of the paper unless the values are "picked off" with a magnifying glass, which again introduces another error. The general conclusions that can be drawn are that the maximum annual stages were confined to elevations between 16 and 18.5 m for the entire period, 620 to 1500 A. D., with occasional wide departures; and that from about 1600, the stages were higher, culminating in high values about 1860 to 1880. The chart of minimum stages shows more fluctuation and depicts the secular rise in the river bed, as pointed out by Mr. Jarvis.

Using the magnifying glass, then, and a suitable scale (in this case, 40), one can determine the ordinate values of the charted data, and the information is ready for statistical treatment. The question arises, as to what can be accomplished.

There are many adherents of the practice of treating river-flow data as chance numbers, and the problem is left to them for their exposition. The writer is convinced that there is some law and order in river discharge (that the data are related numbers), and will endeavor to give his reasons therefor, followed by the type of analysis of river flow that results from such reasoning.

Consider the Nile River. It has a drainage area of about 1 107 227 sq miles. Although a record of the stages of the river is given over a long period, there is uncertainty, nevertheless, as to when any departures, increases, or decreases, may be expected or how long an apparent trend of values will continue. A search is made, therefore, for all available data that might possibly bear on the subject. Not much is really known about the Nile and its behavior, except that its source is now considered to be the Victoria Nyanza, with contributions from the Albert and Albert Edward Nyanzas, and the surrounding swamp countries close to the equator; that as it proceeds northward, it receives the discharge of the Sobat River, which drains a region of heavy rainfall; that farther north, the Blue Nile, rising in Abyssinia, pours its turbulent flows into the main stream, giving rise to the floods that have been recorded. The base, or steady flow, is provided by the White Nile, and the floods by the Blue Nile. Rainfall records are either lacking entirely or are scant, being for only a few years; so that little can be done by correlation with it as a factor. The River Atbara, rising in Northern Abyssinia, discharges into the Nile about 200 miles north of, and into the Blue Nile at, Khartoum.

An analysis of a river's behavior involves one of three methods: (1) Treating discharge data as purely fortuitous; (2) using harmonic analysis; or (3) using what is finally becoming known as cycle analysis. The disadvantages of the first method are that conclusions are drawn from data embraced only in the available record, for possible performance beyond that period; and that several eminent mathematicians have proved that the data are not chance numbers. The disadvantage of the second method is that, although one can break up into component elements a given curve of river flow, by means of the Fourier series, the equations developed by the data will not necessarily reproduce the actual observed data at a later date. The disadvantages of the third or cycle analysis are, that it is as yet not completely developed, there being much to learn; that no treatise is yet available that covers the subject; and that, due to these causes, members of the profession have not become acquainted with it. It has some advantages over the other types of analyses, however, as the writer hopes to demonstrate in what follows.

The principles of cycle analysis will be developed as the writer proceeds with the treatment of the Nile data, but it is deemed necessary first to give some background to show that it is not extravagant nor lacking in consistency.

Briefly, cycle analysis consists of breaking up data into component elements, by suitable reducing means, quite differently than in harmonic analysis, and deriving certain pattern curves or cycles, which are similar to curves derived from sunspot data, giving thereby something to which terrestrial phenomena can be tied, and thus an inkling of what is to come and of what has gone before, beyond the periods of known data.

In order to make any progress, a research worker is obliged to set up certain postulates, for without his imagination, he would be merely an observer of phenomena and a gatherer of observational data. Therefore, he accepts the best that is offered at the moment. Clayton[47], Abbott[48], and others may be all wrong in their contention that the trigger action of the varying heat output of the sun is responsible for the changing weather. Clayton's work as head of the Weather Forecasting Department of the Argentine Republic, some years ago (where he successfully forecasted rainfall and temperature a week in advance) may not have been what it was purported to be, and the weather may be purely fortuitous or governed entirely by terrestrial causes; but even granting these points, it seems to the writer that there should be no objection to utilizing the fact that a certain cycle can be derived statistically from the sunspot numbers, varying in periodicity depending upon the length of two consecutive solar cycles, and which is named the Bruckner cycle[49]; and that also a similar cycle derived by similar processes in river run-off, rainfall, temperature, lake levels, etc., is identical in its general pattern, although varying in phase from place to place. This fact of phase variation, it seems to the writer disposes of much of the previously found confusing results.

It is found that the pattern of weather, as defined by the Bruckner cycle, is general, but with modifications as to intensity and fortuitous occurrence of yearly values, everywhere about the globe, and that the phase varies, depending upon the location, continentality, etc. For example, the Bruckner cycle detectable in the flow of the River Nile, is exactly opposite in its swings up and down, to the Bruckner cycle in the Mississippi River.

The question is frequently asked: "How can the changes in weather, which is different at various places, be brought about by any slight variation in the solar constant, when the sun is more than 90 000 000 miles distant?" There are certain groups who maintain that it is not necessary to depart from this planet to find suitable agents that can cause weather to change. So far, however, this group has failed to bring forward any workable procedure for long-range forecasting, and it is certainly this very thing that the engineer is attempting when he analyzes the flow of a river which has records for only, say, fifty years; and yet he is trying to deduce its performance over a longer period of time in the future. Consequently, whether or not it is recognized, engineers are very much interested in long-range forecasting, in studying a river, designing a bridge, or laying out a great highway. The problem involved, is to ascertain and use, as key factors in design, not only the values in the past and present, but also what will be probable for some time to come in the future.

Studying the data of the Nile River as presented in this paper, with a view to utilizing them for cycle analysis, after several preliminary trials, it was decided to use the Lyons data[13] as charted from 1738 to 1872, and the Roda gauge data from 1873 to 1921, for the maximum annual stages, as well as the records taken from Fig. 3, giving the annual or seasonal volume of discharge at Aswan, from 1870 to 1932.

In performing the computations to secure the cycles, the data are arranged, and manipulated as outlined, in Table 6. Values of the data are included only for 10 yr, in order to illustrate the method. Use paper ruled with vertical and horizontal lines, and enter in Column (1) the dates for the complete record to be analyzed. In Column (2) are the data from the chart after deducting 18.00 (so as to yield as small a number as possible with which to work); call these data 0. Now, add the first two values in Column (2), entering the sum in Column (3) opposite the second value as shown. This Column (3) is headed "Residual No. 1", or R_1. Now, repeat this operation, adding the two consecutive values of R_1, and writing the sum in Column (4), opposite the second value as before, these values being called R_2. R_4 can be derived by repeating the addition twice, and then dividing by 16, but after considerable work in this kind of manipulation, the writer prefers to make only two additions, as shown, to R_3, and then to divide

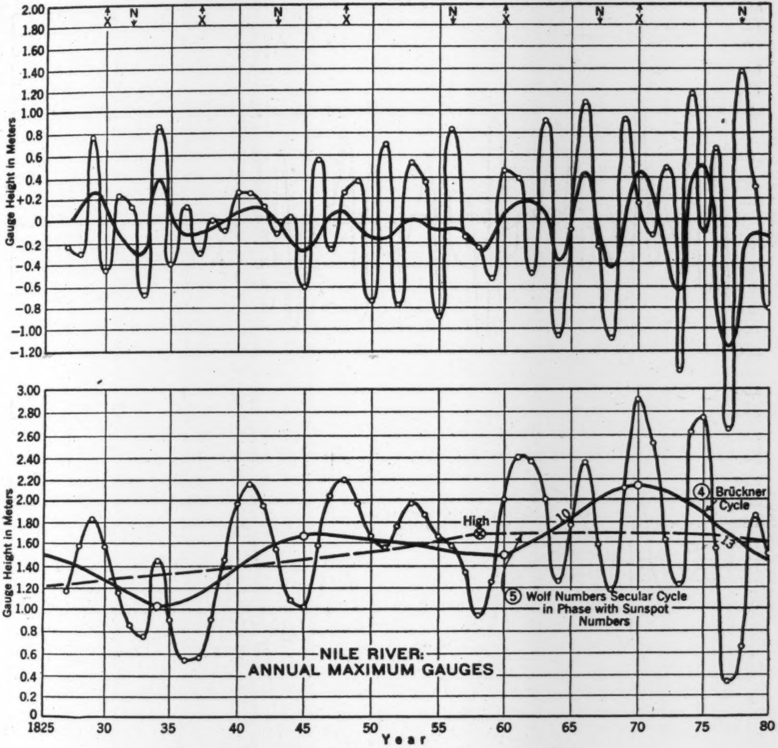

FIG. 10.—ANNUAL MAXIMUM GAUGES, NILE RIVER.

R_3-values by 4 and place the quotient one step upward in Column (5), headed "Scale and Phase". After R_4 is derived, it is restored to "Scale and Phase", and its values are entered in Column (8). Now, subtract the values of R_4 from the original value in Column (2), and enter the results, plus or minus, in Column (9), the values of which are called "Stratum No. 1", or S_1.

After the values of S_1 are secured for the length of the record, they are plotted as shown, for a representative part of the record, in Figs. 10 and 11. Although the original data began at 1738, the earliest value the residual yields is for 1740. Some care must be exercised in adopting proper vertical and horizontal scales, in order that the oscillating values of S_1 will show clearly, and also that the median line, M_1, drawn through the various loops of S_1, will be of sufficient scale that its ordinate values can be read with reasonable accuracy.

After S_1 has been plotted, as shown in Figs. 10 and 11 (Curve 1), one looks over the data of R_4 in Column (8), Table 6, and checks the maximum and minimum values which will alternate through the record. Next, the median

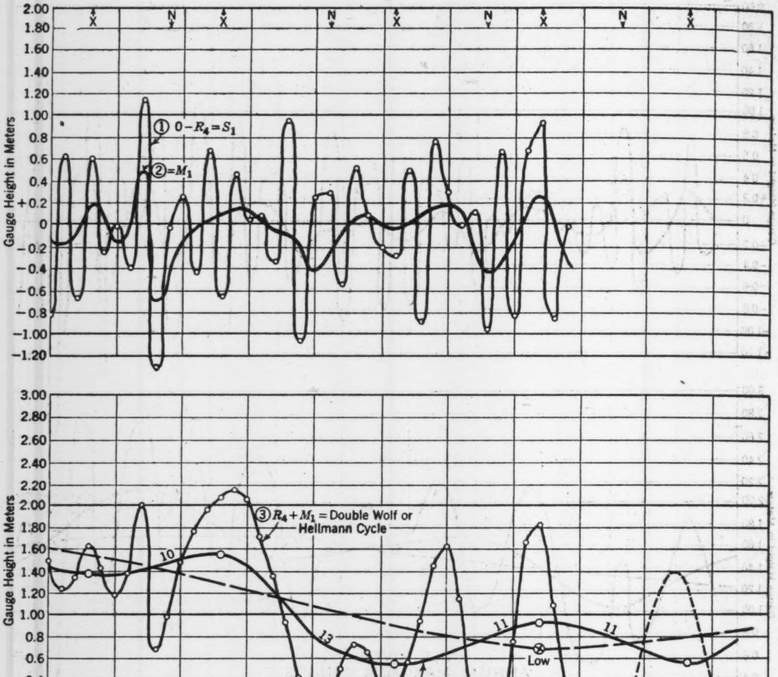

FIG. 11.—ANNUAL MAXIMUM GAUGES, NILE RIVER AND MISSISSIPPI RIVER.

line, M_1 is drawn through the curve, S_1, following as closely as possible, the "ups and downs" of R_4. The ordinate values of M_1, as now derived, are picked from the drawing, and entered as plus or negative values in Column (10), Table 6. Now, if M_1 is subtracted from S_1, the smallest cycle is secured, called the Clough cycle[50]. If M_1 is added to R_4 and the values are entered in Column (11), Table 6, the result is the Double Wolf, or Hellmann, cycle.

Before proceeding further it might be wise to offer a series of definitions, due to the undeveloped state of this type of analysis. The following cycles have all been discussed by various writers, but the notation has not yet been established.

Clough Cycle.—This is a small cycle of 2 to 3-yr periodicity, averaging about 28 months. It is very prevalent and persistent in all meteorological data, and was discovered by Clough, Clayton, and Abbot.

Wolf, or Wolfer Numbers.—These are provisional sunspot numbers; a Wolf number is an empirical index number, derived from the number and area of sunspots. The numbers are usually published after observational data have been slightly smoothed.

Double Wolf, or Hellmann, Cycle.—A cycle that crests about every 5.5 yr, generally just before, at, or after, sunspot maximum and minimum. It is variable and does not always appear consistently, although in some locations it is very clear, consistent, and definite. Hellmann was one of the first to point out the maximum rainfall that occurred twice in a Solar cycle. Horton also referred to it later. Some writers call it the Double Wolf, and some the Hellmann, cycle.

Solar Cycle.—This is the well-known cycle of the sunspot periodicity. From maximum to maximum sunspots, the period averages a little greater than 11 yr. This is commonly called the 11-yr cycle. It is detectable in a great many terrestrial phenomena and is especially prominent in lake levels.

Bruckner Cycle.—This is a cycle of twice the periodicity of two consecutive solar cycles, about 22 to 23 yr in length. It was first discovered by Bruckner[49], but by him given a varying length of 25 to 50 yr, the average value of which was set at ± 35 yr, due to the fact, as shown by Streiff[51] later, that his cycle was a composite of the secular and the cycle of two solar years.

Double Wolf Secular Cycle.—A cycle of twice the periodicity of the Bruckner cycle. First mentioned by Streiff in personal correspondence with the writer, and prominent in many meteorological data, especially in lake levels[52].

Secular Cycle.—The long swing in Wolf numbers is of varying length: The last high point was about 1856, the three previous highs were at 1798, 1704, and 1646. It is a cycle that is apparent in Wolf numbers, in tree-ring growth, varves, rainfall, temperature, lake levels, etc. Sometimes it is of such small amplitude as to be unrecognizable, in certain locations.

[50] *Monthly Weather Review*, April, 1933.

[51] *Loc. cit.*, July, 1926, and March, 1928.

[52] "Notes on Lake Levels", by Jesse W. Shuman, *Monthly Weather Review*, March, 1931.

There are still longer and shorter cycles, but the foregoing are of the most use in analyzing the immediate past and future. Finally, looking back over the foregoing array of cycles, the observational data oscillate above and below the Double Wolf cycle, which, in turn, oscillates about the Solar cycle. This, in turn, oscillates about the Bruckner cycle, which, in turn, oscillates about the Double Wolf secular cycle; and, finally, the latter oscillates about the secular cycle of the Wolf numbers.

The values of $R_4 + M_1$, the Double Wolf cycle in the Nile River data, from Column (11), Table 6, are now plotted in Figs. 10 and 11, on the same time scale, as Curve 3. The break in the records from 1800 to 1825 is shown on the charts.

Now, after the $R_4 + M_1$ cycle is drawn, as in Figs. 10 and 11, it is sometimes necessary to reduce it further by two to four additional operations, before drawing in the median line, Curve 4, which is the Bruckner cycle. In this case, however, the further reduction seems to leave the relative vertical positions of the loops with respect to each other, unchanged. Therefore, the median line (Curve 4, Figs. 10 and 11) is drawn through the plotted data of $R_4 + M_1$. The median line, Curve 5 (the Secular cycle) is now dotted through the loops of the Bruckner cycle, the high point being at about 1860 and the low point, in Figs. 10 and 11, at about 1915 to 1920.

At the top of Figs. 10 and 11, under the scale of years, are placed arrows marked X or N, pointing upward or downward, to identify the times of sunspot maximum and minimum. The analysis is now complete and the analyst is free to examine what has been developed. It must be kept in mind that each plotted point of $R_4 + M_1$ (Curve 3), is a residual derived from five annual numbers, and that the actual yearly value may be more, less, or the same. In general, a peak of the Double Wolf cycle indicates that the average value of the five years' data—two years before and two years afterward—combined by residuation with the data for the plotted year, was at a maximum, and the troughs indicate the reverse.

Examining the Double Wolf cycle (Curve 3), it is noted that a succession of peaks and troughs, oscillate about the heavily drawn Bruckner cycle. At some places on the record they occur quite consistently with respect to sunspot maxima and minima, but by no means sufficiently so that one could rely upon the recurrence. The peak at 1861 occurs one year after sunspot maxima; at 1870, it occurs exactly on that date, as well at at 1883; but it is one year delayed at 1893, etc.; so that in the case of the Nile River, the Double Wolf cycle can be used for purposes of forecasting only in a general sense.

It is to be noticed, however, despite the secular rise in the river's bed, as depicted by the records of the minimum stages in Fig. 1 of the paper, that the period centering around 1870 represented a high point, or increased flood conditions, and that the period about 1905 represented a decreased condition of flow. The Bruckner cycle derived in the flow records of the River Nile, are just about, if not exactly, in phase with the Bruckner cycle in sunspot numbers.[53] The graph shows that the behavior of the Nile River is very strongly influenced by the Bruckner cycle. The data ended at 1921, and the last plotted date of $R_4 + M_1$ was at 1919. The question arises, can any of these cycles be extended into the future, with any dependability? The answer would have to be negative, if these data were all that were available. Fortunately, however, there are many other data on which to perform similar analyses, and results that can be compared with those of the Nile River. After a turning point has been developed in a cycle, it can be extended with considerable accuracy; hence the necessity of cross-identification with data from elsewhere, the phase of which may differ, and upon which a certain cycle may have reached a turning point.

---

[53] For Bruckner cycle in sunspot numbers, see, the writer's Fig. 8 in discussion of "Rainfall Characteristics and Their Relation to Soils and Run-off", by C. S. Jarvis, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 379.

The writer has taken data of tree-ring growth from Douglass[54], for a certain tabulation named "Flagstaff High (F.L.H.) 10 trees", and by using the same type of analysis, to derive the Double Wolf cycle, and, subsequently, drawing a median line through the various loops, the Secular cycle shown diagrammatically in Fig. 12 was secured. It will be noted that the wet periods were at 1646, 1704, 1798, and 1856; that the dry periods were at 1670, 1766, and 1822, and that the last dry period centered around the date 1918. The tree-ring data did not extend far enough to get this last date, and until about 1932, the writer thought that this last date should be about 1905 to 1910; but examination of data from varied and widely placed sources, has led him to believe that the date must be about 1918. Then, too, another confirmation has only recently been given this date. A study[55] of Halbert P. Gillette, M. Am. Soc. C. E., on certain cycles, chiefly the 70 and 152-yr cycles, was presented at Los Angeles, Calif., in June, 1935. The analysis as used herein will not develop this 152-yr cycle, but in examining Fig. 12, giving the Secular cycle in tree rings, it will be noted that from 1646 to 1798 (two Secular cycles) is a lapse of 152 yr; from 1704 to 1856 (again two cycles) is 152 yr; furthermore, from 1670 to 1822 is 152 yr. This remarkable consistency, if genuine, would set the last low of the Secular cycle at 1766 plus 152 yr = 1918, and the next high at 1798 plus 152 yr = 1950. Every record of meteorological data examined recently by the writer seems to confirm this last low date as about 1918. This low is the turning point of the Secular cycle, which is threaded through the Bruckner cycles, so that there will be a low of the Bruckner cycle before, and after, the low of the Secular cycle.

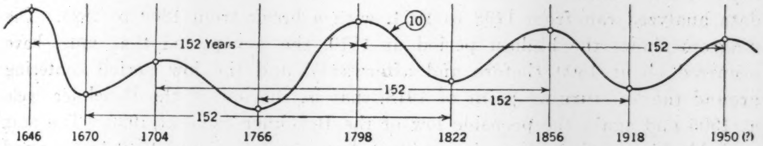

FIG. 12.—SECULAR CYCLE.

---

[54] "Climatic Cycles and Tree-Growth", by A. E. Douglass, Vol. II, The Carnegie Institution of Washington, Washington, 1928.

[55] "The Cycles That Cause the Present Drought", by Halbert P. Gillette, presented before the Annual Meeting of the Am. Meteorological Soc., Los Angeles, Calif., June 26, 1935.

Now, having some conception of what the Secular cycle is like, and the relative magnitude of its previous highs and lows, the student is in a position to draw some conclusions about the behavior of the Nile River, and to make some extensions beyond the times of the recorded data. Fig. 13 is a diagram, showing the Bruckner cycle of the Nile River from 1740 to 1960. The actual data analyzed ran from 1738 to 1921, with a break from 1800 to 1825. The diagram shows the highest period at 1870, the low period that must have occurred about 1800 (before and afterward), and the low period centering around the low turning point of 1918, that is, the low of the Bruckner cycle at 1905 and again the probable low of the Bruckner cycle at 1930. The next probable high period of maximum stages will center around 1940 to 1942 and conditions may equal those of the 1892–94 period; or, if the behavior is erratic, even those of the 1870 period. These ideas are indicated by the trends of the Bruckner cycle oscillating on the Secular cycle.

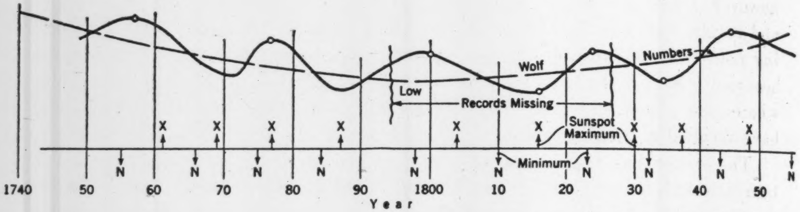

FIG. 13.—BRUCKNER AND SECULAR CYCLES IN

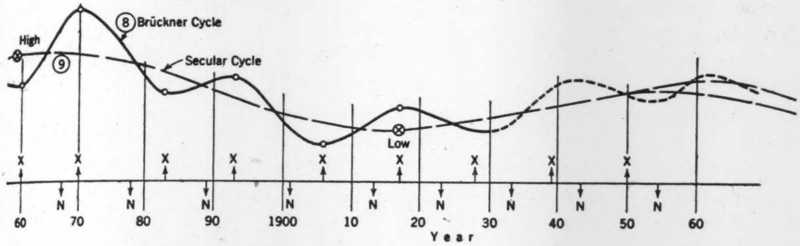
On Fig. 11, at the bottom, with the same time scale, is shown a graph of the Double Wolf cycle and the Bruckner cycle, in the Mississippi River data, taken at Arkansas City, Ark., for annual maximum gauges. The data on this river run back to only about 1885. Note that the Bruckner cycle in this case, is just opposite in phase to the Bruckner cycle in the Nile River. During the early Eighties, the Mississippi River had severe floods; whereas the Nile River was lower then than before or afterward. The last great flood of the Mississippi River was in 1927, a period that must have had relatively moderate stages on the Nile River. In other words, the Bruckner cycle in the Nile River, is ahead of (leading) the Bruckner cycle in the Mississippi River by one-half the Bruckner cycle period—about 11 to 13 yr. The performance of the Mississippi River, in general, can be forecast from the behavior of the Nile. For example, the high stages on the Nile in 1870 were followed in the Mississippi River about 1882 and 1883; the low stage of the Nile in 1883 was followed on the Mississippi River at about 1895, etc. Judging from past performance, the comparison of the Nile River and Mississippi River cycles, indicates that the high stages of the Nile in 1917 would be followed on the Mississippi River about 11 to 13 yr later, with real flood stages. The great flood of 1927 on the Mississippi River, came just ten years later. The low condition of the Nile in 1927 would lead one to expect a downward trend of the Mississippi River flood conditions until about 1940 (bearing in mind, however, that frequently a real flood occurs close to the low point of the Bruckner cycle, as at 1897, etc.)



MAXIMUM ANNUAL GAUGES, NILE RIVER.

Fig. 14 has been prepared to show a comparison between the Nile River and the Mississippi River, using for the Nile, the data from Fig. 3, of seasonal

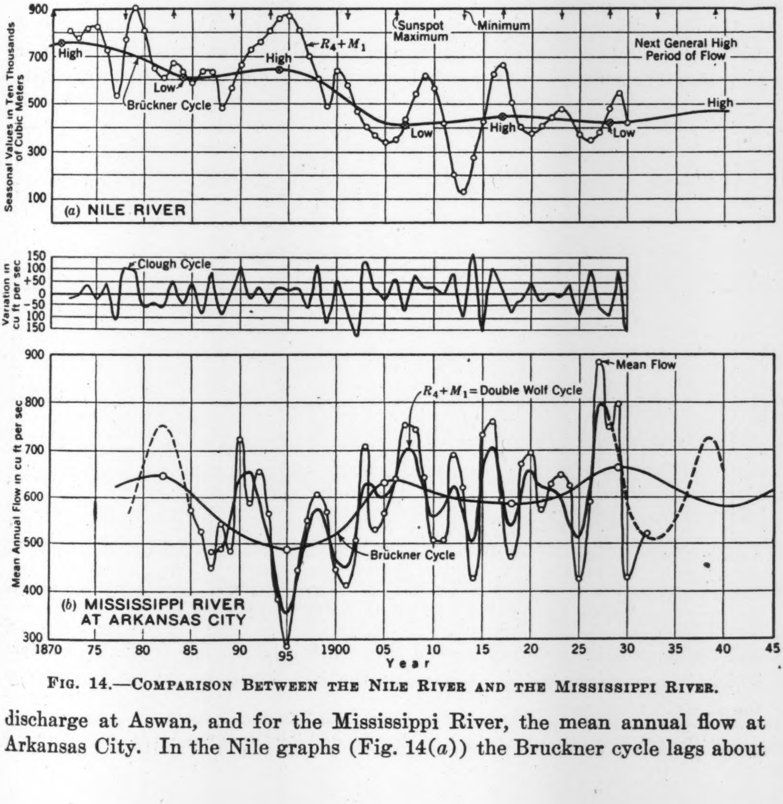


FIG. 14.—COMPARISON BETWEEN THE NILE RIVER AND THE MISSISSIPPI RIVER.

discharge at Aswan, and for the Mississippi River, the mean annual flow at Arkansas City. In the Nile graphs (Fig. 14(*a*)) the Bruckner cycle lags about one year with the same cycle in sunspot numbers, or is nearly if not in phase (although the writer has placed small circles at each turning point of the Bruckner cycles shown in all the graphs in this discussion, it must be understood that it is probably impossible to define the actual turning point so accurately, at least with the type of mathematical procedure used herein. The circles are placed simply to give accent to the change of the trend in that region.)

Although the Secular cycle has not been drawn in, an inspection readily indicates that it is present in the data. For the Nile River, the Clough cycle is shown, secured by subtracting M_1 from S_1 (not shown herein). The algebraic sum of $R_4 + M_1$ and the Clough cycle equals the yearly discharge value.

The same cycles for the Mississippi River are shown in Fig. 14(*b*) as well as the annual values connected by a lightly drawn line. In this case, as in the case of Fig. 11, the same opposition in phase of the Bruckner cycles is in evidence. The Bruckner cycle is trending downward to a low point about 1940, although a peak in value of $R_4 + M_1$ may be expected before that time, of a magnitude considerably less than that in 1927.

Graphs[56] illustrating the varying level of Victoria Nyanza, the source of the White Nile, and the variation in the rainfall of that region are shown in Fig. 15. The sunspot maxima and minima are marked on the time scale, and the dotted line drawn freehand through the lake levels is the Solar cycle, which is beautifully clear. Note that the lake levels are at peak always at the sunspot maximum.

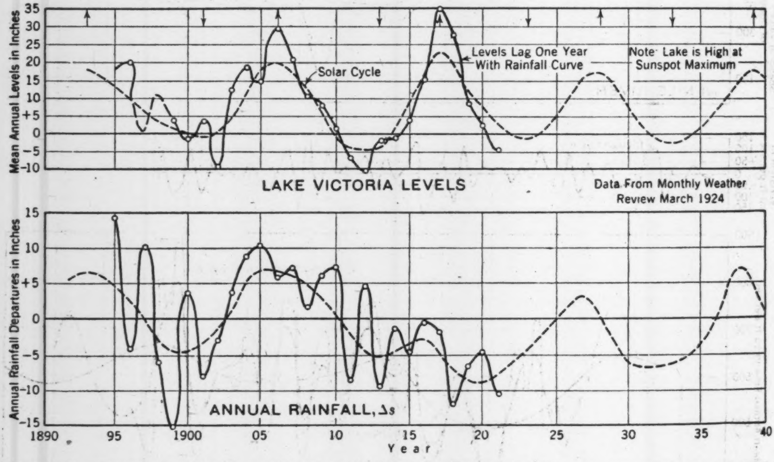

FIG. 15.—DIAGRAMS SHOWING VARYING LEVELS OF VICTORIA NYANZA, THE SOURCE OF THE WHITE NILE, AND VARIATION IN RAINFALL IN THAT REGION.

---

[56] Original data pub. by Mr. C. E. P. Brooks, and later reviewed by Alfred J. Henry in *Monthly Weather Review*, U. S. Weather Bureau, Washington, D. C., March, 1924.

The outflow of this lake forms the base flow of the Nile, but there appears to be but little correlation, as would be expected, between the graphs of the river and the lake. If, however, comprehensive rainfall records were available, distributed over the drainage area of the Nile River, their statistical treatment taken in conjunction with that of the river, would yield immensely important information. This importance would be further enhanced if, in addition, records for temperature were included, and similarly treated, because temperature is a primary factor, whereas rainfall is secondary. For this lake Brooks found[57] that the correlation coefficient between the lake levels and rainfall was + 0.92, and between lake levels and sunspots, + 0.80.

The annual flood stages of the Nile River are of great importance to Egypt, and in bringing together the data described in his paper, the author has placed at the disposal of the profession valuable information, gleaned at great pains, which should ultimately lead to new interpretations. If mean monthly flow records were available for a period of years, this type of analysis would enable one to forecast the probable mean flow for the ensuing future year with considerable accuracy. In this discussion the author's records have been treated only back to 1738, and it is believed that sufficient knowledge can be deduced from this range of values because, although the regimen of the River Nile may be affected by the various causes, as pointed out by the author, the writer wishes to suggest that any such change in behavior would be gradual; so that in comparing values of to-day with those of 4 000 yr ago, when the average annual flood stages were about 23 ft higher than at present, the differences encountered would be of historical interest only. One would not need to consider the old records in designing a dam or other controlling works, which will endure probably not more than 150 to 200 yr.

Cycle analysis presents a conception of the variation in weather as registered by the river's flow, and suggests that extreme values, high or low, are not suddenly brought about, but are approached in an oscillating, pyramiding manner, culminating at the extreme value.

It is not yet 450 yr since Columbus discovered America, so that no structure in this country is that old. Prime movers are likely to become obsolescent in about 25 to 30 yr, and the life of a concrete dam is 50 to 200 yr. If any confidence can be placed in cycle analysis of a river's flow, that attempts to relate it with the changing weather, it follows that only values embraced in, say, 200 to 300 yr, are necessary for any type of analysis. Great catastrophies such as those in the past, probably did not strike from "a clear sky", but were the culminating point in a stormy period of greater intensity than normal, and which developed gradually enough so, that with proper knowledge, due warning of their approach was given.

The Ministry of Public Works of Egypt, in discussing the hydrology of the Nile Basin, states[58] that these records of the flow of the river have been analyzed for periodicities, and periods of small amplitude have been found. Quoting:

---

[57] *Geographical Memoirs No. 20,* Air Ministry, Met. Office, London, England, 1923.

[58] "The Nile Basin", Vol. I, *Physical Dept. Paper No. 26*, Govt. Press., 1931, Cairo, Egypt.

> "They are, however, so masked in irregularities as to be useless for forecasting purposes. A connection exists between conditions in the South Atlantic and the Nile, but up to the present it has not been possible to make a forecast of the flood which is sufficiently reliable for practical purposes. However, as the science of meteorology develops and the nature of the mechanism producing the flood becomes known in detail, it may be possible some day to produce an accurate forecast of the nature of the flood some months in advance * * *."

The writer has already called attention to the connection that must exist in weather at different places, the reflection of which is given in river performance (for one index). It appears from the foregoing quotation that the authorities in charge of the controlling works of the Nile are cognizant of this fact and are working with it. The connection in the long swings, as defined by the Bruckner cycle, has been demonstrated in Fig. 11 between the Nile and the Mississippi Rivers. Doubtlessly, further search would bring to light other connections.

If the entire record of the Nile back to 620 A. D. were analyzed to secure the cycles described herein, interpretations of their probable effect upon the economic life of that region could be made by recourse to the vast storehouse of ancient literature that exists, which mentions here and there conditions that are ascribable to the Nile's behavior at the time. This river alone seems to have not only a very long record but also the written history of the times to accompany it, so that the field should be very fruitful.

Pharaoh Necho II (610 B. C.) was the first ruler[59] to attempt to create a connection between the two seas (Mediterranean Sea and Red Sea). Herodotus records this effort. The canal tapped the Nile at Bubastis, near Zagazig, and mention is made that the Red Sea extended farther inland then than at present. The length of this canal was computed by Pliny to be about 57 English miles. Herodotus states that its construction cost the lives of 120 000 men. Due to an adverse Oracle, warning that it might provide too easy means for approach to Egypt, the project was abandoned. Note that this was a period of ample water on the Nile. The canal was restored under Ptolemy Philadelphus (285 B. C.), and locks and sluices were used. This period also had ample water. Under Cleopatra (31 B. C.) the canal was impassible (a low-water period). Emperor Trajan (98–117 A. D.) found the Pelusiac Branch of the Nile very low, with practically no water. He tapped the Nile very much farther up stream.

Ptolemy wrote, in 150 A. D., the first clearly intelligent account of the origin of the Nile, something that had always been a great mystery. He writes of the two lakes, Victoria and Albert Nyanza, and the Mountains of the Moon. No less than 1 170 yr had to elapse before justice could be done this ancient geographer, and his account verified.

When one scans the history of regions not greatly remote from Egypt, and notes the vicissitudes of climate they have endured, it is significant that the records of the Nile disclose no such changes—merely changes of the weather. It was evidently with good reason that Egypt, with its droughts and famines notwithstanding, was a good place in which to live, by contrast with other not far distant regions, the flow of the Nile River being uniform enough so that even in its low periods, it carried sufficient water to keep the nation from migrating.

---

[59] "History of Egypt", by Rappoport, The Grolier Soc., London, England, 1904.

Kamel Osman Ghaleb,[60] Esq. (by letter).—Since 1926 the writer has been connected with the nilometer on Roda Island, on behalf of both the Irrigation Department and the Committee for the Preservation of Arabic Monuments.

In 1925, the column of the nilometer subsided about 7 cm and became detached from its upper support; it was propped up, to prevent it from falling. In December, 1926, pulsometers were used to unwater the well, so as to fix the column in position but, when the water level was lowered to about 2 m from the bottom of the well, dangerous cracks appeared in the walls and the unwatering had to be stopped lest the entire structure collapse. The Egyptian Parliament voted £20 000 (Egyptian) in the financial year beginning April, 1929, for the repair and restoration of the monument (see Fig. 16), as well as the expropriation of land surrounding it.

The column is an octagonal marble pillar with an enlarged base; the capital is an addition, probably of the Eighteenth Century. The engineer who erected the column in 861 A. D., has left a full description of its graduations. He states that it is divided into 19 equal cubits; in fact, at the upper end of the cubit just below the capital is inscribed in relief, in Arabic in Cufic characters, the words, "nine (&) ten cubits." As far as has been ascertained, the column is broken in three pieces: The top break, which is indicated on the drawing made during the Napoleonic Expedition, has been well repaired; the two ends of the lower break have been badly joined together, and the corresponding cubit now measures 31 cm only instead of the usual length of 54 cm. As in the case of the Suez Canal, the French savants attached to the Expedition, who have left such a wonderful detailed record of the monument, made an extraordinary mistake; in the Canal they had found a great difference in levels between the Mediterranean and the Red Seas; in the Roda nilometer they mistook the top cubit for the sixteenth; and one of them—the famous Arabic scholar, Marcel—when he returned to take service in Egypt years later, indicated that mistake and read the top cubit as the seventeenth. When the well is completely unwatered it will be possible to ascertain whether the French embedded the lowest part of the column, or whether they replaced it on the floor, as formerly, and simply neglected to take account of its base in counting the number of cubits to the top.

However that may be, the reason for the apparent unpredecented rise during the final century of record of another 6 cubits, mentioned in the paragraph following Table 1 of the paper, can now be easily explained; the 3 full cubits suppressed by the French savants, become 6 cubits in the readings for the maxima stages of the river, which are above the sixteenth cubit, where half cubits are read as full cubits. The French thought accordingly that lands watered at the beginning of the Nineteenth Century, when the Nile level was at 16 cubits, were previously irrigated at between 13 and 14 cubits. Another similar error seems to be current now; it is stated in the paragraph following Table 1 of the paper, that the flood-stages that indicated an assurance of plenty progressed gradually from 16 to 20 cubits on the Roda gauge. This statement must be due to a confusion in the translation of the mediaeval chronicles, the three stages of the rise of the river corresponding with the three categories into which the agricultural land of Egypt was divided being taken for one stage only.

---

[60] Insp.-Gen. of Irrig., Lower Egypt, Cairo, Egypt.

The low lands were watered when the Nile reached 16 cubits; the middle lands were irrigated at 18 cubits; and the high ones at 20 cubits. On the occasion of each of these stages there was a special festival, and water was let into a canal by the cutting of a cross-bank. The first of these festivals was for the "wafa", mentioned by Mr. Jarvis, the second was for the "Neirouz" (the New Year's day of the agricultural year, which has now become the beginning of the Coptic year); and the third for the "Saleeb" which falls seventeen days after, and which is now also kept as a religious Coptic festival.

As far as historical times are concerned, the 16 cubits of the Nile have allowed a sufficient supply; that is, there was no chance of starvation when that level of the river was reached. The Arabs, on conquering the country, adopted this same criterion and called it the "wafa." Consequently, there has been no rise in the level of the water required to irrigate the land and, therefore, that land itself cannot have risen appreciably. The writer considers that deducing the secular rise of the Nile flood-plain by dividing the thickness of a local deposit by a number of centuries results in showing Egypt to be much younger than it really is and that (as mentioned by the author under the heading "The River Nile in Egypt") other methods of reckoning, etc., almost invariably indicate much longer periods of geo-morphic development and are more accurate.

Fig. 17 shows the niches in the western wall of the well by which the gauge-reader was guided at the beginning of the rising flood; the "wafa" stage was reached when the water attained the small bottom niche to the right, as the sixteenth cubit coincides with the bottom of the rounded cornice which touches the top of the arch of the main opening. At that stage the column could only indicate the thirteenth or fourteenth cubit due to the misreading of the graduations; that is, considering the highest cubit as the sixteenth or the seventeenth instead of the nineteenth. This led the gauge-reader to add the difference to the "supposed" correct reading of the column, and also to consider the length of the cubits from the sixteenth to the twenty-second as one-half that of the ordinary cubits (this method of reckoning is imaginary, as there are no such graduations as those mentioned in the text following Fig. 1 of the paper; it is amusing to note how a scientific meaning can be attributed to a popular error). The seventeenth cubit coincides with the bottom of the lower Arabic inscription and the highest niche.

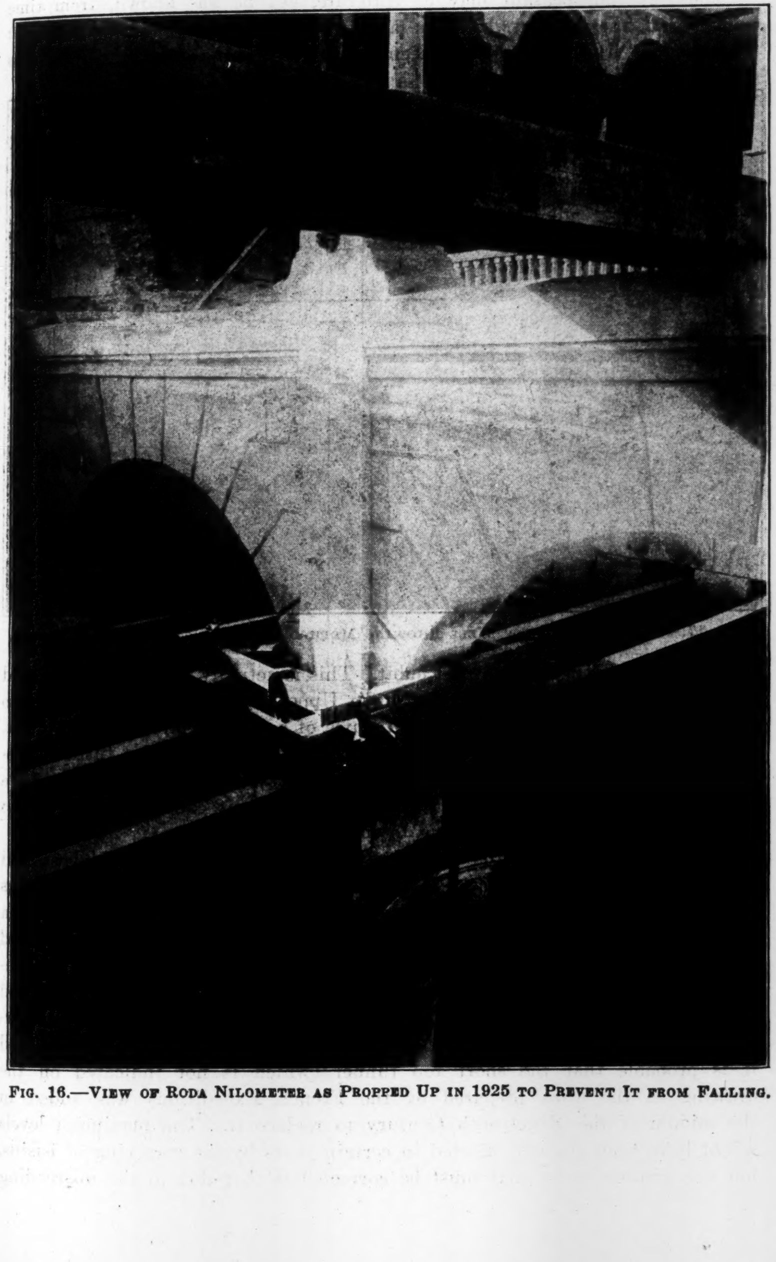

Fig. 16.—View of Roda Nilometer as Propped Up in 1925 to Prevent It from Falling.

The Egyptian peasant may be illiterate, but he has known, from time immemorial, the level at which his land is watered; he will say, for example: "My land is irrigated at the fifteenth cubit" meaning that it will get its water when the Nile rises to that cubit. This is actually the case for the land still remaining under basin irrigation in Upper Egypt. It is the custom to design the level of the floor of a head-sluice of a flood canal to a given cubit, corresponding to the level of the land it has to water. It seems futile, therefore, to resort to the exaggeration of the Nile flood levels and create false records for increasing revenues; a "bad" government can force peasants to pay undue taxes without resorting to such a farce.

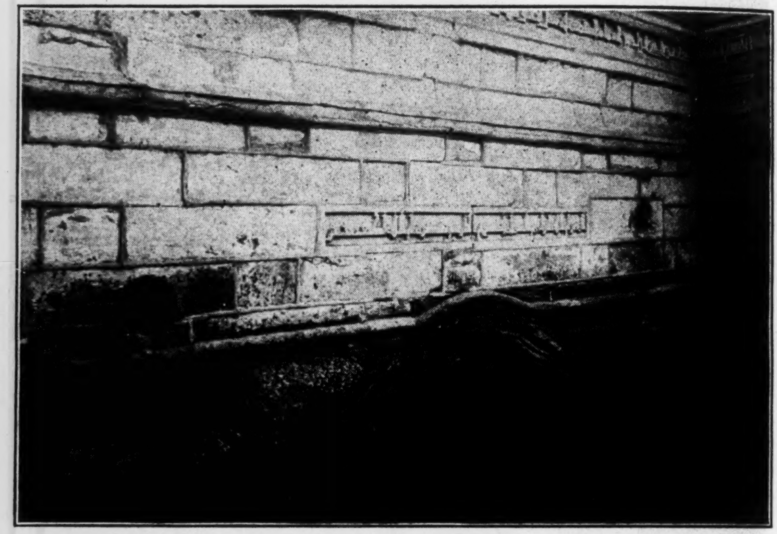

FIG. 17.—WESTERN WALL OF WELL SHOWING METHOD OF GRADUATING THE NILE GAUGE.

The Roda gauge records under review indicate the yearly highest and lowest readings of the level of the Nile at Cairo. The minimum readings that used to occur in May and June (it has even happened that the Roda branch of the river has been quite dry in certain years) have been affected by the regulation on the Delta Barrage during the latter part of the Nineteenth Century and, from the beginning of the present century, the stored water at Aswan has also had its effect. Consequently, the bottom underground-water passage to the well on the eastern side is now inaccessible and it is probable that the short top tunnel (which is not indicated on the drawing in the atlas prepared by the French Expedition) was added in the middle of the Nineteenth Century to replace it. The maximum levels might have been slightly affected in certain years by the emptying of basins, but the greatest error that must be corrected is that due to the misreading of the graduations of the column; it will be fortunate if it can be proved that the pillar was considered as originally designed (that is, 19 cubits), until the end of the Eighteenth Century.

From the Napoleonic invasion onward, the records are unreliable, and it is necessary to know the period during which the readings were made on a column the top cubit of which was considered to be the sixteenth; then it is necessary to know the date at which it became the seventeenth cubit. When was the column broken anew and one of its cubits considerably shortened? When were the sixteenth to the twenty-second cubits considered to be half cubits? In 1887, a metrical scale was fixed in the Roda branch of the Nile; the readings on that scale are trustworthy, but their conversion to cubits gives false results. The two following examples are to the point.

Example (1).—Sir W. Garstin the Under Secretary of State for the Irrigation Department, writes[61] when comparing the flood of 1892 with those of previous years: "The recorded maximum gauges of 1874 and 1878 are appallingly high, but it is more than probable that they are exaggerated, and incorrect." Referring to the year 1887, Sir Garstin continues: "Working on the above lines, it may then be assumed that the maximum height reached at Roda was 25 cubits 15 digits in 1874 (instead of 26 cubits 12 digits as recorded) and 25 cubits 14 digits, in 1878 (instead of 26 cubits 6 digits)."

Example (2).—When Sir William Willcocks was editing an Arabic technical review in the early Nineties, one of his party of engineers (engaged on precise leveling in connection with the fixing of the site for the Aswan Dam) contributed an article on land levels in Egypt. Among other items of information he states that, on October 15, 1893, the gauge reading of the Roda nilometer was 20 cubits 7 digits, which corresponds to a level of 18.04 m according to the method of reading indicated by Falaki (the well-known astronomer), whereas the reading on the 1887 metrical scale is 18.50 m. Where is the truth?

C. S. Jarvis,[62] M. Am. Soc. C. E. (by letter).—The generous response to this paper's presentation as indicated by the various discussions, each contributor working painstakingly along a separate thread and apparently disentangling some of the knots, has amply repaid the writer for the effort.

Mr. Gillette's views regarding cycles as affecting rainfall and related phenomena are the product of many years of study in this field, and deserve serious consideration. Mr. Davenport's studies have resulted in definite contributions to the science of hydrology, particularly as applied to the River Nile. His comparsion of the Nile with the Mississippi River and also with the Colorado River enables one to visualize the Nile floods more clearly and to account for their seeming regularity.

Both Mr. Hurst and Mr. Ghaleb are particularly equipped with information gained from actual experience, in contrast with that collected from

technical research and forming the basis of this presentation. Even the differences of viewpoint and opinion between two qualified observers, such as these, are interesting and instructive. Perhaps the graduations of the Roda nilometer will be better understood by reference to Fig. 18.[63]

Mr. Means was engaged in a study of the Nile River flood records about the same time that this paper was being prepared. His personal observations in Egypt during a period of duty and travel there some years ago probably fitted him for discussing the broad phases of the Nile River discharge so clearly and authoritatively. Mr. Beardsley's personal observations, including the photograph which he furnished (Fig. 7), showing the Roda nilometer, are valuable contributions; likewise, his drawing constituting Fig. 8.

The significance of Mr. Stevens' work in smoothing out the entire record by means of both 10-yr and 50-yr averages should increase with each reference to it. Mr. Shuman has made a strikingly clear exposition of his theories regarding the applicability of various cycles to the Nile flood records, and has added some significant historical notes.

During the preparation of the paper, the writer found the work of making complete statistical analyses of the records of the various centuries too extensive and time-consuming to complete before publication. He has since computed all the arrays, with plotting positions computed according to the modified California method.[64] It is remarkable how nearly coincident the first seven or eight centuries of record are thereby proved to be, with gradual displacement upward to keep pace approximately with the known sedimentation rate in the Lower Valley. Fig. 19 portrays the flood-frequency trends for both the earliest and the latest century of record, and also for the 1 173 items representing the 1 300-yr period.

By reference to the statistical arrays covering the thirteen centuries of record, it is found that, of the 51 annual flood heights registering 20 m, or more, above mean sea level as observed at the Roda gauge, 30 of these occurred during the Thirteenth (or final) Century, whereas 13 occurred during the Twelfth, 3 during the Eleventh, 4 during the Tenth, and 1 during the Eighth of these consecutive centuries. Of the total number of annual flood heights at or above 18.00 m, the tabulated totals for the respective centuries, listed in chronological order, are 24, 20, 22, 13, 24, 44, 33, 67, 79, 32, 37, 61, and 96. Except for the Tenth and Eleventh Centuries, all are complete, or within one or two items of complete century records. The Tenth and Eleventh Centuries have only 33 and 44 items, respectively, and should be combined for comparison with other century records. The number of annual flood events registering lower than 17.00 m for the consecutive centuries presents another series; thus 11, 20, 11, 13, 2, 4, 2, 0, 1, 1, 2, 0, and 0.

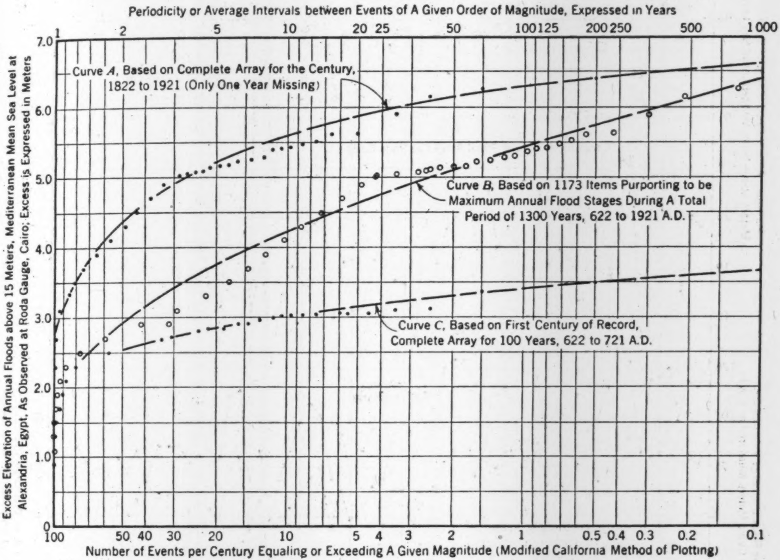

FIG. 19.—COMPARISON OF FLOOD FREQUENCY TRENDS OF THE NILE RIVER AT RODA FOR EARLIEST AND LATEST CENTURIES OF 1300 YEARS.

The foregoing references to the statistical arrays and plottings of the data heretofore presented in this paper and known to be affected by errors and elements opposed to comparability and homegeneity, are made for the purpose of presenting results of tedious calculations so that others may avoid repetition of the process.

Careful comparison of Roda gauge heights attained by annual floods since 1870, with flood volumes, or total annual discharge, as shown in Figs. 1 and 3 of the paper, should convince the most skeptical that Nile River flood peaks are usually fair indications of either the four-month flood discharge, or of the annual volume passing the respective gauging stations (see Figs. 20 and 21).

However, in the textual notes available in French[65], several instances are mentioned in which the peak attained "wafa", but receded so promptly as to cause famine and distress; or, having attained a moderate stage, it continued thus in spite of the use of a portion for basin irrigation, and brought bounteous crops. Generally, however, the high-flood peak meant plentiful water supply and full harvests, unless the stage was too high; and low-flood peaks meant famine and privation. Throughout the ages of history, the gifts of the Nile have been numerous, and reasonably dependable.

DISTRIBUTION OF STRESSES UNDER A FOUNDATION

BY A. E. CUMMINGS,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. CLEMENT C. WILLIAMS, D. P. KRYNINE, L. C. WILCOXEN, MARSHALL G. FINDLEY, M. A. BIOT, JACOB FELD, GEORGE PAASWELL, G. S. SALTER, W. S. HOUSEL, N. M. NEWMARK, A. A. EREMIN, A. CASAGRANDE, AND A. E. CUMMINGS.

SYNOPSIS

The question of the distribution of stress in the ground under a foundation has engaged the attention of engineers for many years. The problem has been studied both theoretically and experimentally and it is the purpose of this paper to compare theory and experiment and to indicate several important factors which must be considered when problems of this kind are being analyzed. The symbols in this paper are introduced in the text as they occur and are summarized for reference in the Appendix. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials"[2] compiled by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

THE THEORY

The problem of determining the distribution of stresses and strains in a semi-infinite, elastic, isotropic solid, bounded by a plane and loaded at a point on that plane by a single concentrated force, was first solved by Lamé and Clapeyron[3] not long after the discovery by Navier of the differential equations of elastic equilibrium. Their solutions in the form of quadruple integrals are of little use for practical calculations. More recently the problem was

---

NOTE.—Published in August, 1935, *Proceedings*.

[2] A. S. A.—*Z* 10 *a*—1932.

[3] "Sur l'équilibre intérieur des solides homogènes," Savants étrangers de l'Académie des Sciences de Paris, 1833, Tome IV, p. 541.

developed in considerable detail by Boussinesq.[4] His solutions are much more usable than those of the older elasticians and have become so well known that the entire problem is often referred to as the "problem of Boussinesq."

Fig. 1 shows the distribution of stresses across planes parallel to the surface as given by Boussinesq. The external force, P, applied perpendicularly to the plane boundary of the semi-infinite solid produces a stress in the direction of the radius vector, R, the magnitude of which per unit of area on any plane parallel to the surface is given by the expression,

$$p = \frac{3\,P\,z^3}{2\,\pi\,R^4} \quad \text{.......................} (1)$$

in which z is the depth from the surface to the plane for which the calculation is being made, and $R = \sqrt{x^2 + y^2 + z^2}$. At the point of intersection

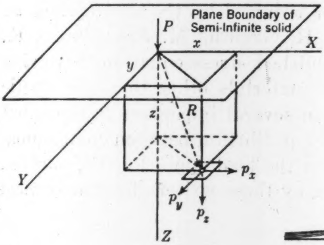

FIG. 1.

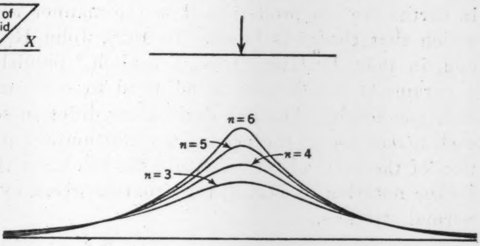

FIG. 2.—RELATIVE FORMS OF STRESS SURFACE FOR DIFFERENT VALUES OF n.

of R with any plane parallel to the surface, this stress may be resolved into three components as shown. The equations for these components as given by Boussinesq[5] are, as follows:

$$p_x = \frac{3\,P}{2\,\pi} \times \frac{z^2}{R^4} \times \frac{x}{R} \quad \text{....................} (2a)$$

$$p_y = \frac{3\,P}{2\,\pi} \times \frac{z^2}{R^4} \times \frac{y}{R} \quad \text{....................} (2b)$$

and,

$$p_z = \frac{3\,P}{2\,\pi} \times \frac{z^2}{R^4} \times \frac{z}{R} \quad \text{....................} (2c)$$

It is evident from Fig. 1, that the two horizontal components, p_x and p_y, are shears and that the vertical component, p_z, is a normal stress. It is also to be noted from Equations (2) that no elastic constants are involved. In connection with these two facts a little further explanation seems desirable.

The three stress components given by Equations (2) apply only to horizontal planes, that is, planes parallel to the boundary plane of the semi-infinite solid. For planes having other directions the stress distribution depends on the elastic properties of the material. In the general case the complete specification of stress at a point within the solid would require six components of stress, three being normal stresses and three being shears, and the elastic constants of the material appear in some of these equations. Because of the fact that Equations (2) do not include any elastic constants, the statement is sometimes made[6] that the distribution of stress is independent of the type of material. This is not exactly true and Boussinesq himself, after calling attention to the non-appearance of elastic constants in the equations, stated[7] that the distribution of stress across planes parallel to the surface is the same in all isotropic solids.

---

[4] "Application des Potentiels a l'Étude de l'Équilibre et du Mouvement des Solides Élastiques," Paris, 1885.

[5] *Loc. cit.*, p. 104.

As long ago as 1897, August Föppl[8] arrived at the conclusion that the behavior of earths under load was not exactly in accordance with the theory of elasticity. He attributed this to the fact that the stresses and strains in earths are not proportional in the manner required by the assumptions on which that theory is based. In 1929, John H. Griffith,[9] M. Am. Soc. C. E., and, in 1932, Dr. Ing. O. K. Froehlich,[10] published stress equations involving a parameter which may be adjusted to suit materials other than the elastic isotropic solids. The two derivations differ in several important respects, but each makes use of the necessary condition of equilibrium between the summation of the vertical forces within the solid and the load applied at the surface. In the notation of Fig. 1, the equation given by these writers for the vertical normal stress is,

$$p_z = \frac{n\,P}{2\,\pi\,R^2} \times \frac{z^n}{R^n} \quad \dots\dots\dots\dots\dots\dots\dots\dots (3)$$

in which n is a parameter that may have different values for different soil structures and loading conditions. When $n = 3$ Equation (3) is exactly the same as Equation (2c). In other words, for elastic isotropic solids stressed within their elastic limits, the value of the parameter, n, is 3. It is also obvious from Equation (3) that the stress on the vertical center line of the load is directly proportional to n since the ratio, $\frac{z}{R}$, is 1 on this line. The general form of the bell-shaped stress surfaces computed from Equation (2c) is well known, and Fig. 2 shows the effect produced on these surfaces by varying the value of n. Because of this effect, n is sometimes called a concentration factor. It is of considerable importance in problems relating to earths and deserves much more attention than it has received.

It is generally conceded that the vertical normal stress, p_z, is the only one that needs to be considered as far as practical problems relating to the settlements of foundations are concerned. Its maximum values occur at points on the vertical center line of the loaded area ($x = 0$ and $y = 0$), where the shears vanish entirely. In the analysis which follows only the vertical normal stress on the vertical center line of the load will be considered.

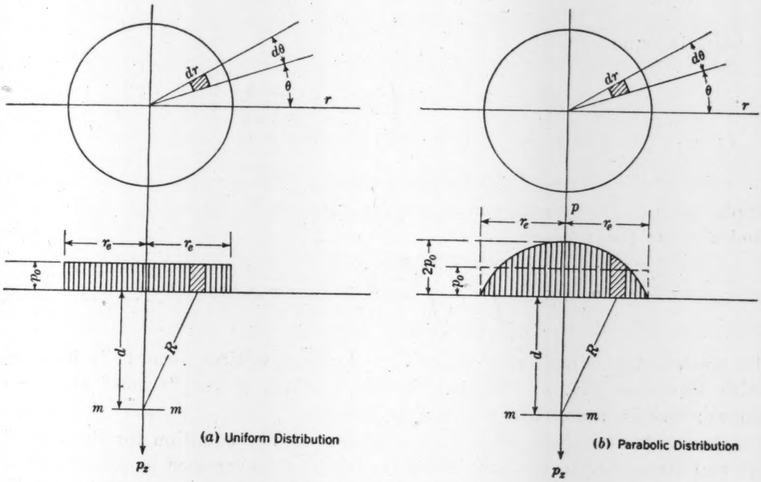
[10] "Drukverdeeling in Bouwgrond," *De Ingenieur*, April 15, 1932, p. B-52.

The factor, P, in Equations (1), (2), and (3), is a concentrated load applied at a single point on the plane boundary. In practical problems relating to foundations it is necessary to calculate with loads distributed over a certain part of the plane boundary. Boussinesq[11] discussed a number of cases of distributed loads and there have been additional contributions to the subject by later writers. The simplest case is that of a load uniformly distributed over a circular area. For bearing areas other than circles and for loads non-uniformly distributed the integrations become increasingly difficult. Inasmuch as the experiments discussed subsequently herein were made with circular plates, the theoretical analysis will be made for the circular bearing area. Two types of loading—uniform and parabolic— will be considered.

Fig. 3(a) is a representation in plan and section of a load uniformly distributed over a circular bearing area; and Fig. 3(b) is a similar representation of a parabolic distribution that is maximum at the center and zero at the edges. Four different cases will be analyzed and in each case a formula will be derived for the vertical normal stress on the vertical center line of the load on a small element of area (Plane m-m, Fig. 3), at a depth, d, below the plane of the load.



(a) Uniform Distribution

(b) Parabolic Distribution

FIG. 3.—LOAD DISTRIBUTION ON A CIRCULAR BEARING AREA.

Case I.—Uniform Distribution ($n = 3$).—This case has been developed by Föppl.[12] The formula for the vertical normal stress produced by a concentrated load is expressed by Equation (3) when $n = 3$ and $z = d$.

---

[11] "Application des Potentiels," pp. 139–179.

[12] "Drang und Zwang," Vol. 2, p. 205.

Using the polar co-ordinates, r and θ, as shown in Fig. 3, the total load distributed over the circular area will be given by,

$$P = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} p_o \, r \, dr \, d\theta \quad \text{....................(4)}$$

in which p_o is the density of the uniformly distributed load. It should be noted that Equation (4) gives the volume of the circular disk of height, p_o. From Fig. 3 there is also the obvious relation,

$$R^2 = d^2 + r^2 \quad \text{..........................(5)}$$

Substituting Equations (4) and (5) in Equation (3), with $n = 3$ and $z = d$;

$$p_z = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} \frac{3\,p_o}{2\,\pi} \frac{d^3}{(d^2 + r^2)^{\frac{5}{2}}} \, r \, dr \, d\theta \quad \text{...............(6)}$$

Integrating and simplifying:

$$p_z = p_o \left[1 - \left(\frac{1}{1 + \left(\frac{r_e}{d}\right)^2} \right)^{\frac{3}{2}} \right] \quad \text{................(7)}$$

Case II.—Uniform Distribution ($n = 6$).—Equations (4) and (5) also apply in this case and they may be substituted in Equation (3) when $n = 6$ and $z = d$; thus:

$$p_z = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} \frac{3\,p_o\,d^6}{\pi\,(d^2 + r^2)^4} \, r \, dr \, d\theta \quad \text{..............(8)}$$

Integrating and simplifying as in Case I, the resulting formula is identical with Equation (7), except that the three-halves power becomes the third power; that is, the quantity is simply cubed.

Case III.—Parabolic Distribution ($n = 3$).—The equation for the vertical normal stress due to a concentrated load is again expressed by Equation (3) when $n = 3$ and $z = d$. In order that Case III may be comparable to Case I, it is necessary to find a paraboloid of revolution with a volume equal to that of the circular disk of Case I. These volumes represent the total load on the bearing area. The equation of the parabola (Fig. 3(b)) will be taken as:

$$p = 2\,p_o \left(1 - \frac{r^2}{r_e^2} \right) \quad \text{.....................(9)}$$

The volume of the paraboloid is then:

$$V = \pi \int_{p=0}^{p=2p_o} \left(r_e^2 - \frac{r_e^2\,p}{2\,p_o} \right) dp = p_o\,\pi\,r_e^2 \quad \text{............(10)}$$

which is also the volume of the disk. Using the polar co-ordinates, r and θ, the total load is now given by,

$$P = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} 2\,p_o \left(1 - \frac{r^2}{r_e^2}\right) r\,dr\,d\theta \quad \text{.............(11)}$$

Equation (5) applies also to this case and, when Equations (5) and (11) are substituted in Equation (3) (with $n = 3$ and $z = d$), the formula for the vertical normal stress becomes,

$$p_z = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} \frac{3}{2\,\pi}\,\frac{d^3}{[d^2 + r^2]^{\frac{5}{2}}}\;2\,p_o \left(1 - \frac{r^2}{r_e^2}\right) r\,dr\,d\theta \quad \text{.......(12)}$$

Equation (12) may be integrated by expanding the quantity in the square brackets as a binomial series, then multiplying, and, finally, integrating term by term. This process leads to the equation,

$$p_z = p_o \left[\frac{3}{2}\left(\frac{r_e}{d}\right)^2 - \frac{5}{4}\left(\frac{r_e}{d}\right)^4 + \frac{5 \times 7}{4 \times 8}\left(\frac{r_e}{d}\right)^6 - \frac{5 \times 7 \times 9}{4 \times 8 \times 10}\left(\frac{r_e}{d}\right)^8 \right.$$
$$\left. + \frac{5 \times 7 \times 9 \times 11}{4 \times 8 \times 10 \times 12}\left(\frac{r_e}{d}\right)^{10} - \ldots + \right] \quad \text{.............(13)}$$

which infinite series is convergent only for $d > r_e$ and, therefore, can be used only at depths greater than the radius of the loaded area.

Case IV.—Parabolic Distribution ($n = 6$).—Equations (5) and (11) apply to this case, and they may be substituted in Equation (3) (with $n = 6$ and $z = d$), giving,

$$p_z = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} \frac{3}{\pi}\,\frac{d^6}{[d^2 + r^2]^4}\;2p_o \left(1 - \frac{r^2}{r_e^2}\right) r\,dr\,d\theta \quad \text{.......(14)}$$

and simplifying as in Case III, the resulting formula is identical with Equation (13), except that the numerical coefficients of corresponding quantities become 3, 4, 5, 6, 7, etc. This series is also convergent only for $d > r_e$. By a transformation to trigonometric functions, Froehlich[13] has derived expressions similar to Equations (12) and (14) in a closed form instead of the infinite series of Equation (13) and its parallel in Case IV.

Equations (7) and (13) and their respective parallels in Cases II and IV may be used to make theoretical calculations for comparison with the stresses measured in the experiments.

THE EXPERIMENTS

Among the earliest experiments made to determine the distribution of vertical normal stresses on horizontal planes at various depths beneath a loaded disk, were those of Steiner-Kick[14] at Prague, in 1879 (see Table 1(*a*)).

---

[13] "Druckverteilung im Baugrunde," Julius Springer, Vienna. 1934.

[14] Handbuch der Ingenieurwissenschaften, 1 Aufl., II. Bd.; *Der Brückenbau,* 2 Abt., S. 195, Leipzig, 1882.

These experiments were made with sand and the bearing area was a circular disk 10 cm in diameter. In 1909, at Graz, Austria, Strohschneider[15] experimented with small circular disks 1.5 cm in diameter, subjecting them to loads of a few kilograms (Table 1(*b*)). He made his experiments with sand and measured the vertical normal stress on horizontal planes at depths to about 4 cm below the plane of the disk. A. T. Goldbeck, M. Am. Soc. C. E., made similar experiments,[16] in 1917, at the United States Bureau of Public Roads (Tables 1(*f*) and 1(*g*)). For bearing areas Goldbeck used circular disks of different diameters (8 in. and 13.5 in.) and measured the stresses transmitted through sand at depths to 60 in. below the plane of the load. At the University of Illinois, M. L. Enger, M. Am. Soc. C. E., conducted further experiments[17]

of the same kind, using circular plates of various sizes to 36 in. in diameter (Table 1(*e*)). At Freiburg, Germany, Kögler and Scheidig have concluded an extensive experimental program[18] which included the measurement of stresses produced in sand fills by loaded plates on top of the sand (Tables 1(*c*) and 1(*d*)).

Values in Column (4), Table 1, are the measured vertical normal stresses on the vertical axis of the loaded area, expressed as a percentage of the average load on the bearing area. The average load is simply the total load applied to the plate divided by the area of the plate.

FIG. 5.—NUMERICAL EXAMPLE (1 KIP = 1 000 POUNDS)

Fig. 4 is a graphical representation of these experimental results, together with the four theoretical curves represented by Equations (7), and (13) for Cases I and III, and their parallels for Cases II and IV. Before considering the relationship between the curves and the experimental points, it is desirable to notice several remarkable facts about the experiments themselves. In time, they cover a period of about fifty years. Geographically; they represent several places on two continents. The sands that were used came from various sources and the stress-measuring devices were of different kinds. The apparatus ranged from the miniatures used by Strohschneider to the large plates used by Enger. Notwithstanding these many possible variables, there is a most noticeable uniformity in the results of the experiments.

---

[18] "Druckverteilung im Baugrund," *Die Bautechnik*, 1927, Heft 29 und 31; 1928 Heft 15 und 17; 1929, Heft 18 und 22.

The theoretical curves show several interesting facts. For a uniform distribution of surface pressure (Cases I and II) the curves show a stress under the center of the plate at the surface equal to 100% of this pressure. This is in accordance with the assumptions made in the analysis. For a parabolic distribution (Cases III and IV) the curves continue out toward the right and these particular curves plotted from the infinite series of Equation (13) and its adaptation to Case IV become asymptotic to the line, $\frac{d}{r_e} = 1$. With the finite integrals obtained by Froehlich[19] for the parabolic distribution, the curves turn upward and give a stress under the center of the plate at the surface which is 200% of the average surface pressure. In the region represented by Fig. 4, Froehlich's integrals and the infinite series give the same results. The importance of the parameter, n, of Equation (3) is clearly indicated by the curves. Stress calculations based on the theory of elasticity in which n is 3 (Cases I and III), give results at any depth on the vertical center line which are much smaller than those calculated with $n = 6$ (Cases II and IV). The character of the pressure distribution at the surface (uniform or parabolic) is especially important near the surface but loses its importance as the depth increases. This is evident from the fact that the curve of Case I (uniform) is the same as the curve of Case III (parabolic) at depths greater than about twice the diameter of the loaded area. The same phenomenon applies to the other pair of curves.

It is easy to note which of the four theoretical curves gives the best interpretation of the experiments. The distribution of pressure at the under side of these test plates was approximately parabolic and the parameter, n, was approximately 6. Both these factors are required to account for the measured stresses.

It seems desirable to point out the fact that the distribution of pressure on the surface is not necessarily parabolic in the manner shown in Fig. 3(*b*). The surface pressure might be a maximum at the center and zero at the edge, but it can vary from this range to a distribution that would be a minimum at the center and infinite at the edge. Boussinesq[20] has discussed several of these possible surface distributions and, in general, they depend on the relative elastic properties of the two bodies in contact. For a square or a rectangular area the distribution of pressure at the ground surface can be fairly complicated as has been shown experimentally by Frederick J. Converse,[21] Assoc. M. Am. Soc. C. E. A. E. H. Love[22] has given a theoretical analysis of the problem for both uniform and variable pressures over rectangular bearing areas. In most practical problems involving large bearing areas, it is customary to divide the large area into a number of small areas and then to make the stress calculation for each of the small areas and add the results. A non-uniform distribution can be treated in this manner by varying the load on the several small areas in accordance with the non-uniformity of the surface distribution.

[21] "Distribution of Pressure Under a Footing," *Civil Engineering*, April, 1933, Vol. 3, No. 4, p. 207.

[22] *Philosophical Transactions*, Royal Soc. of London, Vol. 228, Series A, 1929, p. 377.

Very little experimental work has been done for the purpose of determining the distribution of pressure in the contact area between the plate and the sand-fill. However, it is very probable that this pressure distribution varies to some extent with the load itself. For very light loads or for very large bearing areas the pressure is approximately uniform and the parameter, n, is approximately 3. As the load is increased or as the size of the bearing area is decreased the pressure at the contact plane becomes non-uniform and, at the same time, the value of n increases to 6 if not higher. The value of n also depends to some extent on the elastic properties of the soil. A value of 3 can be used only for elastic isotropic solids stressed within their elastic limits. A very hard dry clay, not too heavily loaded, would behave approximately as an elastic solid, and $n = 3$ would be nearly correct for this kind of material. Granular soils offering almost no resistance to tension cannot act as elastic solids and, in such materials, n has values which may be as great as 6.

NUMERICAL EXAMPLE

Figs. 5(*a*) and 5(*b*) show a footing 16 ft square which is to be built on a 15-ft stratum of sand, overlying soft clay. It is desired to know the vertical normal stress that will be exerted on the top surface of the clay. The footing is subdivided into small squares each 4 ft on a side and because of symmetry there will be only three types of squares, designated *A*, *B*, and *C*. The load will be assumed as concentrated at the center of gravity of each square, and the horizontal distances from the center of the footing to these centers of gravity are shown in Fig. 5(*a*). Fig. 5(*c*) shows this footing with a uniform distribution of surface pressure of 4 000 lb per sq ft. The total load is 1 024 000 lb. Fig. 5(*d*) shows the footing with a non-uniform distribution of

TABLE 2.—STRESS COMPUTATION; NUMERICAL EXAMPLE

* $n = 3$ † $n = 6$

pressure similar to the experimental determination of Converse.[21] The pressure is more than the average in the center squares and less than the average in the middle of the sides and in the corners. The total load for Fig. 5(*d*) is also 1 024 000 lb.

Table 2 gives the stress calculations in condensed form. Table 2(*a*) refers to Fig. 5(*c*); and, in addition to the uniform distribution of pressure at the surface, it is assumed that the distribution of stress through the sand is in accordance with the theory of elasticity; that is, $n = 3$. The total stress exerted on the top surface of the clay on the vertical center line of the footing is 1 484 lb per sq ft. Table 2(*b*) refers to Fig. 5(*d*); and, in addition to the non-uniform pressure distribution, it is assumed that $n = 6$. The calculated stress is 2 672 lb per sq ft, which is almost twice that of the other assumption.

SUMMARY AND CONCLUSIONS

In most problems of soil mechanics dealing with the probable behavior of foundations, the first requisite is a calculation of the stresses produced in the underlying strata by the foundation loads. The accuracy of the subsequent calculation of the effects produced by these stresses will depend on the degree of approximation obtained in the calculation of the stresses themselves. For the problem of the calculation of the stresses, it is believed that the foregoing analysis leads to two important conclusions: (1) The manner in which the pressure is distributed over the contact surface must be considered; and (2) the equations of the theory of elasticity must be modified before they can be applied to soils.

Conclusion (1) is particularly true when the depth for which the computation is being made is equal to, or less than, the diameter of the loaded area. It is to be understood that Equations (7) and (13) for Cases I and III, and their adaptation to Cases II and IV, are not offered for immediate use in the solution of practical problems. These formulas can be used only when the practical problem fulfills all the conditions under which they were derived. Most practical problems involve bearing areas other than circles and the distribution of pressure under the foundation is neither perfectly uniform nor parabolic. However, a reasonably accurate determination of the stresses can be expected only after a careful consideration of the probable pressure distribution at the contact surface and a proper choice of the value of the parameter, n. As a general rule, it is not satisfactory to assume that the pressure at the surface is uniformly distributed and that the equations of the theory of elasticity can be used without modification.

APPENDIX

NOTATION

d = depth from ground surface to a given plane.

e = a subscript denoting "edge."

n = a parameter with values that vary with different conditions; a concentration factor.

o = a subscript denoting uniform distribution.

p = pressure per unit area; p_o = intensity of pressure under a uniformly distributed load; p_x, p_y, and p_z = components of unit stress at a given horizontal plane, distant $z = d$ below the ground surface.

r = variable radius; r_e = radius to the edge of a circular foundation.

z = a variable distance measured parallel to the Z-axis; the depth, d, from the ground surface to the plane for which a given computation is made.

D = diameter of circular foundation = $2r_e$.

P = externally applied, concentrated load.

R = a radius vector.

V = volume.

θ = angular distance.

DISCUSSION

Clement C. Williams,[23] M. Am. Soc. C. E. (by letter).—In his excellent review of theory and experiments relative to pressures under a foundation, the author has performed a helpful service in that his presentation is pointed toward a practical evaluation of their significance. The rather amorphous state of foundation literature represents a stage preliminary to its crystallization into usable principles involving known soil factors. The paper seeks to give point to the theories and experiments that cluster about the geometry of stress distribution in an isotropic elastic solid.

In most experiments relating to pressure distribution under a foundation slab sand has been utilized as the soil. Rankine's theories contemplate a material like dry sand. Within the shear limits of internal friction, the behavior of dry sand in transmitting pressure is similar to that of a granular sandstone, since the cementitious binder of the latter performs no essential function until friction is overcome, except in so far as the solid stone has a weak tensile strength. That there is a close correlation between the theories that are based on either an hypothetical elastic solid, or on a sand bed (which, within limits, behaves similarly to an elastic solid), should not occasion surprise; nor, on the other hand, should it lead to a generalized conclusion applicable to all foundation soils.

Not enough experimental observations have been made with loads resting on elastic soils. The limited observations made by the writer, by William S. Housel, Assoc. M. Am. Soc. C. E., and by others, indicate a behavior different in essential respects to that of granular material under a bearing plate.

As an extreme departure from a load resting on an elastic solid, the case of a box containing a load floated in a lake of water may be cited. The box is supported at a certain flotation depth, but the pressure on the bottom of the lake is not increased (except in so far as the water surface may be raised slightly) and the pressure is evenly distributed over the bottom of the box. In a fluid, the pressures so increase with the depth that the upward reactions on the bottom supports the load.

In a viscous material, such as heavy oil or asphalt, a similar phenomenon occurs, except that flow occurs slowly and only after a long period of time is the theoretical flotation sinking attained. In heavy asphalt, the sinking stops short of the fluid flotation depth, showing that the shear stresses developed have a certain permanent sustaining capacity for holding the load in equilibrium.

The behavior of plastic earths under load has certain points of similarity to viscous fluids. Whereas the pressures assume the typical bell-shaped distribution pattern in a sand bed under load, by virtue of the internal friction, in a plastic soil that is essentially devoid of internal friction, this pressure pattern is fundamentally modified. The spread of the load is probably much wider by virtue of shear and tension than observations seem to indicate, because of the experimental difficulty of measuring small increments of pressure. It is probable also that the depth to which the pressure is perceptibly transmitted in plastic soils is much less than is commonly assumed, owing to the wider spread of the load and the accompanying effect of immeasurably small pressures distributed over a large area, which is much greater than has been generally recognized. An artificial foundation bed for experimentation that would correspond more closely than sand to the prototype would be a thick layer composed of small rubber bands. Instead of using such an artificial bed for laboratory investigations, however, typical earths themselves should be used, because the present plethora of discordant foundation discussion has resulted largely from not basing theories and experiments on soils as they actually occur in Nature.

---

[23] Pres., Lehigh Univ., Bethlehem, Pa.

A relatively small clay content will convert sand to a plastic material in so far as friction and cohesion are concerned. Limited observations made by the writer indicate that, with fine sand of fairly uniform grain, 20% clay will make the mass essentially plastic. Probably with graded sand having a lower percentage of void space, even a smaller proportion of clay would be required. Practical foundations should be considered as saturated, for such will almost certainly be their condition at times, and experiments on dry soils are likely to be misleading.

The bell-shaped pattern of pressure distribution has relatively little significance, therefore, in the practical design of a particular footing, partly because only in clean sand or gravel, or on solid rock, is such a distribution likely to occur. In the second place, even if it should occur when the load is first applied, adjustment in time would tend to make the pressures fairly uniform. Moreover, shifting eccentricities of practical loadings tend to render inapplicable conclusions that may be predicated on an assumption of a fixed point of application of a load. Since the higher pressures at the center of a footing result only from greater rigidity of the soil in that region, the unequal distribution of the pressures will not result in settlement of a footing that is proportioned for a uniform distribution of soil pressure. Any giving way at the center would immediately distribute pressures toward the periphery. Therefore, even if any flexure of the footing slabs that may occur would tend to accentuate the non-uniformity of soil-pressure distribution, a footing designed for uniform soil pressure would generally not result in failure.

In expressing appreciation of Mr. Cumming's excellent paper, which so succinctly sets forth the conception of a foundation as an hypothetical elastic structure, the writer wishes to venture the hope that more experimental and theoretical attention may be devoted to a consideration of actual soils with a view to determining their structural behavior under load. At any rate, more experimentation on plastic soils as a typical foundation material is needed, in order to establish values at the other extreme of soil types.

D. P. KRYNINE,[24] M. AM. SOC. C. E. (by letter).—The most comprehensive discussion of the Boussinesq formula and related problems that has ever appeared in the English language is contained in this paper. For advanced students of soil mechanics the completeness of references and the interesting historical data may be of great value; and readers less advanced are given a concise and clear presentation of the material which furnishes an excellent view of the subject as a whole. In reading this paper, however, the writer faced some difficulties which he wishes to clarify.

---

[24] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Conception of Isotropy.—Bodies termed "isotropic" in reality may possess quite different properties, depending on their degree of isotropy. If the material in a body possesses exactly the same properties throughout, including the stress-transmitting capacity, any point of any line drawn within that body will be a part of an isotropic "continuum," and such a state of isotropy may be termed "monotonous." On the other hand, if the material consists of units or particles interspersed with voids or some other material, with different stress-transmitting capacities, the body may possess "statistical" isotropy. Owing to the presence of a great number of particles pressed against each other, stresses within such a body may be generated so as to simulate a "continuum," and this similarity is the greater, the greater the degree of isotropy approaches the "monotony" referred to; for instance, if two straight lines, 1 in. long, drawn within a sand and a clay mass, pierce 100 and 100 000 soil particles, respectively, it is evident that the clay mass is much more properly termed "monotonously" isotropic than the sand mass. Furthermore, attracted moisture, which is almost solid in the case of a moist clay mass, approaches more the stress-transmitting capacity of the soil particles than water in the voids of a sand mass. Hence, formulas of the theory of elasticity, the Boussinesq formula among them, developed for the case of an isotropic elastic "continuum" should be applied to clays rather than to sands. It does not follow, however, that clays are elastic, and sands inelastic. Each sand particle is an elastic body, as demonstrated by the rebound after releasing a load from a sand mass; but the reason why the Boussinesq formula cannot be applied unconditionally to sands, lies in their lack of monotonous isotropy. Since statistical isotropy requires the presence of a great number of particles, it does not exist at all where this condition is not fulfilled. Hence, an earth mass, especially a natural sand mass, is not isotropic close to its boundary.

The explanations advanced are required in order to understand the following apparent inconsistency in Mr. Cummings' paper. First, he quotes Boussinesq himself who stated that the distribution of stress across planes parallel to the surface is the same in all isotropic bodies, and a few pages following a numerical example dealing with stress distribution in sand shows that an actual vertical pressure is almost twice that computed according to the Boussinesq formula, and so do the experiments described. The reader is thus induced to believe that sands are not isotropic and perhaps not elastic; but the situation clears up if one realizes that under the term, "isotropic," Boussinesq could mean monotonously isotropic bodies only, such as those studied in the theory of elasticity.

Interrelationship Between the Degree of Isotropy and the Value of the Concentration Factor.—Commenting on the opinion of Mr. Cummings, as to the values of the concentration factor ($n = 3$ for clays and $n = 6$ for sands), the writer agrees with it in so far as shallow depths are concerned, but wishes to offer an interpretation. At each point of the earth mass, loaded with its own weight, there is a vertical pressure, p_z, and a horizontal pressure, $p_x = p_y$. The ratio, $\frac{p_x}{p_z} = \frac{p_y}{p_z} = K$, is the coefficient of pressure at rest, according to the terminology of Professor Terzaghi. The value of K in incompressible isotropic elastic bodies (confined water, some metals, etc.), is equal to 1. This value decreases as isotropy ceases to be monotonous; for instance, it equals about one-fourth in the case of coarse sands. Simultaneously, the concentration factor, n, increases; and this can be shown mathematically. In Fig. 6 the vertical and the horizontal angular distances are designated by θ and θ', respectively; d is the depth of a point, A, at which the vertical and horizontal pressures, p_z and p_x, respectively, are to be determined; and z is the variable depth of a point, Q. Equation (3) represents the vertical normal stress, p_z, which may be conceived as the vertical projection of the full stress, p; thus:

$$p = \frac{n\,P}{2\,\pi\,R^2}\left(\frac{z}{R}\right)^{n-2} = \frac{n\,P}{2\,\pi\,R^2}\cos^{n-2}\theta \quad \text{..(15)}$$

FIG. 6

It will be assumed that a projection of the stress, p, on the horizontal plane does not depend on the value of the Poisson ratio. At the point, Q, there is a small earth element (shaded area in Fig. 6). If w is the unit weight of the earth material in question, the weight of this small element is:

$$dP = w\left[\frac{d-z}{\cos^2\theta}d\theta\right]\left[(d-z)\tan\theta\,d\theta'\right]\left[dz\right] = \frac{w\,(d-z)^2\sin\theta}{\cos^3\theta}\,dz\,d\theta\,d\theta' \quad \text{...(16)}$$

In Equation (16) the three dimensions of the earth element at the point, Q, (its length, width, and height) are written separately in brackets. According to Equation (15) the value of the elementary stress acting along the direction, QA, is:

$$dp = \frac{n\,dP}{2\,\pi\,(d-z)^2}\cos^n\theta \quad \text{................(17)}$$

and the horizontal projection of this elementary stress:

$$dp \sin^2 \theta = \frac{n\, dP}{2\,\pi\,(d - z)^2} \cos^n \theta \sin^2 \theta \ldots\ldots\ldots (18)$$

Taking the sum of the horizontal projections (Equation (18)) of the elementary stresses reaching Point *A* from all parts of the earth mass lying above it, the horizontal pressure at Point *A* would be obtained. Hence:

$$p_x + p_y = 2\,p_x = \int_{\theta=0}^{\theta=\frac{\pi}{2}} \int_{z=0}^{z=d} \int_{\theta'=0}^{\theta'=2\pi} \sin^2 \theta\, dp \ldots\ldots\ldots (19)$$

Introducing into Equation (19) the values of *dP* and *dp* from Equations (16) and (17), the first step is to integrate with respect to both *z* and *θ′*, and then with respect to *θ*; thus:

$$p_x = \frac{1}{2}\, n\, w\, d \int_0^{\frac{\pi}{2}} \cos^{n-3} \theta \sin^3 \theta\, d\theta$$

$$= \frac{1}{2}\, n\, w\, d\, \frac{2}{n} \left[- \frac{\cos^{n-2} \theta}{n-2} \right]_0^{\frac{\pi}{2}} = \frac{1}{n-2}\, w\, d \ldots\ldots\ldots\ldots (20)$$

Since the value of the vertical pressure at Point *A* is $p_z = w\,d$, the value of the coefficient of pressure at rest, *K*, would be: $K = \frac{p_x}{p_s} = \frac{1}{n-2}$, from which:

$$n = 2 + \frac{1}{K} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equation (21) expresses the relation between the concentration factor, *n*, and the coefficient of pressure at rest, *K*. It is an approach to the solution of this problem since further research may prove that some other causes also influence this relation. For an incompressible isotropic elastic body, $\frac{p_x}{p_s} = 1$ and, hence, $n = 3$. If the horizontal pressure exerted by a clay is three-fourths of the vertical, the value of *n* in that case is about 3.3. For a sand possessing an angle of friction of $\phi = 35°$ under given circumstances,

$$K = \frac{p_x}{p_s} = \tan^2 \left(45° - \frac{\phi}{2} \right) = \tan^2 27°\, 30' \doteq \frac{1}{4}$$

Hence, according to Equation (21), the value of its concentration factor is $n = 6$. It is also obvious that there is a certain relation between the value of the concentration factor, *n*, and the angle of friction, *φ*, of a given sand.

The writer wishes to emphasize, however, that the few known values of *K* have been determined from experiments practically all of which were in rather shallow test containers. Hence, the corresponding values of the concentration factor, *n*, cannot be applied unconditionally for computations of stresses at greater depths. The writer's belief is that the concentration factor, n, is a function of depth also; apparently, it decreases with the depth, tending to approach the asymptote at $n = 3$. Evidently, the latter value is a minimum, since one cannot visualize any material more free from voids than a "continuum." Probably, at a certain depth within the earth all matter obeys the Boussinesq law with a concentration factor, $n = 3$, and the difference between the stress distribution in sand and clay is merely a surface phenomenon.

The writer bases his opinion on the experiments of Messrs. Terzaghi[25] and Hatch,[26] who proved that the coefficient of friction of sand decreases as the normal pressure increases; and this means that the coefficient of pressure at rest, K, is greater and the factor of concentration, n, smaller, at a relatively greater depth than close to the ground surface. The statement to which Mr. Cummings objects, namely, that the distribution of stress is independent of the type of material, should be corrected by adding the phrase, "at a certain depth." It is true that this unknown depth may be very considerable.

Stresses at the Plane of Contact.—Mr. Cummings' remark that the distribution of pressure on the under side of the experimental test plates in the experiments described is responsible for the stress distribution in the earth mass, cannot be over-emphasized. An interpretation of the fact should be given, however. According to the third Newton law, action and reaction are equal and opposite, and it appears at first glance that if the load on a foundation or experimental plate is uniform, the reaction of the earth mass under it should also be uniform. Such a manner of thinking has proved disastrous in the history of civil engineering and has retarded the development of soil mechanics for many years. What actually matters is not the distribution of load around the foundation, but the distribution of stresses within the footing close to its plane of contact with the earth. The structure and the earth mass together form a statically indeterminate system, and the stress distribution depends on the elastic properties of both bodies in contact. In all cases stresses on both sides of the plane of contact are equal, thus satisfying Newton's third law (Fig. 7(*a*)). As a rule, the stress distribution in question is not uniform, although it may become so in a particular case.

In reference to the interesting statement by Mr. Cummings that for very large areas the pressure is approximately uniform, the writer wishes to state that in some cases there is only an appearance of uniformity. In Fig. 7(*b*) a narrow structure, and in Fig. 7(*c*), a wide structure are represented; both are subjected to the same uniform unit load and both are rigid and constructed on rigid clay, so that the stress would be a minimum at the center. The ordinates, p_1, p_2, p_3, etc., of the stress distribution curve are exactly equal at corresponding points of both structures; but the rate at which the stress increases per foot of width of the foundation is less in the case of the wide foundation.

[26] "Tests for Hydraulic-Fill Dams," by Harry H. Hatch, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), pp. 228–229.

This may create the impression of a rather uniform stress distribution close to the middle of a wide structure.

Mathematics of the Stress Distribution Formulas.—If trigonometric functions were used in developing Equation (7), it would be in a more convenient form for application. In Fig. 8, θ_o, designates a half angle at the vertex of the cone formed by radii vectors drawn from a given point, A, within the earth mass to the perimeter of a round foundation. Then, Equation (7) becomes,

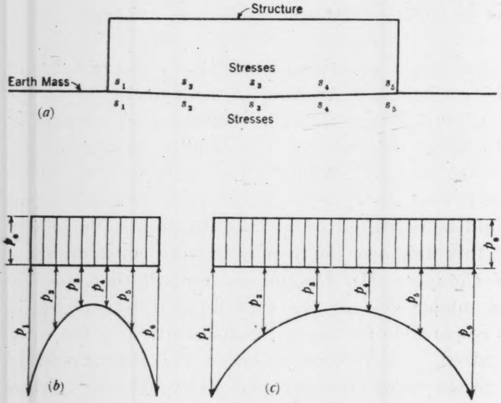

FIG. 7

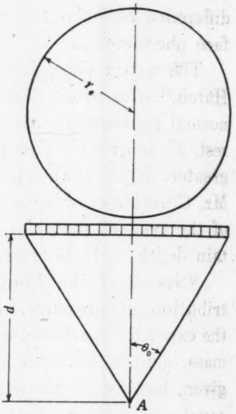

FIG. 8

$$p_z = p_o \left(1 - \cos^3 \theta_o\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Equation (22) is a particular case of a general formula. Actually, integrating Equation (6) for a general case (that is, for a concentration factor, n):

$$p_z = p_o \left(1 - \cos^n \theta_o\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

from which, by making $n = 6$, the stress distribution for Case II may also be obtained. Equation (23) was first developed by Dr. O. K. Fröhlich, of Holland.[27]

To integrate Equation (12), Mr. Cummings uses an infinite series; the problem was also solved by Dr. Fröhlich by a transformation to trigonometric functions.[19] The formula, however, may be integrated in a closed form by substituting t for $\frac{r^2}{r_e^2}$, thus:

$$r\,dr = \frac{1}{2}\, r_e^2\, dt \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

For convenience, let $d = a\, r_e$ in which a is merely a coefficient. Remembering that the limits of integration of the variable, t, are 0 and 1, which corresponds to $r = 0$ and $r = r_e$, respectively, and integrating with respect to θ:

---

[27] "Druckverteilung im Baugrunde," p. 50, Julius Springer, Vienna, 1934.

$$p_z = 3\,p_0\,a^3 \int_0^1 \frac{1 - t}{(a^2 + t)^{\frac{5}{2}}}\,dt$$

$$= 6\,p_0\,a^3 \left[\frac{1}{\sqrt{a^2 + t}} \left(1 - \frac{1}{3}\,\frac{a^2 + 1}{a^2 + t}\right)\right]_0^1$$

$$= 2\,p_0 \left[1 - 2\,a^2 + \frac{2\,a^3}{\sqrt{a^2 + 1}}\right] \qquad \text{.................(25)}$$

By making $a = 1$ in Equation (25), the true value of the vertical pressure, p_z, at a depth, $d = r_e$, may be obtained. It is equal to 0.83 p_o, and not infinity, as indicated by Fig. 4, Case III. A mathematical tool, like any other, can give adequate results only within the limits of its applicability. This is why in this case an infinite series proved inadequate to reflect the actual physical condition between $a = 1$ and $a = 0$. By making $a = 0$, in Equation (25), p_z becomes equal to 2 p_o or 200% of the average surface pressure as obtained from Dr. Fröhlich's integrals. Case IV may be dealt with in a similar manner.

Limits of Application of the Formulas Discussed.—So far as may be concluded from this paper, the following methods are available for computing stresses within an earth mass: (*a*) By Equations (1) or (3) for the case of a concentrated load; (*b*) by Equation (7) for uniform load distribution; and (*c*), by Equations (12) and (14) for parabolic load distribution. A case is also mentioned by Mr. Cummings in which a distribution would be a minimum at the center and infinite at the edge; but no formula is given for this case.

In comparing the curves shown in Fig. 4, the author reaches the conclusion that "the character of the pressure distribution at the surface (uniform or parabolic) is especially important near the surface but loses its importance as the depth increases." This statement, although quite true, should be generalized and strengthened as follows: "At a certain depth, about twice the diameter of the loaded area, ($d \geq 4\ r_e$), any structure acts practically as a concentrated load." In other words, if stresses are to be determined at a depth greater than twice the diameter of the loaded area, the designer need not worry about how the loads are distributed along the structure, nor need he worry as to whether or not the structure is rigid. The Washington Monument, in Washington, D. C., has a base of about 125 by 125 ft; hence, it acts as a concentrated load at a depth of 250 ft beneath the base. On the other hand, the water reservoir behind Boulder Dam, with a length of, say, 100 miles, acts as a distributed load to a depth of 200 miles beneath the site.

The situation changes in the upper layers ($d < 4\ r_e$). If a non-rigid, round structure, such as a water or oil tank, non-rigid masonry structures, etc., is to be constructed on clay or similar soil, Equations (7) and (8) for uniform load distribution should be applied; and if a rigid, round structure is constructed on sand or similar soil, Equations (12) and (14) should be used.

The most interesting problem—that of determining accurately, the value of the bending moment in a footing or in a spread foundation—still remains open. A definite answer can be given only when the behavior of the "disturbed zone" under the structure itself can be studied properly. Although the integral Equation (25) gives a pressure of 200% of the average unit load close to the base of the structure, M. L. Enger, M. Am. Soc. C. E., found about 300% by experiment.[27] The writer believes that this value was not excessive and that stresses in the "disturbed zone" are exceedingly high.

Conclusion.—Mr. Cummings has brought to the attention of the profession one of the most serious problems of soil mechanics and has displayed, in this connection, an unusually broad knowledge of the technical literature. No one can be expected to solve such problems alone; hence, if in discussing this interesting and important paper, corrections and additions are made, this cannot diminish its value.

L. C. WILCOXEN,[28] ASSOC. M. AM. SOC. C. E. (by letter).—The distribution of stresses in an elastic soil under a foundation, based on certain specific assumptions, has been developed mathematically by Mr. Cummings. His conclusions are logical, and he has done well to stress the limitations of his formulas to the conditions assumed.

Examination of the general conditions affecting the distributions of stresses under a foundation more clearly sets forth the significance of the limitations prescribed by the author. The distribution of stresses is modified by: (*a*) The load distribution on the footing; and (*b*) the degree of flexibility of the footing. In practice, there are three distinct types of simple foundations, each having its characteristic stress distribution: (1) The uniformly loaded, perfectly flexible foundation; (2) the concentrated load on a semi-flexible foundation; and (3) the rigid (non-flexible) foundation, in which the character of the load is not a factor. Naturally, there are modifications and hybrids of these three types. Their recognition, however, explains much of the conflicting evidence regarding the behavior of foundations.

The uniformly loaded, perfectly flexible foundation produces a uniform surface load on the soil, as Mr. Cummings has assumed in Cases I and II. The concentrated load on a semi-flexible foundation (and with the proper degree of flexibility) produces a surface load that is parabolic in sections. This covers Cases III and IV. It may also yield a uniform surface load as in Cases I and II, and as will be explained.

The rigid foundation, regardless of the type of loading, produces a maximum surface loading at its perimeter, decreasing toward the center. This type of distribution has been demonstrated by the writer,[29] using the photo-elastic method. The soil loading produces an inverted arch, or dome of maximum stress, the bottom of which (in the case observed) was at a depth, 0.7 *D*, below the foundation. This dome of stress is probably somewhat akin to the cone developed under a small "foundation" when the latter is driven through a soil.

---

[29] Progress Rept. of the Special Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., August, 1933, p. 1054.

In all these different cases, the foundation flexibility is the key to the resulting type of surface stress distribution. Deformation is probably as important in foundation problems as retaining wall movements (however small) are, in determining soil reactions. The latter has recently been demonstrated in a striking manner by Charles Terzaghi, M. Am. Soc. C. E.[30] The former remains to be demonstrated.

Given a concentrated load on a rigid footing, it has been stated that the maximum surface stress is at the perimeter, decreasing toward the center. If flexibility of the footing could be introduced progressively, the pattern of the surface reaction on the footing would change progressively. It would first become uniform; later, it would assume the parabolic distribution, and, ultimately, it would become a concentrated reaction under the load itself. It is one of these intermediate cases which was reported by Frederick Converse, Assoc. M. Am. Soc. C. E., and referred to by the author.[31] Failure by Mr. Converse to report the nature and extent of the footing deformation made the experiment incomplete.

The classical experiment[31] by M. L. Enger, M. Am. Soc. C. E., has been assumed by the author to have been a parabolic surface loading, as in Cases III and IV. This is probably an error, although in this case, it is not important because the data which he borrows are at a depth of at least one footing diameter below the footing. At this level, Dean Enger has shown such a distribution to be correct.

In the original report of this experiment the lines of equal stress were extrapolated from the uppermost plane of observed values (6 in. below the footing) upward to the foundation. Although not supported by tests, and although no conclusions were drawn from it, the diagram showing the greatest surface load at the center has gained wide credence. The footing was relatively rigid, at least in one case (a heavy plate, 13½ in. in diameter, with a load as great as 18 000 lb applied by a jack with a large base). Under this footing, a dome of maximum stress probably occurred with the distribution of the soil reaction, being a maximum at the perimeter and decreasing toward the center. Fig. 9 shows the original stress diagram (*a*) modified, and (*b*) in accordance with the writer's theory of rigid foundation surface stress distribution.

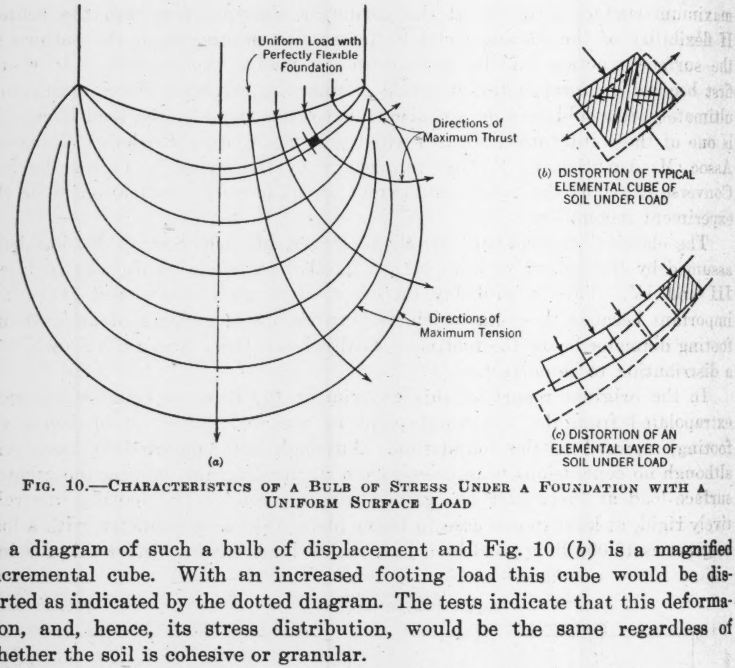
[30] *Engineering News-Record*, February 1 and 22, March 8 and 29, and April 19, 1934, Vol. 112, pp. 136, 259, 315, 403, and 503.

[31] *Engineering Record*, January 22, 1916, Vol. 73, p. 106; and *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 372.

That the pressure under a rigid foundation is greatest at the center is a theory that is widely held. The writer is aware that in many cases the opinion is authoritative, especially when the soil is a granular one. Nevertheless, he offers the following facts and deductions in support of his own view.

It has been demonstrated[29] that, with a uniform surface loading, in both plastic and granular soils, settlement was greatest at the center. Fig. 10 (*a*) is a diagram of such a bulb of displacement and Fig. 10 (*b*) is a magnified incremental cube. With an increased footing load this cube would be distorted as indicated by the dotted diagram. The tests indicate that this deformation, and, hence, its stress distribution, would be the same regardless of whether the soil is cohesive or granular.



Uniform Load with Perfectly Flexible Foundation

Directions of Maximum Tension
(a)

(*b*) DISTORTION OF TYPICAL ELEMENTAL CUBE OF SOIL UNDER LOAD

(*c*) DISTORTION OF AN ELEMENTAL LAYER OF SOIL UNDER LOAD

FIG. 10.—CHARACTERISTICS OF A BULB OF STRESS UNDER A FOUNDATION WITH A UNIFORM SURFACE LOAD

Fig. 10 (*c*) is a diagram of an incremental layer of soil as distorted by an increased load. It is apparent that each successive cube toward the center is displaced downward not only by its own direct load but also by the loads on all the adjacent cubes toward the perimeter. Thus, it seems that, regardless of the character of the soil, the stress distributions under uniform surface loads are the same and the area of greatest resistance is toward the perimeter. If the footing were a rigid one the greatest pressure would necessarily be in the region of greatest soil resistance; that is, toward the perimeter.

That this holds true in sand has been demonstrated conclusively by the writer in an elemental test. A lightly tamped, damp mortar sand was struck level with a straight-edge. First, a piece of typewriter carbon paper (with the carbon side up) was laid on the surface; then a piece of white paper; and, finally, a steel plate, 4 in. square. Pressure was then applied to the plate, by twice plunging a round-ended fence post down upon it. The results (see Fig. 11) showed that the region of greatest carbon transfer (and, hence, the greatest pressure) occurred under the part of the foundation near the perimeter.

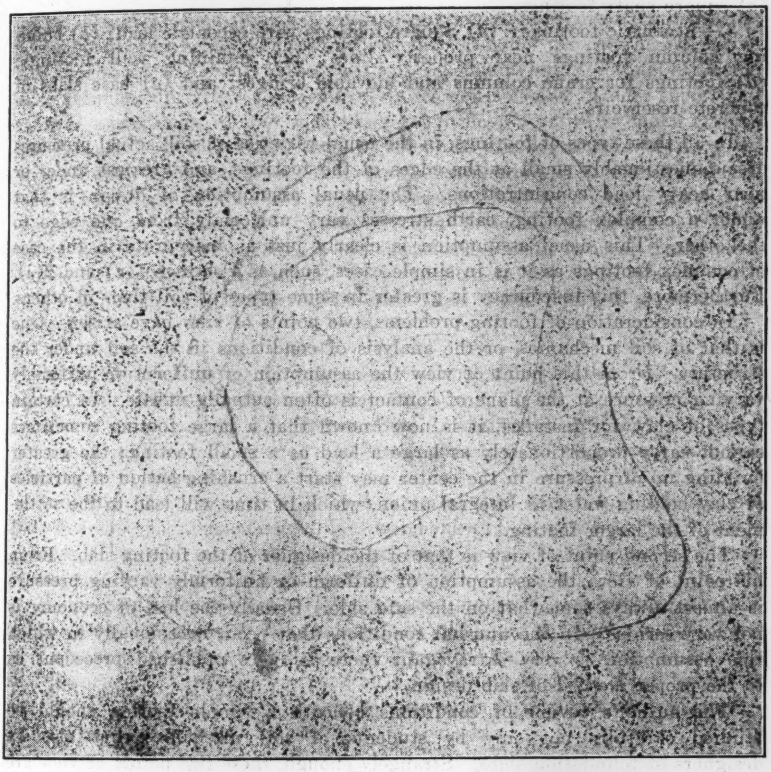

Fig. 11

The problem of analyzing the distribution of pressure under a foundation is a comprehensive one. The author has avoided the complications of footing characteristics by assuming surface, rather than footing, loadings, and has skilfully analyzed two of the three types of surface loadings that occur under foundations.

Marshall G. Findley,[32] Assoc. M. Am. Soc. C. E. (by letter).—The problem discussed by Mr. Cummings is one of a group, which may be suggestively subdivided as follows:

1.—Footings in which one plane section only may be analyzed: (*a*) Wall footings, centered (the simplest case); (*b*) flume footings (rectangular slabs with parallel walls along two opposite edges); and (*c*) continuous footings under a series of parallel walls.

---

[32] Structural Designer, Water Purification Plant, Milwaukee, Wis.

2.—Simple footings symmetrical around a central point: (*a*) Square footings with central load; (*b*) circular shaft footings (chimneys, etc.); and (*c*) square shaft footings.

3.—Eccentric footings: (*a*) Square footings with eccentric load; (*b*) building column footings near property lines; (*c*) retaining wall footings; (*d*) footings for crane columns and movable bridges; and (*e*) base slabs of concrete reservoirs.

In all these types of footings, in the usual varieties of soil, actual pressures are unquestionably small at the edges of the footings, and greatest under or near heavy load concentrations. The usual assumption of design is that under a complex footing, earth stresses vary uniformly from one edge to the other. This usual assumption is clearly just as inaccurate in the case of complex footings as it is in simple cases, such as Footings 1(*a*) and 2(*a*). Furthermore, this inaccuracy is greater in some types of soil than in others.

In consideration of footing problems, two points of view have arisen. One is that of soil mechanics, or the analysis of conditions in the soil under the structure. From this point of view the assumption of uniform or uniformly varying pressure at the plane of contact is often actually unsafe. In certain types of clay, for instance, it is now known that a large footing sometimes cannot carry proportionately as large a load as a small footing; the greater building up of pressure in the center may start a crushing action of particles of clay holding water in integral union, which in time will lead to the settlement of the larger footing.

The second point of view is that of the designer of the footing slab. From his point of view, the assumption of uniform or uniformly varying pressure is almost always somewhat on the safe side. Usually the loss of economy is not very serious. In the unusual conditions that occur occasionally in which this assumption is very extravagant there is little published precedent as to the proper method of slab design.

The author's review of conditions beneath a simple footing should be studied carefully not only by students of soil mechanics, but also by designers of foundation slabs. Strangely enough, these two points of view are not actually co-ordinated as well as they might be.

In the design of footing slabs the exact theoretical formula is often not of great importance. For instance, in the case of a simple wall footing, a sine formula seems to be theoretically correct in stiff homogeneous material for distribution of pressure at the plane of contact; but considering the resulting design of footing, it may not make any appreciable difference whether a sinoid, parabolic, or an elliptic distribution curve of footing pressure is assumed. The important point is to take account of the deflection of the cantilever edges; this may be done even by means of a very rough, straight-line diagram, without serious error in shear or moment diagrams.

Such rough straight-line diagrams may be used with profit in the design of certain more complex types of footings. It is not the intention to cast any doubt on the advisability of theoretical and experimental work such as that cited by Mr. Cummings; but there are certain types of footings, some of which are among those outlined herein, in which even with rough straight-line assumptions as to footing pressures, design becomes very complex mathematically. The exact conditions are not known through experiment; nor are they accessible to exact scientific imagination; the soil is not perfectly homogeneous, although on the whole it is substantial and dependable; and the final conditions as to ground-water are not determined or are not constant. Under such conditions, it seems more in line with exact scientific procedure to make a rough but probable assumption and then to compute, exactly, certain of its consequences, than to use the very improbable assumption of uniformly varying load. Furthermore, the less probable assumption occasionally results in design that is economically impossible, and obviously unnecessary. Painstaking detailed investigation has clearly proved certain general truths about foundation pressure distribution. It is possible to use these general truths in a rough approximate way, under conditions where detailed application is impossible.

M. A. BIOT,[33] ESQ. (by letter).—The classical theory of elasticity is based on a linear relation between stress and strain. This fact introduces an important simplification in mathematical investigations in that the superposition principle can be used and the summation of elementary solutions leads to other solutions.

It is important to note that for a material that does not satisfy Hooke's law, this superposition principle does not hold and, in general, it will not be permissible to add up solutions due to loads acting independently in order to find the stresses due to their combined action.

In the case of certain materials like sand, however, the pressure distribution is assumed to be given by a semi-empirical law more general than that of Boussinesq formulated by Equation (3) of the paper. In case the pressure distribution does not coincide with that of Boussinesq, this must be due to the fact that the material is either not isotropic or does not satisfy Hooke's law. The latter is true, for instance, if some kind of gliding occurs inside the material. Obviously, then, it is not permissible to superpose solutions of the form of Equation (3) in order to find the effect of distributed loads.

JACOB FELD,[34] M. AM. SOC. C. E. (by letter).—The subject touched by this paper really involves two major classes of problems in foundation engineering, namely:

(1) For a foundation unit of a given size, both in area and in shape, carrying a known load, either as a point concentration or as a distribution of known variation: (*a*) What is the distribution of stress at the base of the foundation unit or footing? (*b*) what is the variation in the distribution with changes in the assumed relative and also absolute (for end conditions or cases) stiffness of the footing and of the supporting soil? and (*c*) what is

---

[33] Univ. of Louvain, Louvain, Belgium.

[34] Cons. Engr., New York, N. Y.

the variation in the distribution with increases in the loading, for a given ratio of stiffness of footing and soil, including the end condition where the loading causes a change of the soil, or of the footing, from elastic to plastic material?

(2) For a given load on a footing of given size, the distribution of stress at the base having been determined: (*a*) What is the distribution of pressures through the soil? and, (*b*) what changes in distribution occur with increased loadings?

In all the foregoing problems, it must be remembered that the summation of stresses from various loads can only be made as long as the total does not exceed the elastic limit. As soon as plastic flow (in clays), or failure in shear (lack of tension in sands), occurs, the problem changes.

The author has noted clearly that his paper covers only one case of the general problem, namely, what is the distribution of stresses along the vertical axis of the soil supporting a circular load for: (*a*) Uniform; and (*b*) parabolic distributions of stress at the base of the circular footing? He shows definitely that the assumption of parabolic distribution gives theoretical results which agree with the experimental work with sand, in which all the conditions of the problem are met.

As an opening wedge, the paper is valuable. It is hoped that the author's warning (see "Summary and Conclusions") will be heeded: "These formulas can be used only when the practical problem fulfills all the conditions under which they were derived."

The theoretical formulas are based on the assumption of action in isotropic bodies. The definition of the term, "isotropic", is "having the same physical properties in all directions." This condition eliminates all soils except for very small loadings. In general, the approximate maximum load that can be considered, is the largest load which will not cause a permanent set or deflection after it is removed.

All the tests enumerated in Table 1 are for sand and circular disks. No attempt has been made to correlate the effect of the amount of unit loading with the variation or law of distribution in the soil.

In the tests by Messrs. R. B. Fehr and C. R. Thomas[35] on square and rectangular test areas, for sand, clay, and loam, a definite change in distribution was noted with increased loadings.

The very high unit stresses found in the area at the center of, and just below, the circular disk footing is not serious because in the actual condition there will be a release of support and, therefore, a redistribution of loading in this area. The theoretical solution of the problem is equivalent to a first approximation of a statically indeterminate structure in which deflections are neglected. In addition, the center core of soil under a footing is better retained against lateral movement and, consequently, against vertical movement than the remainder of the soil body. The effect is to permit greater loading without large settlement or flow.

---

[35] "Experiments on the Distribution of Vertical Pressure in Sand", by R. B. Fehr and C. R. Thomas, *Bulletin No. 8*, Pennsylvania State Coll., 1913; and "Further Experiment on the Distribution of Vertical Pressure", by R. B. Fehr, *Bulletin No. 10*, Pennsylvania State Coll., 1913.

Where long loadings, such as quay walls, on soft ground, give high stress concentrations on a long strip of the supporting soil, with consequent settlement and flow of the mud or silt and often failure of the wall, it has been found most economical to eliminate the soft soil directly beneath the wall and replace it with a layer of sand. The entire picture of stress distribution in the soil is then changed not only because the high localized stress at the base of the wall is taken by the sand, but also by the formation of a new soil at the contact zone. A very fine description of the methods and large scale tests on this method of solving the problem is given by Gen. Carlo Barberis.[36]

Under "Numerical Example", the author points out that although greater areas of soil are affected at increasing depths below a loaded footing, the distribution at any depth is not uniform. The assumption of parabolic distribution, made in this example, may apply to sand, but certainly should be modified if clay or any cohesive material is used, chiefly because of the edge effect on the perimeter of the footing. For all soils, the assumed distribution will change as soon as a deflection occurs.

The true distribution at the base of a footing is such that the sum of the works performed in bending, in shear, and in compression of the footing is a minimum, subject always to the condition that no stress exceeds the elastic limit. It would be a very unusual design problem which would warrant such a computation. Probably, photo-elastic methods to show the qualitative conditions would be advisable to reduce the number of possible distributions that should be studied.

GEORGE PAASWELL,[37] M. AM. SOC. C. E. (by letter).—It is gratifying to note the interest in the development of accurate methods of obtaining pressure distributions under foundations. The mechanics of foundations is predicated upon a correct determination of stress distribution in the underlying strata. However, correctness may be defined herein not as a rigorous mathematical solution consistent with all the data, but rather as a general correctness of stress distribution over the broad extent of the strata, subject to distortion by pressure of the foundation loading. In this sense of the word, the "local perturbation effect" immediately adjacent to the point of loading is of no significance in the general stress distribution. The problem may be viewed as analogous to the stress determination in a girder subject to concentrated loads, where the effect on the point of application of the load on the local part of the girder is considered of secondary importance, the general distribution of moment and stresses being the primary problem involved. The manner of loading a foundation and the soil pressures near its loading can generally be ignored in the determination of the stress distribution in the deep strata the distortions of which will usually determine the final movement of the supported structure. The analysis as presented by the author—although of interest to the general theory of stress distribution—

[37] Mgr., Spencer, White & Prentis, Red Wing, Minn.

should not leave a serious doubt in the reader's mind as to the general validity of the Boussinesq equations. These equations, as given in the report[a] of the Society's Special Committee on Earths and Foundations, are sufficiently rigorous and consistent with experiment to permit a scientific prediction of foundation behavior. Their use in foundation design involves the same degree of accuracy as the use of the ordinary Bernoulli formulas for flexure.

It is unfortunate that the development of the Boussinesq equations is buried in the intricate treatises on the mathematical theory of elasticity. The fundamental assumptions of the theory of elasticity are that: (1) All displacements are infinitesimal; and (2), Hooke's law is correct.

Boussinesq was fortunate in discovering an ingenious device for the solution of the differential equations for displacement of elastic solids under a surface load. A function is found, such that its derivatives express the displacement of a given point under a certain type of surface loading. By combining two forms so as to induce the surface loading to a single force at a point, the displacements are evaluated, and from these the forces are found. The force system in horizontal planes (if the applied load is vertical and the boundary plane horizontal) involves no elastic constants. It so happens that the force system on vertical planes contains elastic constants, which, for the usual soils, permits values that cause the terms containing these constants to vanish, so that it may be stated, in general, that the force systems on both vertical and horizontal planes do not involve any elastic constants so far as foundation problems are concerned.

G. S. SALTER,[38] ASSOC. M. AM. SOC. C. E. (by letter).—The problem of the distribution of stresses in a foundation is quite complicated, and much good work has been done on the subject in the last few years, to which this paper is a commendable addition.

The writer has found that most of the investigations on this subject, both theoretical and experimental, have dealt with uniform or parabolic load distributions on the footings (either actual or assumed), whereas in so much of the foundation design encountered in his work the loading is line distribution on semi-flexible footings; also, while most of the literature deals with the determination of stresses at some distance below the contact surface, in many cases (especially on a clay varying from medium stiff through the various gradations to hardpan), the problem is more to determine the pressure distribution directly under the footing than the pressure intensities at some lower depth where the clay is more compact.

It has long been realized that variations in conditions lead to entirely different pressure distributions and that those resulting from line distribution on a semi-flexible footing, such as a heavy wall on a relatively thin slab, give high pressures directly under the wall.

The writer has made some investigations in this field and has come to the conclusion that the following procedure is a logical method of dealing with this particular problem. Make soil-bearing tests to determine settlement for different loading values and then determine, by trial if necessary, such pressure distribution values on the contact area between the footing and the soil so that the differential settlement resulting from the varying soil pressure equals the flexure in the footing.

---

[38] Structural Designer, The San. Dist. of Chicago, Chicago. Ill.

Such line loads give a contact loading distribution somewhat parabolic in character, the variation depending upon the load-carrying capacity of the soil and the relative weights of the wall and the slab. Sometimes, it has been desirable to make various assumptions (within reason) on the bearing capacity of the soil and to design for the worst probable condition. Pressure distributions thus found are far from the uniform pressures commonly assumed, and where footings are somewhat flexible, or when the soil has high load-carrying values, a line load may be distributed over only a small portion of the footing directly under the load.

The foregoing is only one of the many problems on the behavior of foundations and is presented in an endeavor to show, as the author has stated, that, as a general rule, it is not satisfactory to assume that the pressure at the surface is uniformly distributed.

For the general problem of stress distribution which exists in the ground under a foundation to which the theory of Boussinesq applies, the University of Illinois has recently published[39] a *Circular* on simplified computations of vertical pressures.

W. S. HOUSEL,[40] ASSOC. M. AM. SOC. C. E. (by letter).—A contribution to the subject of foundation pressures is embodied in this paper, which has immediate value to the practicing engineer and student of soil mechanics. The concise presentation, with complete references, should make it easy for any one interested in the subject to be well informed on the mathematical treatment of a problem which heretofore has been exceedingly difficult to review completely. The solutions of several cases of pressure distribution, although still dealing with conditions more ideal than real, are a closer approximation to actual conditions encountered in practice and should form the basis of enlightened discussion and further development.

The author's analysis of various experimental results is most valuable in calling attention to the fact that practically all previous investigations introduce a variable pressure distribution on the bearing area which controls the maximum pressure ordinate at depths beneath that area. Scarcely less important is the emphasis on the concentration factor which is discussed in connection with solutions. The writer is inclined to feel that the equations presented are not as convenient as those which have been developed in terms of trigonometric functions, but that does not detract from the value of the analysis and discussion. There is little to be added to the author's use of the tools supplied by the mathematical theory of elasticity and his conclusions mark the point from which discussion may begin. These conclusions are: "(1) The manner in which pressure is distributed over the contact surface must be considered; and (2) the equations of the theory of elasticity must be modified before they can be applied to soils."

---

[39] "Simplified Computations of Vertical Pressures in Elastic Foundations", by Nathan M. Newmark, Jun. Am. Soc. C. E., *Circular No. 24*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

[40] Asst. Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

In the writer's opinion the only fault to be found with the first conclusion is that it might well be made more emphatic. So much confusion and false deduction has arisen from a failure to appreciate the significance of pressure distribution on the bearing area itself that it certainly is gratifying to find this fact recognized as being one of two major conclusions supported by the author's study.

The second conclusion also impresses the writer and, when generally accepted, opens the door to definite progress toward the real problem of how the elastic equations may be altered so that they may be applied to soils. The author suggests the concentration factor, n, as the means of altering the equations and indicates that n must be varied in some manner, depending on the type of material, the load applied whether high or low, and the size of the bearing area whether large or small. With all this there seems to be no room for anything but enthusiastic and unqualified agreement. Thus, the paper establishes the fact that research in foundation pressures in its broadest sense implies much more than a mathematical study of the distribution of load concentrations through bodies of material indefinite in extent. It is also recognized that such mathematical studies have not yet provided foundation engineering with a practical working theory which completely describes the effect of foundation pressures on the soil masses upon which structures must be built.

The writer proposes to discuss the correlation of pressure distribution studies with a practical working theory of soil resistance which may describe soil behavior more completely and which may provide definite methods of measurement by which variable factors not included in the elastic theory may be evaluated. In its fundamental aspects the analysis of soil behavior does not differ from that of any other problem in mechanics of materials. There are two major steps involved in such a problem: First, it is necessary to determine the stresses imposed on the material by application of load; and, second, it becomes necessary to evaluate the resistance of that material to those stresses in terms of deformation and ultimate capacity to carry load. It makes little difference whether the material is in an indefinite mass or an articulated structure, a complete solution of the problems presented cannot be found until both aspects are subjected to analysis.

Pressure distribution based on elastic theory bears only on the first aspect of the major problem and, being limited to materials of assumed ideal properties, has not entirely fulfilled its purposes even there. In the writer's opinion elastic theory has almost, if not entirely, been exhausted in producing results of practical value, and valuable as these results have been they leave a considerable gap to be filled in before foundation problems can be treated on a rational basis. They have given foundation engineers, however, a number of sound conceptions as to how load may be transmitted through soil masses and the type of stresses that would result. The task of securing recognition of the limitations of the elastic theory and the building of new conceptions which may be free from these limitations are fields for further progress.

Before attempting further development along this line it seems pertinent to define the attitude with which the writer proposes to approach these problems and to set up certain criteria which may have value in testing the validity of theories which may be proposed. These criteria which represent the attitude of modern physics toward natural phenomena are nowhere more aptly presented than in the definition of a theory given by Dushman[41]. According to this eminent physicist, a theory is nothing more than a system of conceptions which will enable one to describe the results of experience and observation, a system which shall be as complete as possible but, at the same time, simple and comprehensive. Born[42] also serves warning that "the true laws of Nature are relations between magnitudes which must be fundamentally observable. If magnitudes lacking this property occur in our theories it is the symptom of something defective."

Accepting this creed, the development of theories concerned with foundation pressures consists of an orderly process of collecting data by careful observation; the analysis and correlation of these data; and, finally, the formulation of conceptions describing the results of observations only in terms of magnitudes which may be subject to direct observation.

It is not necessary to attempt complete citation of the various experimental and mathematical investigations in the light of the author's excellent review of both. The writer will attempt only to discuss conclusions which may be drawn from these investigations and limitations which must be recognized in applying the conclusions to practical problems.

Distribution of Pressure Beneath the Surface.—From a survey of the results of the various experimental investigations it appears that there are two types of pressure distribution curves which show a significant difference. This difference is illustrated in Fig. 12, in which Curve 1 denotes the kind of distribution found on horizontal planes relatively close to the bearing area. It yields definite evidence of a concentration of pressure in the region beneath the bearing area, which may be referred to as the central column of the compression cone. This concentration of pressure is a phenomenon that has been noted in practically all experimental studies. It has generally been described in two ways: First, by increased values of the vertical pressure, p_z, in the central column; and, second, by decreased values of the

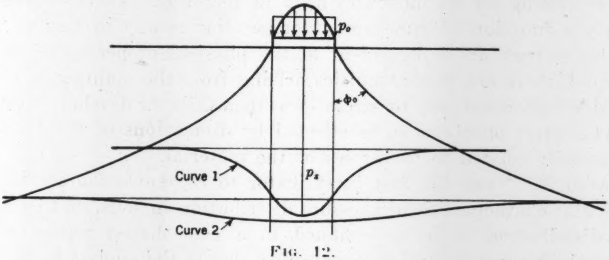

FIG. 12.

---

[41] "Modern Physics—A Survey", by Dr. Saul Dushman, *General Electric Review*. June and July, 1930.

[42] *General Electric Review*, June 30, 1930, p. 332.

angle of lateral distribution, ϕ_0, for planes close to the bearing area. Curve 2, which is typical of pressure distribution at greater depths where intensities of pressure are not excessive, shows no evidence of the foregoing concentration of pressure. Intensities beneath the bearing area appear to be more consistent with those in the compression cone outside the central column and the angle of lateral distribution appears to approach a constant maximum value which, by experiment, has been found to be approximately 60 degrees.

The concentration of pressure in the central column is accompanied by a non-uniform distribution of pressure on the bearing area which the author has demonstrated in his analysis of experimental results. Rather than to state that the non-uniform pressure distribution on the contact surface is the cause of the concentration of pressure in the central column, it seems more logical to conclude that both result from some other phenomenon of primary importance. It is at this point that elastic theory becomes quite inadequate and must be displaced by more basic conceptions not limited by the assumptions of elasticity.

In the first place soils do not possess the properties of the perfectly elastic material necessary to satisfy the very important condition of continuity of stress-strain relationship. The fact that the equations of elasticity yield pressure distribution curves which are at least qualitatively adequate does not alter the fact that the quantitative results are of limited value. This situation arises from the fact that distribution of pressure through soil masses follows laws depending upon statistical regularity which may obtain even in an essentially discontinuous medium.

Failure of the elastic theory appears to originate from two distinctly different sources. First, there are discontinuities arising from boundary conditions which are introduced by the problem of treating load applications over finite areas resting on an indefinite body of material. These considerations are entirely a function of dimensions not peculiar to any particular material and, to that extent, are independent of the physical properties of the material. Second, there are discontinuities arising from the manner in which the material develops resistance to stress or rather fails to develop resistance to stress. The latter phenomenon is affected by dimensions of the loaded area, but is primarily related to properties of the material.

Strohschneider[48] was the first investigator to recognize the significance of this particular characteristic of pressure distribution in soils, and he described pressure distribution as being confined to a cone-shaped region of stress, outside of which there was no apparent effect due to the applied load. He also attempted to alter the elastic equations to produce the concentration of pressure in the central part of the compression cone. His attempt to extend these equations was satisfactory only in special cases, as no single continuous function appeared to be flexible enough to satisfy the wide variation in soil behavior.

In the writer's opinion the concentration factor introduced by later investigators and discussed by the author will not prove to be any more satisfactory in the final analysis. The imperfections in the elastic theory as applied to soils are more deeply seated than that. The discrepancies arise from actual discontinuities in behavior, and it appears fairly obvious that no amount of adjustment will fit these phenomena into a framework based fundamentally on continuity.

---

[48] See "Pressure Distribution in Building Soil", by Dr. F. Kögler and Dr. A. Scheidig, *Die Bautechnik*, No. 29, 1927.

The lateral distribution of vertical pressure from a finite area is primarily a boundary phenomenon. This may be illustrated by some results obtained experimentally by Kögler and Scheidig[44]. These results, shown in Fig. 13, represent the pressure distribution obtained at some depth beneath a large rigid plate resting on the surface of a sand fill. The dimensions and rigidity of the plate are such that the load distribution at the contact surface is essentially uniform except for some secondary boundary effects which may be neglected in the present illustration. The important point is that at a depth slightly less than one-fourth the diameter of the loaded area the initial pressure, p_0, was transmitted downward without change in the central region beneath the bearing area. The original pressure distribution is shown assuming a uniform pressure, which is approximately true in this case. The manner in which lateral distribution occurs may be described in simple terms and demonstrates that it is essentially a boundary effect.

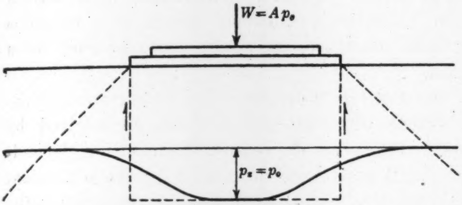

FIG. 13.

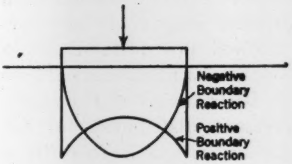

FIG. 14.

If the central column is to be relieved of any of the applied pressure as the load is carried downward this must be accomplished by means of shearing resistance developed on the vertical planes through the edge of the bearing area. The increase in pressure ordinates outside the central column and the decrease in ordinates inside the central column both originate at the boundary and this combined effect extends horizontally in both directions from that plane as the depth increases. As long as the horizontal plane considered is sufficiently close to the bearing surface, the effect from opposite edges does not overlap and the maximum pressure, p_0, may be transmitted downward without change over some width dependent on the limiting angles of influence.

It is also a necessary condition that the areas of the pressure diagram at each depth be equal. The areas taken from the original pressure diagram should be equal to the areas transferred to the region outside the central column. This condition is not entirely fulfilled in the present illustration due to inaccuracy in assuming a uniform distribution of pressure in the absence of more complete information regarding distribution on the contact surface.

---

[44] "Pressure Distribution in the Soil", by Dr. F. Kögler and Dr. A. Scheidig, *Die Bautechnik*, 1927, No. 31, pp. 1–3.

One further point to be brought out in connection with Fig. 13 introduces the resistance of the soil itself as influencing the transmission of pressure. If the loading is continued beyond the point that produces shearing stress on the perimeter planes in excess of the shearing resistance of the soil no more pressure can be transmitted to the region outside the central column. It is obvious then that such additional increments of load must be carried by the central column as a concentration of pressure, a condition which may obtain until the central column is loaded beyond its capacity. Thus several distinct stages of behavior are introduced between which the relations involved are quite dissimilar and, therefore, may not be expressed by a continuous mathematical function.

Distribution of Pressure on the Contact Surface.—The importance of the pressure distribution at the surface of contact has been emphasized by the author and in this discussion. The type of pressure distribution depends primarily on boundary conditions and resistance developed by the soil mass; and it varies depending on the relative rigidity of the bearing plate, the dimensions of the loaded area, and the relative intensity of the load. With all these factors involved, the most fruitful line of attack appears to be to consider types of pressure distribution and their relation to the manner in which resistance to load is developed. It may then be possible to formulate methods of evaluating resistance to load which are dependent on direct measurements and independent of quantitative determination of the actual pressure distribution. This seems to be the only feasible method of approach as it is evidently impracticable in general practice, if not impossible, to measure actual pressure distribution on all foundation substructures.

There are two major types of pressure distribution curves which are illustrated in Fig. 14, and which depend upon the type of boundary reaction developed. In general, materials that are cohesive develop stress concentration at the edge of the bearing area which may be described as a positive boundary reaction. As a result the pressure on the bearing area is maximum at the edge and minimum at the center. In this case the boundary is a source of strength and the reaction developed at that point contributes to the bearing capacity in proportion to the perimeter-area ratio. There are also cases in which the boundary is a source of weakness due to inability to develop resistance to vertical pressure which may be expressed as a negative boundary reaction. The resulting pressure distribution gives maximum ordinates at the center of the bearing area and minimum ordinates at the edge. Such a condition obtains at the surface of bodies of granular material and is typical of most of the experimental investigations of pressure distribution that have been made.

The loss of bearing capacity at the boundary of the loaded area is not difficult to explain by the manner in which load is transmitted through a granular mass. Particles in contact with the bearing plate transmit vertical load to other particles below the surface through points of contact. There being no cohesion the only means of transmission is by arching action, with the reaction to horizontal thrust in the elementary arches being furnished by adjacent particles. At the edge of the area and at the free surface the resistance to horizontal thrust is zero, and the mass is incapable of furnishing resistance to vertical load. In the center of the bearing area horizontal thrusts are partly balanced and, consequently, the elementary soil arches have some stability and are capable of carrying higher intensities of vertical load.

The situation described is not generally encountered in practice although it is representative of the conditions under which most experimental investigations have been performed. Substructures and footings are seldom located on an exposed surface, but are located at some depth with sufficient static head, due to overburden, available to furnish a considerable resistance to lateral displacement. Bearing-capacity tests on granular material conducted under the writer's supervision have shown a positive boundary reaction for the range during which there is sufficient resistance to prevent lateral displacement of the granular material at the edge of the bearing plate[45]. The behavior of foundation mats in general indicates that boundary reactions are more often positive than negative, inasmuch as such mats almost invariably become dish-shaped with the concave surface upward. The smaller settlements at the edge of such mats, over which the loads are fairly well distributed, can only be accounted for when the reaction of the soil mass is greater at that point. The writer has encountered very few cases in which foundation mats settled more at the edge than at the center, and these settlements could be traced definitely to heavy load concentration at the edge of the mat.

Somewhat apart from dimensional effects and soil reactions which affect pressure distribution on the contact surface, consideration must be given to rigidity of the bearing plate. All other things being equal, the pressure distribution may vary from one extreme type to the other, depending upon this rigidity. Flexible bearing plates carrying a distributed load will conform in general to the deformation of the soil mass sufficiently close to develop a uniform pressure on the plane of contact. Concentrated loads on flexible plates are generally transmitted through the plates without fully developing the contact area, resulting in high concentrations of pressures directly under the load.

Pressure distributions on rigid bearing areas are largely controlled by reactions in the soil mass regardless of whether the load applied to the plate is concentrated or distributed. Some of the most effective studies of this type of problem have been made by photo-elastic methods[46], an example of which is shown in Fig. 15. A bakelite sheet, pressed on by a rigid steel die, yields a stress pattern with high concentrations at the edges of the die and a point of minimum stress in the center. Similar experiments with flexible plates show that the concentrations of pressure at the edge disappear, and that the distribution may become practically uniform.

In the preceding discussion the writer has attempted to call attention with some degree of completeness to those factors which enter into a determination of stresses in a foundation. Most, if not all, of these factors are fairly well recognized although they may be described in different terms. The attempt has been made in this discussion to place emphasis on certain aspects of pressure distribution which the writer believes may be correlated and built into a system of conceptions that will serve as a practical theory of soil resistance.

[46] "Kinematography in Photoelasticity", by M. M. Frocht, *Transactions*, Am. Soc. M. E., Vol. 54, No. 11, p. 83.

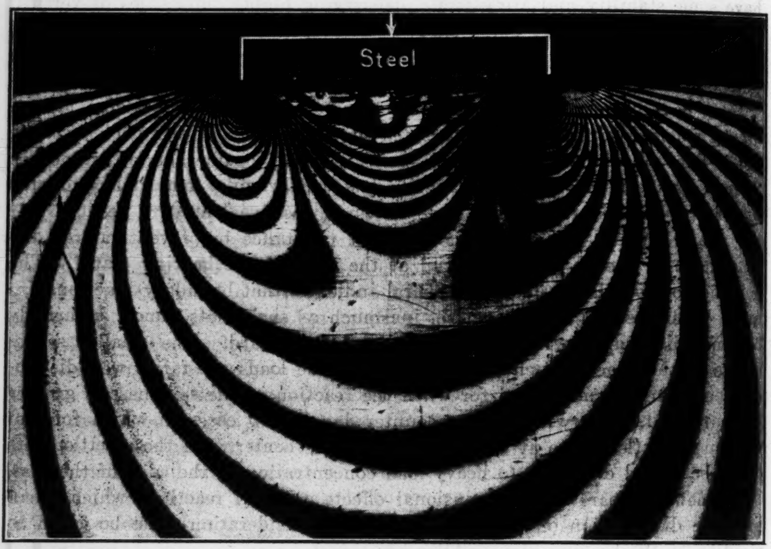

FIG 15.—STRESS DISTRIBUTION BY PHOTO-ELASTICITY.

Because of the fact that some of the assumptions of elastic theory cannot be applied to soils, the distribution of stress predicated on elasticity cannot be considered satisfactory except in a qualitative sense. These limitations of elastic theory lead one to the conclusion that it is essential to simplify the methods of dealing with the problem, thus making it possible to include some important factors that otherwise may be ignored. It seems entirely logical in a qualitative treatment of pressure distribution to accept such simplification as long as the results are only used to establish other relations which may be determined on a proper quantitative basis. This procedure is particularly necessary in order to describe pressure distribution in regions close to the bearing area where dimensional effects and discontinuities due to several different stages of soil resistance are most critical.

A Simplified Method of Pressure Distribution.—Such a simplified method of pressure distribution is shown in Fig. 16, in which it is proposed to deal with pressure distribution by linear relations combining triangular and rectangular pressure distribution. All the examples in the succeeding discussion will be treated in terms of the two-dimensional problem for a bearing area of finite width, b, and indefinite length. The solution of this problem based on the elastic theory is credited to Michell and has been reviewed[47] by George Paaswell, M. Am. Soc. C. E. The problem will be treated in terms of a uniform pressure, p_0, at the contact surface and the effect of a non-uniform distribution discussed as a separate consideration. The transition from the pressure diagram for the bearing area to the pressure diagram on any horizontal plane is accompanied by satisfying the condition that the area of the respective diagrams is equal, as shown in Fig. 16(b).

FIG. 16.

In Fig. 16(a) the distribution curve as given by the Michell equation is replaced by a straight line which varies from zero at the limiting angle of distribution with a slope of 1 on 2 to a maximum ordinate at the vertical plane through the edge of the bearing area. A uniform pressure or rectangular distribution is used under the central column of the compression cone. An average or uniform pressure commonly assumed in practical problems is obtained by a redistribution or juxtaposition of equal triangles, 1-2-3 and 3-4-5. In order that the areas of the pressure diagram shall be the same, the angle of average pressure distribution must be 45°, or a 1 on 1 slope which is a value commonly assumed. The proper value of the limiting angle of distribution is an important factor and is taken as a slope of 1 on 2 or 63° 26′ for several reasons. In the first place the experimental investigations have indicated an angle of about 60 degrees. It is improbable that the very small pressures near the limiting zone of influence would be recorded by the measuring devices thus far used; therefore, the difference of 3.5° is not significant. As will be shown subsequently the relation between the angle of average pressure distribution and the limiting angle of influence verifies the slope of 1 on 2 since the equilibrium of elements within the compression cone requires that the average angle of distribution be 45 degrees.

---

[47] "Transmission of Pressure Through Solids and Soils and the Related Engineering Phenomena", by George Paaswell, *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1563.

For the purpose of discussion, accepting the assumption that the distribution angles are correct, three cases of pressure distribution arise, defined by the ratio existing between the width of the bearing area and the depth to the horizontal plane considered. First, if the depth is less than $\frac{b}{4}$ as in Fig. 16(*b*) the full intensity of the applied pressure reaches the horizontal plane over the middle of the central column. Such a distribution takes into account the fact that the lateral distribution is a boundary effect which depends upon the shearing resistance, m', acting on the vertical planes through the edge of the bearing area. The result is also in conformity with results of Kögler and Scheidig shown in Fig. 13. Second, a special case exists in which the depth, d, is equal to $\frac{b}{2}$. As illustrated in Fig. 16(*c*) the same principles are applied in obtaining the pressure distribution as were used in the previous example. Pressure triangles are taken out of the original pressure diagram equal to the pressure distributed on either side of the central column. The triangle, 1-2-3, is subtracted twice, being included in the distribution to both sides and reducing the ordinate of the rectangular part of the diagram to $\frac{P_0}{2}$. The average pressure distribution may be used to obtain the same result, considering the average pressure within a 45° angle of distribution, and changing from the rectangular to the triangular distribution outside the central column in the same manner as indicated in Fig. 16(*a*). Third, in all cases when the ratio is greater than $\frac{b}{2}$ it is necessary first to obtain the average pressure to determine the center ordinate as shown in the diagram, as it is impossible to work directly from the original pressure diagram as illustrated in Fig. 16(*b*).

The comparison between the simplified pressure distribution and the elastic solution by Michell has been made for the purpose of correlating the proposed method with previous investigations. In the light of the limitations of the elastic theory, the writer does not feel, however, that the mathematical solution is entitled to any pre-eminence as a criterion of accuracy as far as quantitative results are concerned. Nevertheless, it is interesting to note wherein the two methods are at variance and, in the light of all factors that should be considered, to discuss the probable accuracy of the results obtained.

For the case in which the depth considered is less than $\frac{b}{4}$, the agreement is quite close, but the Michell solution fails to give a center ordinate equal to p_0 which should be the case if the boundary effects are properly treated. As soon as the boundary effect from either edge overlaps, as for depths greater than $\frac{b}{4}$, the elastic solution gives a center ordinate greater than that obtained from the simplified method. In view of the factors involved, the writer can see little choice in either method in judging the accuracy of the result. The simplified method appears to include the more rational treatment of boundary effects; but at best it is only an approximation. In all cases the elastic solution gives smaller ordinates in the regions more remote from the central column.

When non-uniform distribution on the contact surface is considered in relation to the phenomenon of lateral distribution of pressure the results of the simplified method appear more favorably. In that range of load where shearing resistance on the boundary planes has not been exceeded, distribution on the contact surface would tend toward maximum pressures at the edge and minimum pressures at the center. Translating these conditions into pressure distribution on planes below the bearing area, it is apparent that center ordinates would be decreased and ordinates outside the central column increased in closer conformity with the simplified pressure diagrams. It is felt that this is the case more commonly encountered in practice.

If the pressure distribution on the contact surface is maximum at the center and minimum at the edge as in most experimental results available, this behavior may be traced to a failure to affect lateral distribution at the boundary, and there is a consequent concentration of pressure in the central column. In this case the simplified method does have a real advantage because it affords a simple and logical method of treating concentration of pressure in the central column. The importance of this advantage lies not so much in the determination of pressure ordinates in the central column as it does in the correlation of stress distribution beneath a loaded area with ability to carry load. After all, the determination of stresses in the soil mass is merely the first step in developing methods of evaluating bearing capacity. Thus, from a study of pressure distribution, it has been found that one of the two major types of stress is shown to be concentration of pressure in the central column, and the other, to be resistance developed on the boundary planes of the central column which affects a lateral distribution of vertical pressure.

The problem now becomes one of evaluating the resistance of the soil mass to these two types of stress in terms that may be subject to direct measurement. In Fig. 17 are shown the stress conditions in the compression cone in terms of which it is possible to study the equilibrium of the various elements and establish their ultimate resistance to load.

Fig. 17.

Element 1, taken from the central column, offers resistance to deformation by two distinct stress reactions. The first is the summation of three similar pressure components: n_1, the vertical pressure representing cubical compression with lateral components furnished by the confining influence of the surrounding body of material and involving no shearing stresses within the element; n_2, the vertical pressure transmitted downward without increase in lateral components up to the full capacity of the soil to develop shearing resistance on 45° planes of maximum shear; and n_3, a third increment of vertical pressure arising from the static pressure due to surcharge, which in some cases may be available as additional confining influence. All three of these factors are included in a stress reaction which may be defined as developed pressure and represents the capacity of the central column to transmit vertical load directly downward without failure due to lateral displacement.

The second stress reaction must be considered because of the lateral distribution of pressure through the shearing resistance, m', acting on the boundary planes. The vertical load carried in this fashion is a function of the perimeter of the area and may be expressed in terms of the bearing pressure on the area by dividing the total boundary force, $m'P$, by the area, A, as shown in the equation for total bearing capacity, p_0. The equilibrium of Element 2 within the compression cone and outside the central column establishes certain conditions which must be satisfied and leads to some significant relations. As long as the shearing resistance, m', is not exceeded, no concentration of pressure will develop within the central column and the pressure distribution across the compression cone may be represented as uniform pressure, n_1. Element 2 must also furnish the lateral component, n_1, resulting in a shearing stress, m', on the horizontal plane bounding the element. Under the condition that the normal pressures, n_1, acting on both the horizontal and vertical planes of Element 2 are equal, the shearing resistance, m', on both planes must also be equal to n_1. In the first place this condition requires that the angle of average distribution be 45° as no other value of the angle will satisfy all three equations of equilibrium, which require that the summation of horizontal and vertical forces and the summation of moments be zero. The quality of shearing stress on planes at right angles to each other, as stated in Cauchy's theorem[48], also may be used to define the angle, ϕ_a, as having a specific value of 45 degrees. Thus, all the requirements for equilibrium of elements in a body of material are satisfied except the commonly accepted condition of continuity of stress. In the problem under consideration the discontinuity of stress introduced at the boundary of the compression cone is an agreement with experimental observations, particularly the cone-shaped region of stress noted by Strohschneider.[43]

The increments of pressure transmitted as concentrations in the central column do not affect the lateral distribution, as this path of force transmission is cut off when the ultimate shearing resistance of the soil is exceeded on the perimeter planes. The supporting power of the soil is not exhausted, however, until the capacity of the mass to develop pressure is exceeded. Thus, the concentration of pressure in the central column is possible, resulting in a pressure distribution that cannot be represented by an average pressure for the full width of the compression cone. Any attempt to use such an average pressure distribution results in an erroneous value of the angle of distribution. It is important to note that apparent values of this angle of less than 45° are due to a changing proportion of two separate and dissimilar stress reactions rather than to a change in the angle of lateral distribution.

Correlation of Pressure Distribution and Bearing Capacity.—With a complete understanding of the nature of the stresses imposed on a body of soil by foundation loads, it is possible to correlate these stresses with the resistance developed by the soil and to isolate those factors which must be measured in order to evaluate the bearing value of the soil. It is apparent from the review of pressure distribution that two separate stress reactions are involved in the problem and these may be defined as developed pressure and perimeter shear. The bearing capacity, which is the combined effect of these two types of resistance, may be expressed by the following straight-line equation developed in connection with Fig. 17 which is valid for constant value of a third variable, settlement:

---

[48] "The Mathematical Theory of Elasticity", by A. E. H. Love, pp. 74 and 79.

$$p = \frac{mP}{A} + n \qquad (26)$$

in which p = bearing pressure, in pounds per square foot; m = perimeter shear, in pounds per linear foot; P = perimeter, in feet; A = area, in square feet; and, n = developed pressure, in pounds per square foot.

The developed pressure, n, is the summation of all the increments of pressure developed by the soil mass and designated as n_1, n_2, and n_3 in the previous discussion. For the purpose of interpreting load tests on soil, it is not necessary to measure the separate effects although the subdivision is useful in some other respects. The developed pressure is the source of the major part of the bearing capacity in practical design, the effect of perimeter shear being small for large bearing areas with small perimeter-area ratios.

The perimeter shear is an important factor, however, in the usual sizes of bearing areas for testing purposes and, unless it is properly evaluated, load tests cannot be used to determine the supporting value of large foundations. The perimeter shear, m, is expressed in terms of a concentrated force per unit length of the perimeter because the boundary effects, either positive or negative, involve irregularities in the distribution of shearing stress on the boundary planes which have not been subjected to analysis.

Evidently, there are two types of behavior involved due to boundary stresses. The primary effect of the shearing stress on the perimeter planes is in the lateral distribution of the pressure which controls the depth affected by the surface load. The larger the area the greater the depth required for distribution and, consequently, the greater the settlement for any given intensity of bearing pressure. This leads to the familiar statement that the settlement for a given intensity of pressure is proportional to the diameter of the bearing area. Conversely stated, it may be said that for a constant settlement the bearing pressure is inversely proportional to the diameter, or that it is proportional to the perimeter-area ratio. This statement is correct in so far as one type of reaction is concerned, but it ignores the fact that developed pressure is an important factor in the bearing capacity and it is to some degree independent of the stress reaction at the boundary.

In addition to the primary boundary stresses, there are secondary stress reactions which lead to the non-uniform pressure on the bearing area. These secondary stress concentrations appear to be independent of the width of the area and are rather a function of rigidity of the bearing area, or as in granular materials, are controlled by a lack of resistance to lateral displacement. It appears impossible at present to measure these boundary stresses except in terms of a concentrated force acting at the perimeter and being the integrated result of the complex reactions which have been recognized.

The analysis of a series of bearing-capacity tests has shown that the straight-line equation does reproduce the load-settlement relations for different sizes of bearing area to a satisfactory degree of accuracy within a range of size for which the secondary boundary effects are similar. However, due to a change in boundary conditions, load tests of bearing areas of somewhat less than 1 sq ft do not conform to the linear equation for larger plates. Although the reasons for this discontinuity are not completely exposed by present data it appears to be due to the secondary boundary reaction which is independent of the width of the bearing area for the larger test sizes. In the smaller sizes the secondary boundary effects from opposite sides of the area overlap, and failure takes place due to lateral displacement before the full supporting value of the soil can be developed. In both cases, however, the only factor affected is the boundary stress or perimeter shear, and the analysis of tests indicates that the developed pressure remains the same for all sizes of bearing areas. Until further investigation has been made, it appears desirable to avoid the discontinuities referred to and this may be done by the proper selection of test sizes. When this procedure is followed, the straight-line equation is valid and furnishes a reliable determination of soil resistance.

Conclusion.—In this discussion limited space does not permit of a more complete elaboration of the conceptions of soil resistance herein presented, and particularly a general relation which correlates bearing capacity with settlement of foundations. Such a general equation has been developed with examples in which the relations were applied to the actual design of substructures.[49] Examples of a number of series of load tests are available in which the factors of soil resistance have been evaluated successfully[50]. Some progress has been made in developing a method of measuring the resistance of cohesive soils and correlating the cohesion or shearing resistance with the concentration of pressure beneath a loaded area, which has been emphasized in the paper[51].

Progress in foundation engineering or, more exactly, soil mechanics has been rapid in the last few years and important contributions to the science have been made by a number of investigators working in widely separated localities. The most difficult problem to-day, in all this development, is for the investigators themselves, to say nothing of others who are interested, to find an opportunity to engage in a free exchange of ideas which is essential for real progress. It is seldom that a paper as comprehensive and thorough as that presented by the author is available for discussion, and in providing this opportunity Mr. Cummings has made a contribution of double value to the profession.

N. M. NEWMARK,[52] JUN. AM. SOC. C. E. (by letter).—The close agreement between the wide range of experimental data gathered by Mr. Cummings and the hypothesis of stress distribution in sand attributed to Professors Griffith and Fröhlich is quite remarkable. It seems that the experimental data are limited to measurements at depths of less than 5 ft, and in all but a few cases at depths of 3 ft or less. It appears reasonable that, at great depths, sand should act more nearly in the manner of an elastic and homogeneous material than at shallow depths. The experimental data cited, for example, give, for a ratio of depth to radius of plate of approximately 9, and for depths of 60 in. and 36 in., the respective values of pressure as 2.5% and 3.5% of the intensity of load applied. Thus, it seems that n possibly decreases with the depth.

[52] Research Asst. in Civ. Eng., Coll. of Eng., Univ. of Illinois, Urbana, Ill.

It does not appear to be convenient to consider a varying value of n in the equations given by the author. However, other empirical relations may be found by which it is possible to take into account the change in properties of the sand with depth and also to account for the proper effect near the surface.

A simple method which the writer has devised seems to offer certain advantages. It consists, briefly, in transforming the depth of the given material in an arbitrary manner, the transformation depending only on the depth, and then applying Boussinesq's equations to find the vertical stress on horizontal planes of the transformed material. The vertical stresses thus obtained are taken as acting at the corresponding untransformed depth and will be in statical equilibrium. Statically possible stresses in other directions may be determined as well, but it is not necessary to discuss this matter herein.

Let the depth to a given horizontal plane in the given material be denoted by z, and the depth after transformation by h. Assume that each element of depth, dz, is to be transformed by the relation,

$$dh = \psi \, dz \qquad \text{(27)}$$

in which ψ is a function of the depth, z, alone. Then the transformed depth, h, is given by the equation, $h = \int_0^z \psi \, dz$. When ψ is a constant, the transformed depth is, $h = \psi z$.

The value of ψ may be chosen in such a way that the stress at various depths along the line of action of a single concentrated force will be the same as the stress computed for a particular value of n. This value of ψ is found to be,

$$\psi = \sqrt{\frac{3}{n}} \qquad \text{(28)}$$

In general, the stress surface for a particular value of n and that for a value of ψ given by Equation (28) will not be the same. However, the difference will be very small, as it apparently must be, since the volumes under each of the stress surfaces are equal, the center heights are equal, and the shapes are somewhat similar. For example, the curves in Fig. 18 show vertical sections through the stress surfaces for $n = 3$, $n = 6$, and for a constant value of ψ equal to $\sqrt{0.5} = 0.707$.

Computations for varying values of ψ are no more difficult than for constant values. Furthermore, all existing tables, coefficients, and formulas for vertical stress due to various given loadings may be used directly merely

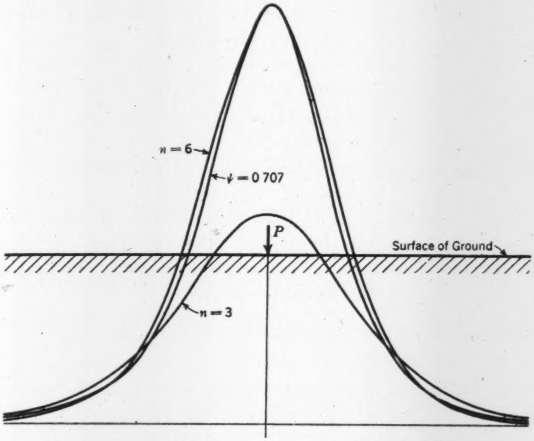

FIG. 18.—RELATIVE FORMS OF STRESS SURFACE.

by taking the value of the transformed depth, h, instead of the actual depth, z. The entire process is essentially the same as a change in the scale of depth, other conditions remaining the same.

Close agreement with the experiments cited by the author will also be obtained by use of a transformed depth. For example, in Fig. 4, curves corresponding to Cases II and IV may be obtained from Cases I and III by transforming the vertical scale of these curves by multiplying by the quantity, $\frac{1}{\psi} = \sqrt{2}$. These curves will lie very close to Curves II and IV, and, consequently, will fit the experimental data as well.

Approximate solutions of problems similar to those discussed by the author may also be obtained by various depth transformations. Pressure distribution through sand to clay, or through alternate layers of sand and clay, might possibly be treated. Of course, the proper method of depth transformation must be chosen, and, apparently, there is very little experimental data upon which to base a choice.

A. A. EREMIN,[53] ASSOC. M. AM. SOC. C. E. (by letter).—Basing his computations on the Boussinesq equations, Mr. Cummings has developed some empirical formulas for computing stresses under a foundation resting on sand fill. These formulas yield stresses that are smaller than those obtained from

---

[53] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

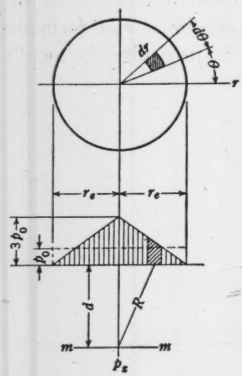

FIG. 19.—CONIC DISTRIBUTION OF LOADING BENEATH A CIRCULAR BEARING AREA.

the experiments shown in Fig. 4. The stresses at the center of the boundary area in Cases III and IV are equal to 200% of the stresses produced by uniformly distributed loading.

In Fig. 4 they are shown, erroneously, as being infinite. Evidently, stresses under a foundation computed on the assumption that the load distribution is in the form of a cone, will check experimental observations closer than those computed for Cases I to IV, inclusive.

Case V.—Conic Distribution ($n = 3$).—In the case of a conic distribution of stress beneath a foundation, the volume of the cone equals the total load and the reaction at the center is equal to $3\,p_o$ (see Fig. 19). The equation of the cone is expressed by:

$$p = \frac{3\,p_o}{r_e}\,(r_e - r)\,\ldots\ldots\ldots\ldots(29)$$

Substituting Equation (29) and Equation (5) in Equation (3) (with $n = 3$ and $z = d$), the formula for the vertical normal stress becomes,

$$p_z = \int_{r=\theta}^{r=r_e}\int_{\theta=0}^{\theta=2\pi} \frac{9}{2\,\pi}\,\frac{d^3}{(d^2 + r^2)^{\frac{5}{2}}}\,\frac{p_o}{r_e}\,(r_e - r)\,r\,dr\,d\theta\,\ldots\ldots\ldots(30)$$

Integrating and simplifying:

$$p_z = 3\,p_o\left(1 - \frac{d}{\sqrt{d^2 + r_e^2}}\right)\,\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

In Equation (31), by making $d = 0$, the pressure at the boundary plane, p_z, becomes equal to $3\,p_o$, or 300% of the pressure for uniformly distributed loading.

Case VI.—Conic Distribution ($n = 6$).—Substituting Equation (29) and Equation (5) in Equation (3) (with $n = 6$ and $z = d$), the formula for the vertical normal stress is,

$$p_z = \int_{r=0}^{r=r_e}\int_{\theta=0}^{\theta=2\pi} \frac{18}{2\,\pi}\,\frac{d^6}{(d^2 + r^2)^4}\,\frac{p_o}{r_e}\,(r_e - r)\,r\,dr\,d\theta\,\ldots\ldots\ldots(32)$$

Intergrating and simplifying,

$$p_z = 3\,p_o\left(1 - \frac{d^4}{4\,(d^2 + r_e^2)^2} - \frac{3\,d^2}{8\,(d^2 + r_e^2)} - \frac{3\,d}{8\,r_e}\tan^{-1}\frac{r_e}{d}\right)\,\ldots(33)$$

By making $d = 0$ in Equation (33) the pressure at the boundary plane is $p_z = 3\,p_o$, or 300% of the pressure computed for uniformly distributed loading. At the deeper planes the pressures computed for conic distribution of loading, with $n = 6$, are close to the average stresses shown in Fig. 4, which were determined by experiments.

The Boussinesq equations have considerable theoretical value. Various simplified theories of computing the stresses under a foundation are based on them. In computing the stresses under a large foundation, however, a theory based on an assumed pyramid distribution of the stresses has considerable advantage. Paul Müller[54] has computed the stresses and deformations under a foundation in this manner and has found that such stresses and deformations are closely in agreement with those determined by the Boussinesq equations. He assumed a pyramid the sides of which were inclined at an angle of 35° to the vertical. In plastic soils the side angles vary from 35 to 90 degrees.

The problem of computing stresses under a foundation is very complicated and requires extensive experimental and theoretical study. Mr. Cummings has contributed a valuable experimental analysis.

A. CASAGRANDE,[55] ESQ. (by letter).—The question of stress distribution in a semi-infinite elastic body, which was treated so successfully by Boussinesq fifty years ago, has since been extensively elaborated. Unfortunately, most publications on this subject are little known to foundation engineers, in spite of the fact that these solutions could be applied to many problems in the field of earth and foundation engineering. This situation is probably due to the intricate mathematics involved. It is desirable, therefore, that the results of such theoretical findings should be presented to the Engineering Profession in a form easily understood and adapted to ready application.

The author has been successful in presenting, in a concise and clear manner, those results of Boussinesq's studies which are most important in foundation engineering. He has also presented a recent modification of Boussinesq's equations which makes possible a semi-empirical approach to the problem of stress distribution in soils that do not follow Hooke's law; and, finally, he has compared the most outstanding experimental investigations with theory. This comparative analysis of experimental results and theoretical solutions is very enlightening, and its careful study is heartily recommended to those who desire information on the degree of deviation which may be expected between computed and actual stress distribution in a homogeneous mass of soil.

Mr. Cummings has confined himself to considerations of stress distribution within a semi-infinite, elastically isotropic body. Frequently the boundary conditions or the lack of homogeneity of the soil mass is such that the assumption of an isotropic, semi-infinite body represents only a rough approximation. Fortunately, mathematical solutions are available for a number of cases with more complicated boundary conditions, and even for elastically anisotropic materials, restricted only by the assumption of the validity of Hooke's law.

A condition frequently encountered is the presence of a practically incompressible stratum (rock) underlying a compressible soil stratum. Usually, it will be correct to assume the surface of the incompressible stratum to be so rough that no slippage between the two strata can occur. The other extreme would be represented by a frictionless rigid bed. In either case the vertical displacement in the elevation of the rigid surface is reduced to zero by forces acting in an upward direction, thereby increasing the concentration of stresses.

---

[54] *Die Bautechnik*, 1934, p. 377.

[55] Prof., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

The presence of thin sand layers within an otherwise isotropic mass of clay has a restraining influence which can be idealized by the assumption of an infinitesimally thin, inextensible, flexible layer.

Following a suggestion by the writer, M. A. Biot[56] made a comparative study of the effects of such discontinuities on the stress distribution for point and line loading. For this analysis he used an original approach, although some of the solutions were found before by Michell, Melan, and Marguerre.

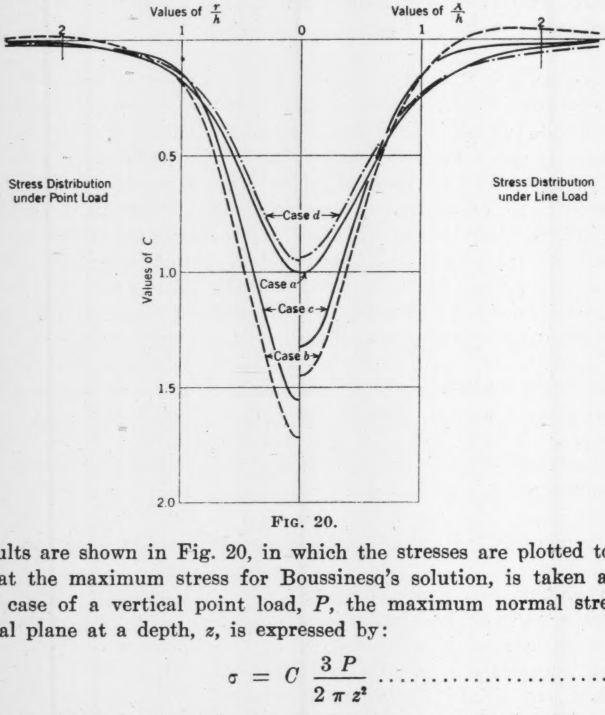

FIG. 20.

The results are shown in Fig. 20, in which the stresses are plotted to such a scale that the maximum stress for Boussinesq's solution, is taken as unity. For the case of a vertical point load, P, the maximum normal stress on a horizontal plane at a depth, z, is expressed by:

$$\sigma = C \frac{3\,P}{2\,\pi\,z^2} \quad \ldots\ldots\ldots\ldots (34)$$

in which, in addition to the notation of the paper, σ = the maximum normal stress on a horizontal plane; and C = a constant with values as shown in Table 3. For the case of a line load, $\overline{p}$, per unit length, the maximum normal stress on a horizontal plane at depth, z, is expressed by:

$$\sigma = C \frac{2\,\overline{p}}{\pi\,z} \quad \ldots\ldots\ldots\ldots (35)$$

---

[56] "Effect of Certain Discontinuities on the Pressure Distribution in a Loaded Soil", by M. A. Biot, *Physics*, December, 1935.

It will be noted that Equations (34) and (35) are built up so that they consist of the product of a numerical constant and another term which is identical with Boussinesq's solution. Thus, these constants immediately indicate the degree of deviation which the presence of the boundary produces if compared with the stresses in the semi-infinite homogeneous body.

TABLE 3.—VALUES OF C IN EQUATIONS (34) AND (35)

Case (see Fig. 20)	Description	Equation (34)	Equation (35)
a	Boussinesq's distribution	1.000	1.000
b	Frictionless rigid base	1.711	1.441
c	Rough rigid base	1.557	1.291
d	Inextensible flexible layer	0.942	0.935

The relative amount of concentration caused by the presence of an incompressible sub-stratum decreases with an increasing ratio of the width of the loaded area to the depth of the rigid bed. When this ratio is greater than unity, the stresses beneath the interior of the loaded area approach those computed by the integration of Boussinesq's solution.

Although the presence of a single, inextensible layer causes only a small reduction in the maximum stresses, it is likely that the presence of many such layers (as is the case, for example, in certain varved clays) would cause an appreciable spreading of the load, if compared with Boussinesq's distribution. According to Professor Biot it would be possible to solve such cases, although it would require a large number of computations. In view of the fact that such computations need to be made only once, and if available in published form, could readily be applied, they would represent a worth-while contribution to soil mechanics.

Another way to approach the problem of determining the stress distribution in stratified soils is by assuming an anisotropic material possessing a greater modulus of elasticity in the direction parallel to the planes of stratification. Solutions for anisotropic, elastic materials, corresponding to those of Boussinesq, have been found by Michel[57] and Wolf[58].

If, for example, a soil stratum consists of alternating layers of sandy silt and clay, the moduli of elasticity, E_1 and E_2, of each of these materials can be determined from tests on undisturbed samples. Assuming, for the sake of simplicity, these layers to be of equal thickness, then the average moduli of elasticity in a horizontal and a vertical direction for the entire stratum can easily be derived mathematically, and are found to be:

$$E_h = \frac{E_1 + E_2}{2} \qquad \text{(36)}$$

and,

$$E_v = \frac{2\, E_1\, E_2}{E_1 + E_2} \qquad \text{(37)}$$

---

[57] *Proceedings*, London Math. Soc., Vol. 32, 1901.

[58] *Zeitschrift für angewandte Mathematik und Mechanik*, Vol. 15, No. 5.

Equations (36) and (37) become somewhat more complicated if the thicknesses of the alternating layers are not assumed to be equal. For example, if $E_1 = 1\,000$ kg per sq cm, and $E_2 = 100$ kg per sq cm, Equations (36) and (37) yield $E_h = 550$ kg per sq cm, and $E_v = 182$ kg per sq cm, respectively. When substituting these values in the formulas derived by Wolf[58] for a line load, one arrives at a maximum stress along the center line which is only about one-half the value for such a stress in an isotropic material. It is true that integration over a finite area and relatively shallow depth results in a smaller reduction of the stresses. However, even an average reduction of 20% or 30% in the stresses in that part of the soil which contributes most to the settlement of a structure, is of great importance in a settlement analysis, particularly when the soil is preconsolidated under loads greater than the present over-burden.

Such cases are much more difficult to evaluate analytically where a thick stratum of sand or gravel overlies a stratum of compressible soil, because the assumption of an average modulus of elasticity for the sand layer deviates materially from the actual conditions. The modulus of elasticity within the sand layer increases in proportion to the depth, and there is an additional increase in its magnitude beneath the loaded area, due to the stresses produced by the load. Taking all factors into account, the modulus of elasticity in the sand layer is largest below the center of the loaded area.

For such conditions, computations based on Boussinesq's stress distribution may lead to estimates of amount and distribution of settlements far in excess of those actually observed. The writer has had opportunity to study a number of such cases and he has noticed invariably that such sand and gravel layers, overlying compressible strata, reduce the magnitude of the stresses in the compressible layer by spreading the load, and are very effective in smoothing out those differential settlements which would take place if Boussinesq's equations were applicable.

An analytical approach to the problem of stress distribution in a stratum of clay that is overlaid by a stratum of granular soil is very difficult. For an approximate solution one may replace the actual thickness of the harder, upper stratum by a thicker layer of the softer underlying soil, whereby the assumed increase in thickness is a function of the ratio of the moduli of elasticity of both soils, a method suggested by Terzaghi[59].

In connection with an investigation of the probable settlements of an extension to an existing utility structure, of which accurate settlement records were available, the writer has applied the foregoing method, as well as Equation (3) in the paper, with n-values less than three, to obtain computed settlement curves which would correspond in shape to the observed settlements. These buildings are resting on a layer of sand 30 ft thick, that is underlaid by 100 ft of clay. The results obtained with both methods are practically identical. One might argue that, from a purely theoretical standpoint, the method of increasing the thickness of the upper stratum is preferable because Boussinesq's formula permits the application of the law of superposition.

---

[59] "Bodenpressung und Bettungsziffer", von Charles Terzaghi, M. Am. Soc. C. E., *Oesterreichische Bauzeitung*, No. 25, 1932.

However, when one considers the large variations of the modulus of elasticity within the sand stratum, both methods are equally objectionable from a theoretical point of view.

The actual settlements of the edge of the loaded area are larger in relation to the settlement of the central part, than according to either of these approximate methods. Due to the larger stresses beneath the central part, the modulus of elasticity in that region of the sand is large and hence individual loads are distributed over a wider area, than the same loads near the edge, where the smaller stresses mobilize a smaller modulus of elasticity. Furthermore, the distribution of the loads near the edge is unsymmetrical with the greater concentration on the outside of the loaded area. Although it is not possible to consider these variations by either of the aforementioned approximate methods, the writer has found that one can arrive at satisfactory solutions by assuming the loads in the central part acting at a higher elevation than the loads along the edge, with a gradual transition for loads intermediately situated. This procedure is similar to the method in which the thickness of the harder stratum is increased, except that the increase is not constant, but a minimum at the edge. The writer found that, for a layer of sand overlying a medium stiff clay, the loads may be assumed distributed over a thickened layer, the upper border forming a semi-ellipse with the horizontal axis equal to the width of the loaded area, and the vertical axis equal to one-half the thickness of the sand stratum. This simple rule is, of course, subject to modification as more observation data become available.

The objection may be raised against this solution that the surface on which the loads are applied is not plane, and that, therefore, Boussinesq's formulas do not apply. However, it must be remembered that as soon as one deals with sand, none of the suggested methods has any scientific value, but that these methods only represent rules-of-thumb for arriving at stress distributions which are similar in character to those actually observed. There would be neither more nor less reason to assume a probability function for such a distribution, rather than Boussinesq's equation, or the modification by Griffith-Froehlich, if it can be shown that such a function also approaches the observed distributions. If one tried to retain Boussinesq's formulas, it would be merely for the sake of convenience, since very useful numerical and graphical solutions are available for such formulas.[60]

Stress computations of the foregoing type are used, in combination with the necessary data on the physical properties of the soils, for analyzing settlements and the stability of foundations.

For a settlement analysis one is often satisfied to compute the volume decrease due to the normal stresses on horizontal planes. This approach is simple but involves two approximations: First, that the rate of volume decrease is equal to the volume decrease observed in a compression test with lateral confinement (consolidation test), and is independent of the distortion of the mass; and, second, that the effect of the normal stresses on vertical planes, and of the shearing stresses on volume decrease, can be neglected.

---

[60] Influence table by Glennon Gilboy, Assoc. M. Am. Soc. C. E., pub. in the Progress Report of the Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., May, 1933, p. 781; tables for normal and shearing stresses, for various load conditions, by L. Jürgenson in "The Application of Theories of Elasticity and Plasticity to Foundation Problems", *Journal*, Boston Soc. of Civ. Engrs., July, 1934; and graphical solutions for distribution of normal stresses and deformations under rectangular loaded areas, by W. Steinbrenner, in "Tafeln zur Setzungsberechnung", *Die Strasse*, No. 4, 1934; and influence tables for the same case by N. M. Newmark, Jun. Am. Soc. C. E., in "Simplified Computation of Vertical Pressures in Elastic Foundations", *Bulletin*, Univ. of Illinois, Vol. XXXIII, No. 4, 1935.

Regarding the first assumption, in 1931, the writer[61] succeeded in demonstrating with a new type of shearing apparatus that the compressibility of clays is increased by simultaneous deformation. Unfortunately, no data are as yet available as to the amount of this increase for undisturbed clay, and for the magnitude of distortion as normally encountered in the soil underlying structures. The writer believes that for such conditions this influence is negligible.

The second assumption leads to errors which, for the majority of foundation problems, are tolerably small. Besides, in many cases, where the loading is simple, it is not necessary to introduce such an approximation, because it is possible with equal, or even with less, work to apply directly the formulas for strain which Boussinesq and others have derived. This procedure will be illustrated by the following example which the writer has used for instruction purposes since 1932.

A circular area with the diameter, *D*, resting on the surface of a semi-infinite body with a constant modulus of elasticity, is loaded with *p* per unit of area. The theory of elasticity gives for the total displacement, Δ, of the center of the area (settlement) the following formula:

$$\Delta = \frac{p}{E} \times \frac{m^2 - 1}{m^2} \times D \ldots\ldots\ldots\ldots (38)$$

in which *m* represents Poisson's number.

For the extreme cases of a perfectly incompressible material, with $m = 2$, and a perfectly compressible material, with $m = \infty$, the displacements are as follows:

For $m = 2$,

$$\Delta = \frac{3\,p\,D}{4\,E} \ldots\ldots\ldots\ldots (39)$$

and for $m = \infty$,

$$\Delta = \frac{p\,D}{E} \ldots\ldots\ldots\ldots (40)$$

The settlement in the center, therefore, corresponds to the decrease in length of a cylinder of the same material, loaded with the same unit load, and of a height equal to 0.75; or, 1.00 times the diameter of the area.

Although in most materials, deformation and volume change cannot be separated, their relation being expressed by Poisson's number, such a separation is possible for clays. If stresses are introduced into a mass of plastic soil it will first deform without volume change, and, subsequently, a gradual volume decrease will take place at a rate which is dependent on the dimensions, drainage, and consolidation characteristics of the mass of soil.

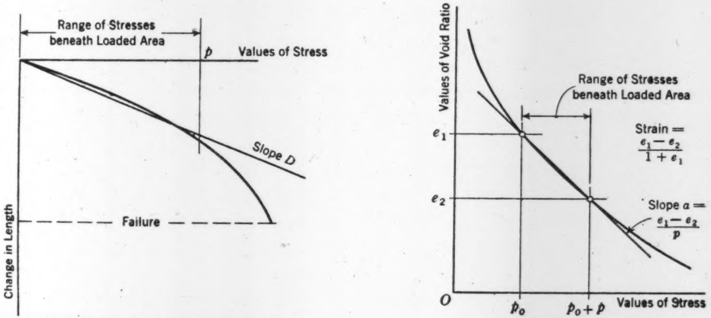
[61] "Research on the Shearing Resistance of Soils", by A. Casagrande and S. G. Albert, Mass. Inst. Tech., 1932; see, also, "The Shearing Resistance of Soils", by L. Jürgenson, *Journal*, Boston Soc. of Civ. Engrs., July, 1934; "New Facts in Soil Mechanics from the Research Laboratories", by A. Casagrande, *Engineering News-Record*, September 5, 1935; and "Characteristics of Cohesionless Soils Affecting the Stability of Slopes and Earth Fills", by A. Casagrande, *Journal*, Boston Soc. of Civ. Engrs., January, 1936.

The settlement due to immediate deformation, without volume change, can be found by utilizing the stress-strain diagram from an unconfined compression test on a undisturbed sample of the clay. A typical result of such a test is shown in Fig. 21(*a*). In the majority of cases the stress-strain curve for the range of the stresses which are introduced into the soil by the load, can be very well replaced by a straight line. The slope of this line is designated as the modulus of deformation, *M*. In its effect this modulus corresponds to the modulus of elasticity used in the theory of elasticity. With the assumption of a straight-line relationship with the same slope in the entire mass of soil one fulfills all requirements to permit the application of the theory of elasticity. Since for the deformation without volume change, $m = 2$, one arrives at the settlement in the center of the circular area, due to deformation only, by replacing, in Equation (39), the modulus of elasticity, *E*, by the modulus of deformation, *M*.

The subsequent settlement, due to gradual volume decrease, can be determined with the help of the pressure-void ratio relationship shown in Fig. 21(*b*), which is obtained from a consolidation test (confined compression test) on an undisturbed sample. Since a homogeneous mass of soil is assumed, the entire mass is preconsolidated under the same load, p_0. The loading raises this intrinsic stress in the soil in varying amounts, to a maximum of $(p_0 + p)$. For this range of stresses the change in volume may be represented with sufficient degree of accuracy by a straight line with the slope equal to the coefficient of compressibility[62], $a = \frac{e_1 - e_2}{p}$. From this value the corresponding ratio of stress over strain is derived, thus:



(*a*) UNCONFINED COMPRESSION TEST (*b*) CONSOLIDATION TEST

FIG. 21.

$$A = \frac{p}{\frac{e_1 - e_2}{1 + e_1}} = \frac{1 + e_1}{a} \qquad \text{.................. (41)}$$

---

[62] "Erdbaumechanik", von Charles Terzaghi, M. Am. Soc. C. E., Vienna, 1925.

which is defined as the modulus of volume change. This modulus corresponds to the modulus of elasticity of a material following Hooke's law, and with $m = \infty$. The only assumption made in this analysis is the same as that made previously, namely, that the rate of volume change is independent of deformations.

Thus, the consolidation of the mass of clay has been reduced to the behavior of a material following Hooke's law, and with $m = \infty$. Therefore, the settlement of the circular area, due to consolidation only can be found by replacing in Equation (40) the modulus of elasticity, E, by the modulus of volume change, A. Hence, the total settlement of the center of this area will be:

$$\Delta = \left(\frac{3}{2} \frac{1}{M} + \frac{2}{A} \right) p\, D \ldots\ldots\ldots\ldots (42)$$

In a similar manner one can derive formulas for the settlement of other points on the surface, and for other areas.

In closing, the writer wishes to note that, in his experience, settlement due to consolidation in genuine clays can be analyzed and predicted, on the basis of tests on undisturbed samples, with a satisfactory degree of accuracy. However, for slightly plastic silt clays, non-plastic silts, and certain organic silts, no amount of care can prevent sufficient disturbance to the samples to cause an appreciable increase in compressibility. For such materials, predicted settlements have frequently been too large.

The immediate settlement due to deformation of clay under large loaded areas was found by the writer to be always less than the values computed on the basis of unconfined compression tests on undisturbed samples. Sometimes, this discrepancy has been very large. The cause of this behavior is, at present, unexplained.

A. E. CUMMINGS,[63] ASSOC. M. AM. SOC. C. E. (by letter).—The discussion has served to bring out at least three important phases of the problem of the distribution of stresses through soils. These appear to be: (1) Questions of isotropy and Hooke's law; (2) the distribution of pressure on the contact surface; and (3) the effect of depth on the stress distribution. The writer proposes to devote this closing discussion to a consideration of these three topics.

Before considering the various topics mentioned during the discussion, however, the writer wishes to demonstrate the derivation of the stress equations for another type of surface-load distribution as shown in Fig. 22. To distinguish it from the parabolic distribution of Fig. 3(*b*), this will be referred to as an inverse parabolic distribution, varying according to the equation:

$$p = 2\, p_0 \left(\frac{r^2}{r_e^2} \right) \ldots\ldots\ldots\ldots (43)$$

so that the volume generated by rotating the shaded area around the vertical axis is equal to the volume of the circular disk of Fig. 3(*a*).

---

[63] Dist. Mgr., Raymond Concrete Pile Co., Chicago. Ill.

Case VII.—Inverse Parabolic Distribution (n = 3).—Substituting Equation (43) and Equation (5) into Equation (3), with $n = 3$ and $z = d$, gives:

$$p_z = \int_{r=0}^{r=r_e} \int_{\theta=0}^{\theta=2\pi} \frac{3}{2\pi}\, 2\, p_0 \left(\frac{r^2}{r_e^2}\right) \frac{d^3}{(d^2 + r^2)^{\frac{5}{2}}}\, r\, dr\, d\theta \ldots\ldots\ldots\ldots (44)$$

With the method used by Professor Krynine in the derivation of Equation (25), the integration and simplification of Equation (44) leads to:

$$p_z = p_0 \left[4\, a^2 - \frac{4\, a^3}{(a^2 + 1)^{\frac{1}{2}}} - \frac{2\, a^3}{(a^2 + 1)^{\frac{3}{2}}} \right] \ldots\ldots\ldots\ldots (45)$$

Case VIII.—Inverse Parabolic Distribution (n = 6).—In a manner similar to Case VII, the substitution of Equation (43) and Equation (5) into Equation (3), with $n = 6$ and $z = d$, can be shown to give:

$$p_z = p_0 \left[\frac{a^2 + 3\, a^4}{(a^2 + 1)^3} \right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

It is easily seen by substitution of $a = 0$ into Equations (45) and (46) that the vertical normal stress on the vertical center line at the ground surface is zero. This is in accordance with the load condition of Fig. 22. The manner in which this stress varies with the depth is of considerable interest and the graphs of Equations (45) and (46) are shown in Fig. 23.

Isotropy and Hooke's Law.—This subject is mentioned by Messrs. Williams, Krynine, Biot, Feld, Paaswell, Housel, and Casagrande. As is well known, Hooke's law is a very simple statement that "stress is proportional to strain." Isotropy is not quite so easily defined. Professor Krynine uses the terms, "monotonous" and "statistical", to describe different degrees of isotropy. His conception of a "continuum" and the number of particles in a given volume connotes the idea that in some way isotropy is related to density. Mr. Feld describes an isotropic body as one "having the same physical properties in all directions." The writer prefers Mr. Feld's statement, and believes that the chances of misunderstanding will be lessened materially by a strict adherence to the definition of isotropy commonly used in the mathematical theory of elasticity. Max Planck[64] states that,

> "The necessary and sufficient condition for a body to be elastically isotropic—that is, that it should have no favored directions at all—is that its elastic constants should all be invariant with respect to any change of the coordinate system, or, what amounts to the same thing, that it can be made to coincide with itself by means of any arbitrary rotation. * * * Hence, it follows that the elastic potential of an isotropic body has only two constants which are independent of each other * * *."

It is the writer's belief that this definition precludes the idea of different "degrees of isotropy." A body is either isotropic, or it is not, and if it is not isotropic it is anisotropic or aeolotropic.

With the exception of Mr. Paaswell, all who contributed to the discussion appear to be agreed that soils do not always follow Hooke's law and that they are not isotropic in the sense in which this word is defined in the mathematical theory of elasticity. Mr. Paaswell states that the use of the Boussinesq equations "in foundation design involves the same degree of accuracy as the use of the ordinary Bernoulli formulas for flexure." These flexure formulas, of course, are based on the assumption that the displacements are infinitesimal and that the material in question follows Hooke's law. However, in the closing sentence of his discussion, Mr. Paaswell mentions the horizontal normal stresses as well as the vertical normal stress which is represented by Equation 2(*c*). The equations for these horizontal normal stresses include the elastic constants of the material and the sum of the three normal stresses is one of the well-known invariants of the mathematical theory of elasticity. In other words, in an elastic isotropic solid obeying Hooke's law and subjected to infinitesimal displacements which are within the elastic

---

[64] "Introduction to Theoretical Physics", Vol. II, p. 66.

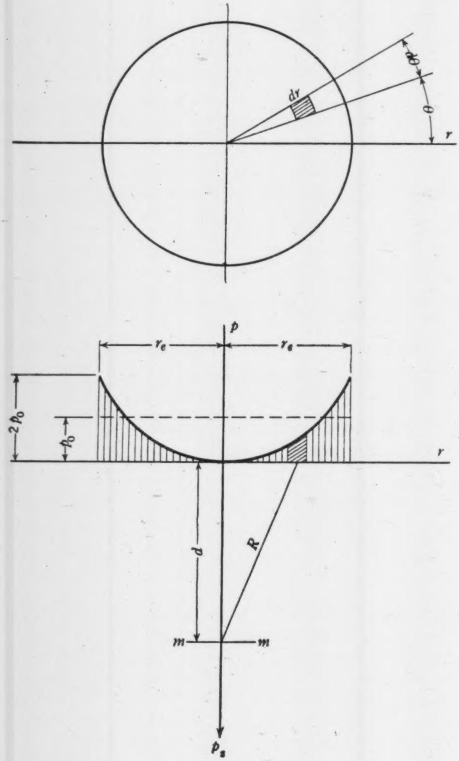


FIG. 22.—INVERSE PARABOLIC DISTRIBUTION.

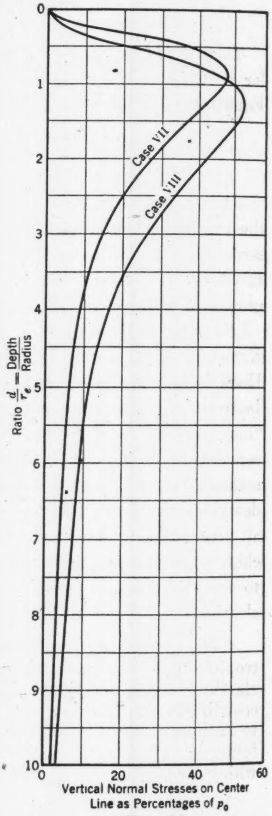

FIG. 23.

limits of the material, the stress system at a point within the solid includes three normal stresses and two of these stresses contain elastic constants.

For ordinary soils, Mr. Paaswell states that the terms containing these elastic constants will vanish. However, the writer is unable to understand how this problem can be expected to work both ways. According to Boussinesq, two of the three normal stress equations contain elastic constants. With the terms containing the elastic constants eliminated from the stress equations, it is evident that they are no longer those given by Boussinesq. It appears, therefore, that Mr. Paaswell agrees with the writer's Conclusion (2), namely, that the equations of the theory of elasticity must be modified before they can be applied to soils.

If it is taken for granted that soils do not obey Hooke's law and that they are not elastically isotropic, there arises the question as to what is to be done about calculating stress distributions in soils. In the writer's opinion there are several possible methods of approach: (1) By assuming that soils are anisotropic; (2) by modifying the equations for elastic isotropic solids; and (3) by eliminating the theory of elasticity in favor of a "rational method".

(1) The problem can be attacked on the assumption that soils are anisotropic and that it is necessary to use additional elastic constants to represent the variations of the elastic properties of the soil in different directions. This method has been demonstrated by Professor K. Wolf.[65] It is also the method used in the study of the elastic behavior of crystals.[66]

(2) The equations for elastic isotropic solids may be modified with parameters in the manner demonstrated by Griffith[9] and Froehlich.[10] The numerical values of the parameters are to be determined by comparison with experiments. This is the method used by the writer.

(3) The theory of elasticity may be eliminated entirely and the problem attacked on what may be termed a rational basis. This method is represented by the procedure outlined by Professor Housel who attributes considerable importance to surface phenomena, particularly the edge effect at the perimeter of a footing. Professor Housel's method is similar to that developed by Froehlich[67] and referred to by him as "die kritische Randbelastung." In this method the coefficient of internal friction, ϕ, plays an important part.

The interesting fact about these several methods of attacking the problem of stress distributions in soils is that, to some extent, they appear to be related in various ways. By his Equation (21), Professor Krynine shows a relationship between the Griffith-Froehlich n and Terzaghi's coefficient of pressure at rest, K. The coefficient K, in turn, is related to the coefficient of internal friction, ϕ. Mr. Newmark has developed a function, ψ, which he expresses in terms of n by Equation (28). With the aid of the Rankine stress circle, Froehlich[68] has shown a relationship between the concentration factor, n, and the coefficient of internal friction, ϕ. The same writer[69] has demonstrated mathematically that the concentration factor, n, is more or less than 3, depending on whether the elastic modulus of the soil increases or decreases with the depth. By means of Fig. 16, Professor Housel compares his solution with that of Michell which is based on the elastic theory.

This problem presents an interesting field for further study particularly by means of large-scale experiments on actual structures. Information available on the subject at present is insufficient to enable one to state that any particular method of calculating stress distributions is to be preferred to all others.

Distribution of Pressure on the Contact Surface.—This problem has been discussed by Messrs. Williams, Krynine, Wilcoxen, Findley, Feld, Salter, Housel, and Eremin. There is no question but that it is an important factor in the behavior of foundations. The subject is not fully understood, and yet, of all the unsolved problems of foundation engineering, it is probably the least difficult to investigate experimentally on a large scale. It is neither difficult nor expensive to bury pressure cells under full-sized structures in order to determine actual pressures in the plane of contact between foundation and soil. Pressure readings continued over a period of time would show the nature of any changes that might occur in these surface-pressure distributions.

In his discussion of the problem, Mr. Wilcoxen presents Fig. 9(*b*), showing a surface distribution which is a maximum at the edges and zero in the center of the plate. Within the solid he shows a stress distribution in which the vertical stress on the vertical center line reaches a maximum of 300% of the average surface load. This maximum is shown at a depth of about one-half the diameter of the plate. Mr. Wilcoxen implies that an error has been made in the interpretation of this experiment, and that Fig. 9(*b*) represents the true explanation.

The distribution of surface pressure in Fig. 9(*b*) is the same as that of Fig. 22. The vertical normal stress on the vertical center line, for the load condition of Fig. 22, is shown in Fig. 23. It is easily seen from Fig. 23 that at no point on the vertical center line is this stress anywhere near 300% of the average surface load either in the elastic isotropic solid ($n = 3$) or in sand ($n = 6$). The distribution of surface pressure and the stress distribution within the solid, as shown in Fig. 9(*b*), are not compatible. The experiment performed by Mr. Wilcoxen is difficult to interpret, but it appears to have been an impact experiment rather than one of static pressure. The thickness of the steel test plate is not given so that it is impossible to state whether or not the plate would act as a rigid body under the blows of the fence-post.

However, some very careful experiments have been performed by Kögler and Scheidig[70] for the purpose of determining the distribution of pressure in the contact plane between a rigid body and a bed of sand. For the rigid body, they used a heavy circular block of concrete, 63 cm (24.8 in.) in diameter. Pressure cells were embedded in the lower face of the block so that the variation of pressure over the contact plane could be determined. At the same time, pressure cells were placed in the sand bed at a depth f 40 cm (15.7 in.) The block was loaded and simultaneous readings were made of the pressure distribution at the surface and of the stress distribution in the sand. The results obtained in these experiments agreed with Mr. Wilcoxen's Fig. 9(*a*). In the contact plane the pressure was a maximum at the center. Mr. Wilcoxen states that "foundation flexibility is the key to the resulting type of surface stress distribution." In the writer's opinion this is only half the problem. The other half depends on the elastic properties of the material on which the foundation is built.

---

[69] "Druckverteilung im Baugrunde", p. 90.

[70] "Druckverteilung im Baugrunde", *Die Bautechnik*, November 29, 1929, Heft 52, p. 828.

A factor in this problem that is sometimes overlooked is the horizontal friction force that may be developed in the plane of contact. The point load, *P*, in Fig. 1, is normal to the surface of the solid. When Equation (3) is integrated over a finite area there is an implied assumption that the pressure under the finite area is normal to the surface of the solid and that no horizontal forces are acting in the contact plane. In the case of an actual footing, it is almost certain that, under some conditions, appreciable horizontal forces are generated in the contact plane. These forces affect the stress distribution within the solid. Almost no information is available as to the nature and magnitude of these horizontal forces under a foundation or even under a test plate. However, Boussinesq[71] has discussed several theoretical solutions involving horizontal forces applied at the surface of the solid in various ways.

Messrs. Findley and Salter have discussed this question from the point of view of the practical designing engineer. Serious complications are involved, of course, in dealing with the general problem of a given foundation on a given soil. There is also the question of how far a practical designer should go in his efforts to determine the probable distribution of pressure on the contact plane. At present, the practical designer is not able to go very far in this direction due to the lack of field data as to the actual pressure distributions that exist under full-sized structures. Without these data with which to check the theoretical analysis, the problem is still more or less in the field of speculation as far as actual foundations and actual soils are concerned.

In this connection it is to be noted that Boussinesq's methods do not lead to a solution of this general problem. The surface load distributions shown in Figs. 3(*a*), 3(*b*), 19, and 22, are not to be confused with actual plates or footings. They are simply normal loads distributed over a part of the surface of the solid. If these surface distributions are known, Boussinesq's methods of applying potential functions can be used to determine the distribution of stresses within the solid. If, instead of these surface pressures, the displacements at the surface are given, Boussinesq's analysis can also be applied, and the stress distribution within the solid can be found from the surface displacements.

---

[71] "Application des Potentiels", p. 72.

However, in the general problem, neither the pressure distribution nor the surface displacements is given. A footing with certain elastic properties is to be placed on a soil with other elastic properties. The footing is to be loaded by means of a concentrated column load, or otherwise. The available methods for attacking this problem and the solution of a practical problem of this type, were outlined in 1935 by Froehlich.[72] The solutions for a number of cases involving circular plates carrying various types of loads have been published by Dr. Ing. Ferdinand Schleicher.[73] The equations for stresses and displacements include the elastic properties of the plate as well as the elastic modulus of the foundation material.

The Effect of Depth on Stress Distribution.—This subject was mentioned several times during the discussion. Professor Krynine states that, "probably at a certain depth within the earth all matter obeys the Boussinesq law * * *." Mr. Newmark calls attention to the fact that "* * * the experimental data are limited to measurements at depths of less than 5 ft * * *", and that, "* * * at great depths, sand should act more nearly in the manner of an elastic and homogeneous material * * *".

It is true, of course, that the physical properties of soils depend to some extent on the pressures under which they exist. In sand, it is generally agreed that the elastic modulus increases directly with the depth. For a homogeneous sand bed of great depth, the elastic properties at a depth of 50 ft would certainly differ from those at a depth of 5 ft. It is a question, therefore, as to how far the experiments may be extrapolated for application to full-sized structures. As has been shown, the experiments indicated a value of about 6 for the concentration factor, n. Whether or not a stress concentration factor as high as 6 would apply to a full-sized structure on a deep bed of sand is largely a matter of speculation. It seems probable that, in a bed of compact sand of indefinite depth, the average stress concentration factor might not reach a value of 6, although it would be more than 3.

In discussing this question of depth, Mr. Paaswell mentions Boussinesq's theory of "local perturbations" and states that, "the manner of loading a foundation and the soil pressures near its loading can generally be ignored in the determination of the stress distribution in the deep strata * * *". This is correct if the strata under consideration are deep enough. However, when an analogy is drawn between the foundation problem and the girder problem, as is done by Mr. Paaswell, there is one important factor in the foundation problem that must not be overlooked.

"Depth" in the foundation problem is a relative term and the vertical co-ordinates of Figs. 4 and 23 are not absolute depths; they are ratios of depth to radius of loaded area. The concentrated load in the girder problem is not exactly analogous to the distributed loads in the foundation problem. In general, the stress distribution calculations are made for structures that cover ground areas on the order of 100 or 200 ft in diameter. Even if the structure were supported by isolated footings, it is the entire loaded area that would have to be considered. At the same time, the depth from ground level to rock or hardpan, over the greater part of the surface of the earth, is also on the order of 100 or 200 ft. There are well-known exceptions, of course, such as the City of Mexico and the mouths of the Mississippi and the Yangtse Rivers. However, the most common condition is one in which the depth of soil and the diameter of the loaded area are of the same order of magnitude. In other words, in a practical foundation problem, it is the region represented by the upper parts of Figs. 4 and 23 that is of particular interest. In this region the distribution of surface pressure is especially important and, regardless of the probable value of the concentration factor, there are large variations in the magnitude of the soil stresses due entirely to the manner in which the ground surface is loaded. The foundation problem, therefore, appears to be largely a question of surface phenomena and local perturbations rather than one of stress distributions in a semi-infinite solid at depths so great that the surface load conditions can be ignored.

---

[72] "Die Bemessung von Flachgründungen aus Eisenbeton und die neuere Baugrundforschung", *Beton und Eisen*, 1935, Heft 12.

[73] "Kreisplatten auf elastischer Unterlage", Berlin, 1926.

This problem of stress distributions is also influenced by other important factors, such as those mentioned by Professor Casagrande. Rigid underlying strata; planes of discontinuity due to stratification in the soil mass; soft clay beds under beds of dense sand—all affect the stress distributions. These problems have been attacked theoretically and for some of them a theoretical solution is available. Proof of the accuracy of the theoretical analysis must await the collection of data in the field. It is interesting to note that in the case of a rigid underlying stratum, Dr. Biot's equations (Fig. 20) indicate stress concentrations in excess of those given by the Boussinesq equation. In most of the experiments shown in Table 1 and Fig. 4, the pressure cells were placed on the more or less rigid concrete floor of the laboratory. The experiments produced stress concentrations similar to those required by Dr. Biot's analysis.

Summary and Conclusions.—The number and variety of the discussions on this paper are indicative of the great interest that has developed in foundation problems and soil mechanics in recent years. Nevertheless, there can be no question as to the truth of Professor Williams' remark concerning the "rather amorphous state of foundation literature" at the present time. However, Professor Williams sees no reason for discouragement in this situation; nor can the writer. It is believed that a parallel can be drawn between the development of soil mechanics and the development of the theory of elasticity which is the basis of modern structural analysis.

Galileo, in 1638, was the first mathematician to endeavor to determine the nature of the resistance of a beam to rupture. During the next 200 yr the development of the elastic theory was in the hands of such men as Galileo, Hooke, Mariotte, Young, Euler, Daniel Bernoulli, James Bernoulli, La Grange, Coulomb, and others. These are all well-known names and yet, in the "Historical Introduction" to his "Mathematical Theory of Elasticity," Love writes, as follows:

> "At the end of the year 1820 the fruit of all the ingenuity expended on elastic problems might be summed up as * * * an inadequate theory of flexure, an erroneous theory of torsion, an unproved theory of the vibrations of bars and plates, and the definition of Young's modulus."

However, Love goes on to state that "* * * such an estimate would give a very wrong impression of the value of the older researches". The year 1821 marks the discovery by Navier of the general differential equations of elastic equilibrium. Since then another hundred years have elapsed during which elastic theory and structural analysis have made great progress in many directions.

In comparison with this record, soil mechanics and foundation engineering are very young sciences. Rankine's work is about eighty years old and his theories are now termed "classical". Boussinesq's great works on pulverulent masses and on the theory of stress distributions are only fifty years old. Terzaghi published his theory of the consolidation of clay about fifteen years ago. In the past ten years much progress has been made, although many important problems remain unsolved. The most serious obstacle in the way of further progress at the present time is the lack of accurate information as to the behavior of existing structures.

In conclusion, the writer wishes to express his sincere thanks to those who contributed to the discussion. He feels that the value of his paper was materially increased by reason of the discussion, and he believes that the discussion has demonstrated the validity of his original conclusions.

SOME LOW-TEMPERATURE CHARACTERISTICS OF BITUMINOUS PAVING COMPOSITIONS

By Hugh W. Skidmore,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Philip W. Henry, J. T. L. McNew, Roy M. Green, W. W. Crosby, Joseph Zapata, M. Hirschthal, and Hugh W. Skidmore.

Synopsis

Stability at temperatures approximating hot-weather temperatures in the pavement has become thoroughly established as a basic requirement of bituminous compositions. Means of measuring and rating this important property have been perfected as a result of laboratory experiments and have been proved sound through several years of practical application. Two contemporary tests have evolved with resistance to shear the basic principle of both: In one (the extrusion test) the shear is measured indirectly and in the other (the direct test), simple shear is measured directly, and values are expressed in pounds per square inch. The latter method is distinctly convenient in comparing a variety of compositions which may have been tested in cylinders of from 1 in. to 6 in., or more, in diameter, since values by the extrusion test are not reducible to unit loads.

Although much work has been done in connection with summer temperature characteristics, with the result that the elements of mixture design involved have become thoroughly understood, little, if any, study has been made concerning low-temperature performance in paving compositions. With the thought that such an investigation should throw much light upon several questions that have long been unanswered and have given engineers much concern, the results of a systematic course of study, begun in 1931, are reported in this paper.

Introduction

It was recognized that some engineers have avoided the use of bituminous pavements because they were not always certain of the capacity of these types

---

Note.—Published in August, 1935, *Proceedings*.

[1] Pres., Chicago Paving Laboratory, Chicago, Ill.

to withstand winters, although it is well known that many bituminous compositions have withstood severe low temperatures for long periods. Just why some pavements have failed to do so has never been clearly explained. Aside from failures definitely attributable to base or to sub-grade, bituminous compositions may crack too profusely, or they may become brittle, and ravel at low temperatures. Definite means of avoiding these faults have not been at hand because scientific data have not been available with reference to the characteristics of bituminous paving compositions over a wide range of temperatures, particularly low temperatures.

One of the early disclosures in experimental work with stability at temperatures above normal air temperature was that mixture resistance to shearing forces mainly resided in the mineral structure (especially the finely divided mineral filler) and that the bituminous cement was of decidedly secondary importance. Although there were noticeable differences between various cements in a given mineral structure, and although differences in consistency of a cement accounted for some change in stability, these differences were of minor importance as compared with those in stability that were due specifically to changes in mineral composition.

One of the first items of significance encountered in studying mixtures at low temperatures was the important rôle of the bitumen in such mixtures, both with respect to its normal consistency and to its inherent qualities, such as may result from refining methods or from the parent crude oil. As the temperature is reduced, the bituminous cement becomes more and more the outstanding factor in the strength of the composition. For example, there are obvious characteristic differences between straight-run materials and cracked or oxidized cements; and there are equally as distinctive differences between tar and some asphalts and between asphalts from mid-Continent, California, and South American sources. Such facts were suspected, but certainly they were not actually known until the studies were undertaken.

Although the data reported herein pertain to sheet asphalt mixtures of the hot-mix type, sufficient work has been done with other compositions to demonstrate that typical characteristics as disclosed by these studies are common to bituminous paving compositions in general. Important avenues of further investigation with reference to specific differences between fine and coarse aggregate mixtures, hot and cold-mix types, and other such comparisons, are clearly indicated.

Composition of Mixtures Studied

In order to develop a general comparison of the twenty or more cements included in this study, a normal sheet asphalt composition was chosen, with the bitumen the only variable. The commonly used consistency of 50 to 60 penetration was selected, with a few examples of a given cement over a complete range of consistencies from low to high penetration. Normal mixtures were designed with bitumen filling the voids in the dry, compacted, mineral aggregate. Variations from normal design were also studied with the bitumen content both less and more than mineral voids. A moderate filler content of 20% by weight of total mineral aggregate (about 14% of mineral passing a 200-mesh sieve in the finished mixture) was used in the main group, with more, and less, filler used in one group to determine the general effect of variations in filler content. Thus, a fairly wide scope of possible variables applicable to fine aggregate compositions was covered by these studies.

MINERAL AGGREGATES

Sand.—In order to eliminate possible sources of uncontrolled variables, a sand of controlled grading, obtained from a single source, was selected. It is recognized that, in all likelihood, similar mixtures with sands from other sources and gradations would produce different values, but extensive investigations in the past have indicated quite conclusively that there is a characteristic order of values for any given aggregate material and that, in so far, as practical sheet asphalt gradations are concerned, the order of stability is rather well defined, depending mainly upon filler content for marked increases or decreases. Hence, it was felt that although the studies of a variety of sands and fillers would be interesting academically, the chances were slight that any really vital information would be developed by such studies.

The Lake Michigan sand that was selected is common to the territory in the Great Lakes region, and has been used for many years in asphalt paving construction. Although it is not the best sand encountered, it has the advantage of extreme cleanliness, uniformity of composition, grain shape, and size within the range of material passing any given sieve opening. The sand was separated on the 10, 40, and 80-mesh sieves and recombined to a definite grading as follows:

Percentage passing the 80-mesh sieve, and retained on the 200-mesh sieve...........	21.6
Percentage passing the 40-mesh sieve and retained on the 80-mesh sieve............	47.3
Percentage passing the 10-mesh sieve and retained on the 40-mesh sieve............	31.1
Total (percentage)..................	100.0

The specific gravity of this sand was 2.65.

Mineral Filler.—The limestone dust filler has also been used extensively in the Chicago area for many years. It is made by pulverizing a hard, durable white limestone and, in the tests, had the following characteristics:

Percentage passing a 325-mesh sieve........	61.3
Percentage passing a 200-mesh sieve and retained on a 325-mesh sieve............	15.0
Percentage passing a 80-mesh sieve and retained on a 200-mesh sieve............	23.7

The specific gravity in this case was 2.71.

Sand-Filler Aggregate.—Voids were determined[2] for several sand-filler proportions such as 0, 12, 20, 25, 30, and 100% of filler. Fig. 1, which is the voidage curve for these two minerals, is the basis for calculating the bitumen required in the mixtures. Because this curve was so typical for the materials, points intermediate between 30 and 100% of filler are omitted, since more than 30% of filler is rarely used in practice.

* Cracked kerosene residuum. †American Petroleum Institute. ‡ Test described in *Journal of Industrial and Engineering Chemistry,* Vol. 6, No. 12, p. 976.

tional information as source and methods of refining, in as complete form as such data could be obtained from the producers.

In procuring samples of representative products, asphalt of three ranges of penetration were requested: 40–50, 50–60, and 60–70. Although these penetrations represent the grades commonly used in paving construction, it was considered desirable, after much work had been done, to include some softer materials, and these were secured in some cases.

Specimens 4, 16, and 24, Table 1, were three special cements prepared in the laboratory. For Specimen 4, a vertical-oven gas-house tar was reduced to grade by steam distillation. The crude tar showed the following characteristics:

Water content (percentage by weight)	1.3
Specific gravity (at 25° C.)	1.098
Viscosity (in seconds, Saybolt Furol) at 50° C.	21
Viscosity (in seconds, Saybolt Furol) at 40° C.	37
Viscosity (in degrees, Engler, specific) at 40° C.	8.7
Percentage soluble in carbon disulphide	98.2
Distillation (percentages by weight) to:	
170° C.	0.72
235° C.	14.12
270° C.	23.34
300° C.	32.61
Softening point of residue	106° F

For Specimen 16, a regular Mexican flux (gravity, 11°, American Petroleum Institute) was blown to grade in the laboratory blowing-still. This material had a penetration of about 200 before blowing. For Specimen 24, a refined lake asphalt from the Island of Trinidad was fluxed to grade with the same Mexican flux used in manufacturing the oxidized Mexican cement. Tests were made for cementing value, with contained mineral present.

Supplementary comments referring to Table 1 should also be made regarding Specimens 5, 15, 19, 21, 22, and 23, as follows: Specimen 5 was a synthetic asphalt derived from residual, cracked kerosene; Specimen 15 was run to a penetration of 150 to 200 and then blown to grade; Specimen 19 was a flash-vacuum residual of 100 penetration, blown to grade; in the case of Specimens 21 and 23, tests for cementing value were made with contained mineral present; and Specimen 22, identified in Table 1 as a "blend," was probably a blend of steam-refined Venezuelan, and cracked domestic asphalt.

Preparation of Mixtures

Sand-filler aggregate was thoroughly mixed dry and heated to 350° F; then it was mixed thoroughly with hot asphalt cement at the same temperature. In the case of the more fluid binders, such as coal tar and the cracked asphalts, lower temperatures were used for both aggregates and binders, depending upon the viscosity of the bitumen. Some were heated to 325°F, some to 300° F, and the tar, to 250° F. In this particular the best field practice was simulated.

During the preliminary experiments, mixtures were prepared in a small, laboratory, power mixer, but the practice was abandoned in favor of careful hand-mixing for the study proper, due to the fact that too large a batch was required for the mechanical mixing. It was found that, in the case of an open pug-mill and hand-mixing, oxidation was identical. Therefore, accuracy was in no manner affected as compared with actual practice, since open mixers of the pug-mill type are still predominantly characteristic of asphalt paving manufacture despite important advantages inherent in sealed rotary mixers.

Each mixed batch was then weighed into the small batches to be moulded into the set of test cylinders. The small batches were stored in an oven at mixing temperatures during the few moments required for moulding.

Preparation of Test Cylinders

The normal size of compressed cylinders for sheet mixtures has commonly been 2 in. in diameter by approximately 1.5 in. in depth. For ordinary temperatures used in testing for stability, this is quite satisfactory for the capacity of the testing machine, but it was soon discovered that low temperatures would produce shearing strengths in excess of the capacity of the machine when using that size of cylinder. It was also found that results on cylinders 1 in. and 2 in. in diameter agreed for sheet mixtures. Therefore, the smaller diameter was used in these studies so as to provide for shearing strength possibilities in excess of 3 000 lb per sq in., if required, without building a new testing machine.

Cylinders were compressed at mixing temperatures in seamless steel tube moulds, using a double plunger, on a hydraulic press under a vertical load of 5 000 lb per sq in. Pressure was released as soon as the dial registered the required load. The compressed mixture was then cooled before being extruded from the moulds on the press, by means of a plunger and over-sized tube or split mould.

As has previously been described elsewhere,[8] this procedure has become standard laboratory practice after several years of experimenting and checking against field compression of paving mixtures. It has been found, repeatedly, that densities thus obtained in the laboratory agree well with those obtained in the field by adequate compacting with 10-ton rollers. The use of a double plunger assures uniform density throughout the specimen.

Testing Procedure

Density determinations (specific gravity) were made upon compressed cylinders a few hours after their preparation. Customary laboratory routine required that the mixtures be tested the day following their preparation, but there is no reason why they may not be tested as soon as they have been properly cooled and their densities determined.

The testing machine stands in a bath sufficiently large to provide storage for a considerable number of cylinders. Small cylinders, 1 in. to 2 in. in diameter, are maintained in the bath at testing temperature for 1 hr before they are tested, whereas larger ones are held for 2 hr or more, depending upon their size. It is not necessary to remove them from the bath to place them in the machine.

---

[8] "Practical Application of the Shear Test to Bituminous Mixtures," by H. W. Skidmore, *Proceedings,* 7th Annual Asphalt Paving Conference; also, *Roads and Streets,* January, 1929.

For all temperatures above 32° F, water was used for the bath, adding sufficient ice to secure a temperature of 41° F. Alcohol and dry ice were used for 32° F, 0° F, and −20° F, and proved to be an excellent bath medium for the low temperatures; accurate temperature control was readily maintained.

When the shearing strength test was developed several years ago, it was found by experiment that, by applying the shearing load on cylinders 2 in. in diameter at the rate of 2 lb per sq in. per sec, the most concordant results were obtained for a wide range of mixture composition and temperatures. For this reason it was adopted as the standard rate, and in order to maintain consistent results for various diameters of test cylinders, the rate must be kept proportional to the diameter, since the load is applied circumferentially; for example, one-half the 2-in. rate was required for cylinders, 1 in. in diameter, and double the 2-in. rate was necessary for 4-in. cylinders. These were the rates of load application used in the studies reported herein.

The dynamometer of the testing machine is equipped with a maximum load indicator. In the present studies, values are the average of three test cylinders of each mixture at each temperature. In the application of the stability test at normal air temperature and above, maximum variation in well designed mixtures has been found to be within 5% of the average of the group of individual test cylinders. Poorly designed mixtures usually show greater variation, and if badly out of balance, wide differences between minimum and maximum results are common. In studying mixtures at low temperatures the same general rule seems to apply, except that with highly susceptible bitumens, such as tars and cracked asphalts, even well designed mixtures show erratic results at 0° F and below. In fact, if the curve for a given mixture tends to reverse its direction as the temperature drops, the spread between minimum and maximum becomes much wider as the temperature becomes progressively lower beyond the approximate point of reversal of direction.

TEST RESULTS

Results obtained in the use of a common mineral composition are plotted in Fig. 2(*a*), with Fig. 2(*b*) an enlargement of horizontal scales for the lower temperatures. The principal value of this general curve is to demonstrate graphically the spread from maximum to minimum values for the several binders (of common consistency range) studied, and it reveals nicely the characteristic trends of the widely divergent types of cement, with respect to source and refining methods.

The common mixture was composed approximately as follows: Bitumen, 10%; filler, 18%; and sand, 72 per cent. Pro rata variations were made to compensate for differences in the specific gravity and bitumen content of the binder, in order to maintain a constant mixture with reference to pure bitumen, filler, and sand.

As a sidelight upon the accuracy of the shear test in detecting characteristic differences between bitumens at low temperatures, attention is called to the fact that points on the curves for two Mexican cements of practically the same consistency and the same refining process (Specimens 7 and 8, Fig. 2), agreed so closely that one curve serves for both, and the third Mexican cement, of slightly lower penetration (Specimen 6), falls close to the other two; likewise, the California cements from three different refineries (Specimens 1, 2, and 3) fall upon a single curve.

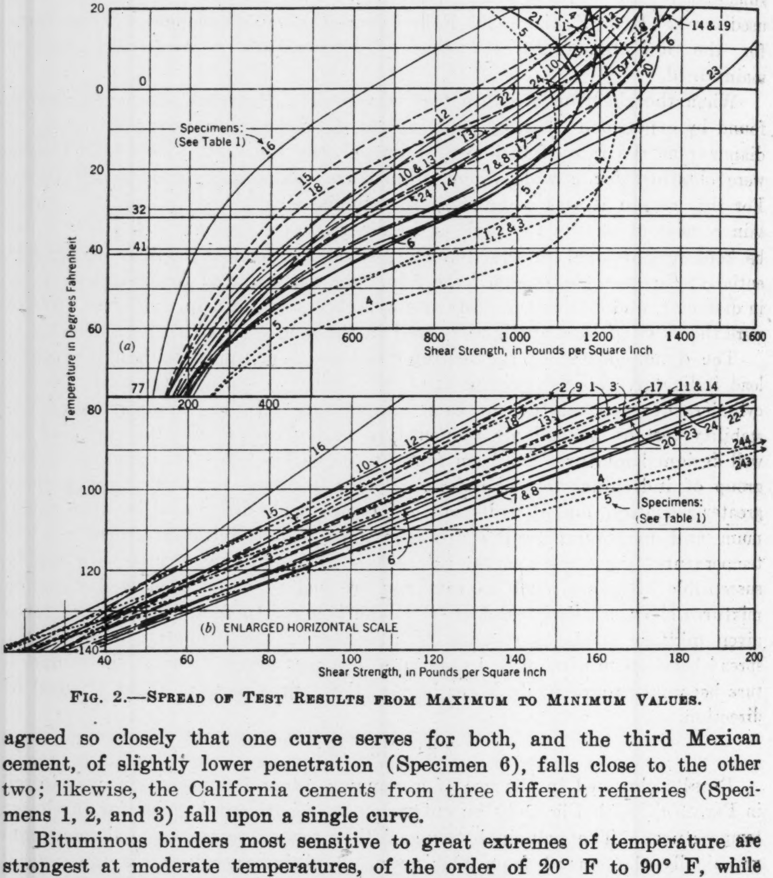

FIG. 2.—SPREAD OF TEST RESULTS FROM MAXIMUM TO MINIMUM VALUES.

Bituminous binders most sensitive to great extremes of temperature are strongest at moderate temperatures, of the order of 20° F to 90° F, while being characteristically weaker at summer sun heat and severe winter cold, of zero, or below. This is most certainly borne out in practice.

Oxidation tends to smooth out the curve for a given cement and, in doing this, stability (or strength) is reduced at all temperatures, especially at low and moderate temperatures. Past experience has demonstrated repeatedly that highly oxidized asphalts are poor paving cements, particularly in climates in the temperate and frigid zones. Such binders have caused severe cracking of pavements in these localities. Likewise, asphalts which were not oxidized during the process of manufacture, but which underwent severe oxidation while in thin films on hot mineral aggregate (in the mixer), have cracked badly in pavements which have undergone very low temperatures. Furthermore, the addition of certain salts to the paving mixture for the purpose of oxidizing or hardening the binder, has caused excessive cracking of such compositions. Every student of bituminous pavements has seen these facts demonstrated repeatedly.

This delayed effect was especially noticeable some five or six years after the introduction of the first so-called high filler mixtures (about 1922). At that time, the necessity had not been generally recognized for providing ample dry-mixing periods before introducing the asphalt and thus reducing the temperature of the hot sand (which had to be hotter because of increased filler content), by contact with cold mineral filler, to a degree not dangerous to the asphalt. Most pug-mills revolve at about 75 rpm. Consequently, freshly coated mineral is agitated severely and the asphalt (in thin films) is exposed to air rapidly, during a period of 15 to 60 sec, depending upon the enlightment of the specification writer and enforcer. If one is inclined to doubt the effect of rapid agitation of asphalt under these conditions, let him perform the following simple experiment: Weigh out 50 grams of asphalt into a tin and place it upon a hot-plate, heating it to, say, 400° F and maintaining it at that temperature for about 2 hr. Then determine its penetration and ductility. Repeat the process with a fresh sample of the same asphalt, but this time stir it for 15 min; then determine its penetration and ductility. In the first instance, it shows little if any alteration from its original characteristics, whereas in the second case it has hardened considerably and its ductility has been drastically curtailed.

Many supposedly experienced technologists still fail to take cognizance of these extremely important facts; poorly informed or ill-advised engineers continue to write specifications requiring the introduction of the bituminous binder without adequate (if any) dry-mixing of aggregates or with long wet mixing periods of 1 min, or more; and few plant operators and their employers recognize this important and inescapable result of exposing thin films of bitumen to temperatures in excess of 300° F to 400° F (depending upon the cement) in the presence of free air. If any engineer feels that he must require long mixing time, to be perfectly safe, let him apply such precaution to the dry-mixing of aggregates and, to be really safe, require only 15 to 30 sec of wet mixing in any type of mixer, such as a pug-mill, to which free air has access.

Even a hasty inspection of Fig. 2 will disclose the unusual performance of fluxed Trinidad (with South American flux) cement through the low temperature range. This disclosure quite naturally indicated further study to the investigators. Steam-reduced Mexican cement (Specimens 6, 7, and 8, Fig. 2) seemed to come nearest to duplicating the performance of fluxed Trinidad cement, taking into consideration the shape of curve and values throughout the temperature range. Fig. 3(*a*) is introduced to demonstrate the effect of increasing the filler content in the case of Mexican cement, as well as the effect of retaining the same filler content but using a slightly softer cement. The composition of the mixture is shown in Table 2.

The filler was increased under the assumption that the self-contained mineral in the Trinidad cement might possess some special value as a mineral filler, and softer asphalt was tried because the Trinidad product does not oxidize as readily as the Mexican cement. The slightly softer Mexican cement (Curve *B*, Fig. 3(*a*)) produced an excellent and very smooth curve only slightly above the Trinidad curve (Curve *A*) throughout the temperature range; whereas the higher filler with the same consistency of cement (Curve *C*, Fig. 3(*a*)), practically duplicated the results of the Trinidad product. This is simply an illustration of intelligent design of composition in the light of the materials to be used.

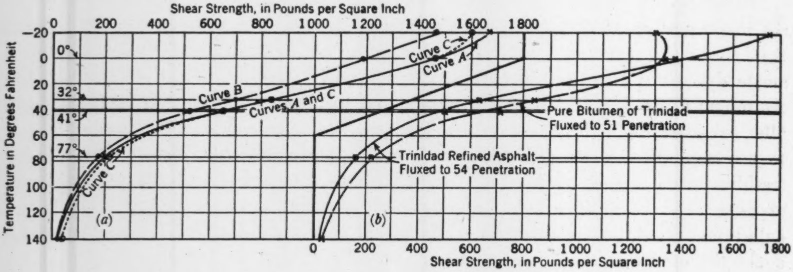

FIG. 3.—COMPARISON OF DESIGN VALUES, MEXICAN AND TRINIDAD CEMENTS.

TABLE 2.—MIXTURE COMPOSITION; CURVES *A*, *B*, AND *C*, FIG. 3(*a*)

Material	Curve *A*	Curve *B*	Curve *C*
54-Penetration, Trinidad asphalt cement; South American flux	14.5	....	....
Pure bitumen	10.0	....	....
51-penetration, Mexican asphalt cement; Panuco	....	....	9.6
64-penetration, Mexican asphalt cement; Panuco	....	9.9	....
Filler; limestone dust	13.5	18.0	22.6
Filler; Trinidad mineral	4.5	....	....
Sand; identical grading	72.0	72.1	67.8

From these studies it seems clear that the mineral in Trinidad asphalt is an efficient filler, but that this value can be duplicated readily by proper design when using another cement. Additional indication of the filler value of Trinidad mineral is apparent from the examination of Fig. 3(*b*), in which a South American flux was used in both cements plotted. The relatively pure bitumen of the Trinidad refined asphalt was recovered by an excellent method described[4] in 1933 by Mr. Gene Abson. This asphalt, in its almost mineral-free condition, was fluxed to the consistency shown by the addition of South American (Trinidad) flux; it showed 1.041 specific gravity at 77° F, and was 95.72% soluble in carbon disulphide.

---

[4] "Methods and Apparatus for the Recovery of Asphalt," by Gene Abson, *Proceedings*, Am. Soc. for Testing Materials, 1933, Pt. II, p. 704.

This investigation gives proof that the presence of the mineral in the Trinidad cement is of value in the pavement to the extent indicated herein. It is important to agitate the fluxed Trinidad cement adequately in the melting kettles, or in the tank car, as it is drawn for use in the mixture. If it is necessary (as has often been the case) to remove several inches of sludge from the kettle at more or less regular intervals, the filler value of the product has been largely dissipated.

In recent years, practical experience has shown, without question, the desirability of using softer bitumen in hot-mix compositions. Stability against displacement at summer temperatures can be secured so easily by suitable mineral content, that the very slight increased stability afforded by ten points of lower penetration becomes insignificant, especially in view of the danger attending the use of harder asphalts when they are likely to be subjected to more or less severe oxidation in the pug-mill mixer commonly used. This study shows conclusively that in climates where comparatively low winter temperatures prevail, bitumens of relatively soft consistency should be used. Asphalts of 70 to 80 penetration have been used successfully in hot-mix pavements in the North Central States to withstand trunk-line traffic during the summer and the sub-zero temperatures of severe winters. (For many years 90-penetration asphalt has been used in hot-mix pavements at Calgary, Alberta, Canada, with remarkable freedom from cracking.) When they are well designed, such pavements have been practically free from contraction cracks and have not been displaced during hot weather.

Further proof of the effectiveness of soft asphalts at low temperatures is shown in Fig. 4, the mixture composition being: Asphalt cement, 9.9% (9.8% for 91-penetration and 175-penetration); limestone dust, 18.0%; and, sand, 72 per cent. The only variable was the consistency of the asphalt, which was the product of one refiner in Fig. 4 (*a*) and of another in Fig. 4(*b*), using the same crude (Mexican) and the same refining process supposedly for all grades. The reversal of the curve for the 44-penetration cement (supplied by the refiner) is a rather conclusive indication that in the case of this harder grade the refiner varied the manufacture, either by altered processing of the residuum or by blending it with another material. The striking result of

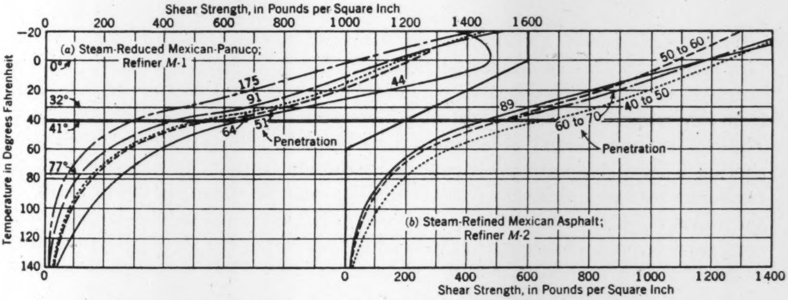

FIG. 4.—EFFECTIVENESS OF SOFT ASPHALTS AT LOW TEMPERATURES.

the 175-penetration material undoubtedly will be a surprise to many who have always thought in terms of asphalts with 40 to 60 penetration; but when one takes into consideration the more or less satisfactory performance of some cold-lay mixtures and some rock asphalts, it seems more logical. There is no doubt that, with proper design of mixture, 100-penetration cement may be used successfully in sheet asphalt mixtures in almost any climate, and although there is no need for such a soft material in tropical or semi-tropical regions, it would be highly desirable in all sections subject to temperatures of 0° F, or below. The use of soft bitumens in such sections would probably be found the most important forward step in recent years.

Effect of Varying Mixture Composition

This study has disclosed two important facts not heretofore thoroughly appreciated: First, that there is an optimum proportioning of ingredients that will produce the greatest strength of mixture throughout the entire temperature range from sub-zero to summer sun temperature; and, second, that for best resistance to low temperatures, mixtures should contain slightly more bitumen than will just fill mineral voids, as determined in compacted, dry aggregate. To the present time, technologists have been of the opinion that mixtures should carry slightly less bitumen than will fill the voids, as determined in the dry mineral.

In Fig. 5(*a*) will be seen the results obtained in four designs of mixture using the same materials in all, and ranging from low filler content to high, with bitumen filling the voids in dry aggregate. The mixture composition of materials in Fig. 5 is listed in Table 3. It seems quite certain that too much filler can be used with a given sand or coarse aggregate and a definite guide in this respect is indicated in Fig. 5(*a*). It will be seen that Mixture *D* is inferior to Mixture *C* throughout the temperature range, so that low temperature results, in this case, are not necessary for intelligent selection. Higher bitumen, a greater compaction of mixture, might tend to prevent Curve *D* from reversing itself, and might also increase its strength at all temperatures. There is positive danger of bitumen films being too thin. Only so much compaction is available with practicable construction equipment and safe working temperatures, and although increased filler may continue to lower voids in the mineral, a certain point is reached at which the mixture becomes less compressible, and, consequently, instead of increasing the strength and density of the finished pavement, additional filler actually decreases these important properties.

Increasing the bitumen beyond that required to fill voids in the dry mineral is certainly beneficial at low temperatures, whereas decreasing it has the opposite effect. In Fig. 5(*b*), Mixture *B* of Fig. 5(*a*) was made with both plus and minus 1% bitumen content (equivalent to 10% of the normal bitumen content) with the results shown. Decreased bitumen tended to decrease the stability very slightly at high temperatures and drastically reduced the strength at temperatures of from +20° F to −20° F. This tendency is reliable proof of the danger of using mixtures with less bitumen than will fill the voids; and it offers an excellent explanation of cold-weather cracking in dry mixtures. Reasonable excess of bitumen, on the other hand, only slightly reduced the stability at maximum pavement temperature and substantially increased the strength at low temperatures. Obviously, in warm climates, this particular phenomenon has no significance.

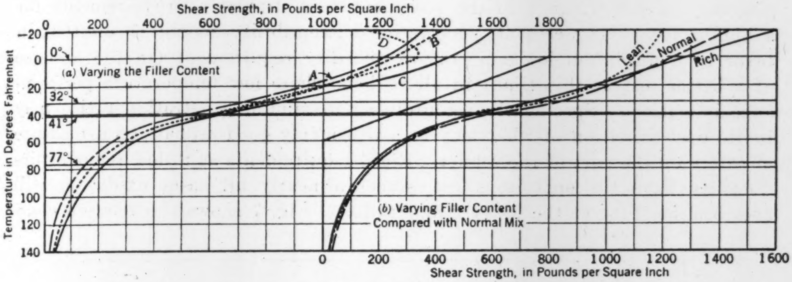

Fig. 5.—Design of Asphalt Mixtures.

* 51-penetration. † Normal bitumen fills the voids in the mineral.

In Fig. 6, eight distinctly different asphalt cements of the same grade, as determined by the penetration test at 77° F, are compared as to penetration

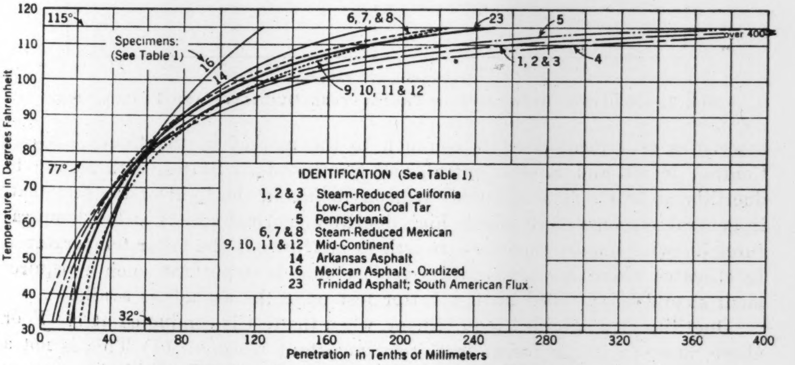

Fig. 6.—Consistency-Temperature Relation.

at the other two standard temperatures, in order to show the wide differences in susceptibility as measured by this test. Such a test, as usually interpreted, can be very misleading. The ratio of penetrations at the several temperatures, when specified with a maximum limit only (as is usually the case) is no guaranty of performance in the pavement. In stipulating requirements for a high-grade paving cement, penetration susceptibility should be omitted in favor of a minimum low-temperature ductility requirement (in the absence of a better test at this time) in all regions where low temperature performance is critical. Specifications containing maximum penetration ratios may invite over-oxidation of what may be a reasonably good asphalt, as a measure of safety on the part of the refiner. Rigid requirements as to low temperature ductility have the opposite effect, since in nearly all cases oxidation will decrease ductility at the lower temperatures. Fig. 7 shows the relative characteristics of typical cements common to the market in the Central, West-Central, North and South-Central, and Southwestern States, with respect to ductility at 5° C. These studies are convincing in the light of the fact that, in general, cements of relatively high ductility (normal speed) at low temperatures likewise impart superior strength to mixtures at the lower temperatures. In climates where low temperature performance is important, such a requirement should be specified until a better test upon the asphalt is available.

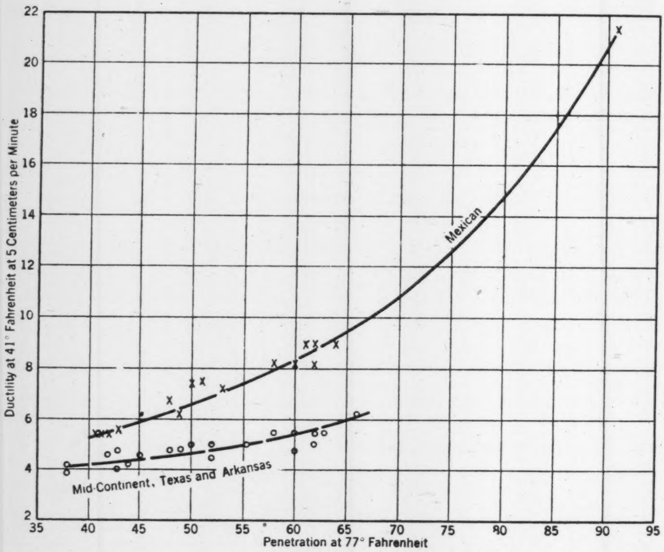

FIG. 7.—RELATION BETWEEN LOW-TEMPERATURE DUCTILITY AND PENETRATION.

Ductility as a specified requirement, when the test is conducted at 77° F, or above, means nothing for at least two important reasons: (1) This is not a critical temperature in any bituminous pavement; and (2) all binders possess ample ductility at such temperatures. Although this test may have some value in comparing a variety of cements, it is practically worthless in a pavement specification.

In an effort to translate shear strengths of bituminous pavement mixtures into comparative values familiar to engineers in general,[5] standard Portland cement mortar cylinders were subjected to the same test over the same range in temperatures. In offering these data, it is recognized that standard mortar is not concrete of the composition used in pavements, but such mortar is generally used as an indicator of concrete strength, and its values are well known from the vast amount of published data available. On the other hand, almost no data are available with respect to bituminous concrete mixtures, and, therefore, the average engineer has a limited understanding of the strength of such compositions, especially at low temperatures. Consequently, a comparison, limited as this one is, seems sufficiently valuable from the standpoint of engineering knowledge in general, to be included in this record as a means of evaluating previously unknown values in terms of well known ones.

Even a brief analysis of Fig. 8 will convince any engineer that bituminous and Portland cement concrete structures are not directly comparable. Portland cement concrete has a non-ductile binder as a cementing medium in contrast with a ductile binder in a bituminous mixture, of otherwise quite similar composition. Plastic flow is much more pronounced in bituminous compositions than in Portland cement concrete mixtures. Furthermore, the strength of a bituminous mixture is much more a function of temperature than is the case of Portland cement concrete, except at temperatures below freezing. Plastic flow is definitely related to ductility. Contraction forces in bituminous concrete mixtures are obviously absorbed by the ductility of the binder in addition to being resisted by the tensile strength of the structure, whereas in Portland cement concrete these forces are resisted by tensile strength. Patently, the modulus of elasticity will be much higher in the case of Portland cement concrete than in that of bituminous concrete.

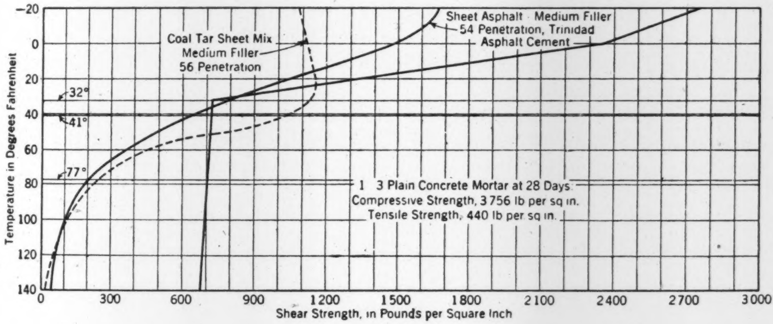

FIG. 8.

SUMMARY

The studies described herein have revealed some facts that were previously unknown and have confirmed others that were suspected as a result of experience and observation, as follows:

(1) The inherent characteristics and quantity of the bitumen in the mixture are much more important at low temperatures than at normal and higher temperatures in the pavement;

(2) There is an optimum proportioning of the several ingredients of the paving mixture that will insure the best performance over the entire range of temperatures;

(3) In regions where low temperatures obtain, the adoption of considerably softer bitumens than have been used commonly, will constitute one of the most important advances in the direction of better pavements;

(4) Ample bitumen content is essential; relatively rich mixtures are much safer than lean ones (bitumen slightly in excess of the void content of the mineral aggregate improves low temperature performance without impairing stability at high temperatures);

(5) Mineral filler in excess of the optimum for a given binder and coarse aggregate should not be used; and,

(6) The ductility of the binder at the lower temperatures appears to be an important characteristic. The test for ductility probably should be made at the standard rate of 5 cm per min, and a temperature of 4° or 5° C is about as low as may be used.

(7) At least in so far as resistance to shear is concerned, Portland cement concrete and bituminous concrete are not similar structures due to the fact that their cementing mediums are of decidedly different character.

DISCUSSION

PHILIP W. HENRY,[6] M. AM. SOC. C. E. (by letter).—Although the author may be justified in stating (see "Synopsis") that "little, if any, study has been made concerning low-temperature performance in paving compositions" and (see "Introduction") that "scientific data have not been available with reference to the characteristics of bituminous paving compositions over a wide range of temperatures, particularly low temperatures," nevertheless, as early as 1887, it was the practice to use a softer asphalt cement in such cities as Buffalo, N. Y., and Omaha, Nebr., where asphalt pavements laid a few years earlier had cracked badly. In 1887 the Company with which the writer was connected used a softer asphalt cement without any change in the mineral aggregate or percentage of bitumen to meet this situation. When the writer became Superintendent of the Company in Omaha, in 1889, he continued the practice, with the result that although the asphalt pavements laid a few years previously showed the worst cracking that he ever beheld before or since, all the pavements laid with the softer asphalt cement came through the winters without cracking. It was also the practice to use a still softer asphalt cement on streets of light traffic.

In those days no attention was paid to the mineral aggregate, and little to the percentage of bitumen. In all cities practically the same number of pounds of sand, stone dust, and asphalt cement were used in the batch, regardless of the grading of the sand. Fortunately, in most cities, suitable sand was at hand, although in a few cities, St. Louis, Mo., particularly, the sand then used was deficient in fine material (as was discovered later), and the pavements lacked the durability which pertained to most of the asphalt pavements of those days.

Until 1888 there was no method of recording the consistency of a given asphalt cement. Previous to that time the consistency was determined by chewing the cement, and the foremen of the asphalt plants became so expert that they could determine in this way the penetration of a given asphalt cement within four or five points.

Mr. Clifford Richardson, the author of the first authoritative publication concerning all phases of an asphalt pavement, was well aware of the importance of meeting low temperatures with a softer asphalt cement. In discussing certain pavements laid in 1897 he wrote[7]:

> "Experience has shown, however, that in these surfaces, although the average percentage of bitumen reached 10.5, it was in most cases too hard, averaging 58, which has resulted in some cracking. In subsequent years, therefore, it has been the practice to use softer asphalt cement. The results have been very satisfactory."

In another place he states[8]:

> "Cracks of the second description, due to the use of asphalt cement which is too hard or which has become hardened by being mixed with too hot sand,

[8] *Loc. cit.*, pp. 480–483.

or to this cause combined with others, are the form which is most commonly met with * * *. Such cracks are due to the fact that the hard asphalt is too brittle at low temperatures to yield to the contraction of the surface. It fractures under the tensile stress imposed upon it. * * * Cracks which are due to the fact that the mixture is deficient in bitumen, in consequence of which the surface does not possess sufficient tensile strength, regardless of ductility, at low winter temperatures, are not as frequent as those due to a hard bitumen, since in such a mixture, disintegration with the formation of holes takes place, as a rule, before cracking."

Notwithstanding this early general knowledge, arrived at through costly experience (in those days, asphalt pavements were guaranteed from 5 to 20 yr), the data furnished by the exhaustive study made by Mr. Skidmore would seem to establish a scientific basis for designing asphalt pavements to meet the low winter temperatures.

Incidentally, it is curious to note that there has been practically no change in the method of laying asphalt pavements on city streets in the past fifty years and more. In the Eighties the same types of tampers, smoothers, fire-wagons, and rollers were used as are used to-day. This is in contrast to the laying of the concrete base, which was then mixed entirely by hand.

J. T. L. McNew,[9] M. Am. Soc. C. E. (by letter).—It is indeed gratifying that Mr. Skidmore has presented the results of this particular investigation. Undoubtedly, he has treated a phase of the subject which is very important, and one, perhaps, which has been neglected too long.

Notwithstanding the fact that technologists have always admitted that asphalt mixtures have no appreciable strength in flexure, the tendency of many engineers in practice has been to build as much beam strength in the mixes as possible, with the result that flexibility, self-healing, and shock-resisting properties were sacrificed. This tendency is indicated by specifications which provide for extremely high filler content, low bitumen content, and harder asphalt. Part of this tendency toward so-called highly stable mixtures has been due to a misconception as to what construction methods are feasible for field use. Mixtures that are compressible under laboratory conditions may be entirely unworkable on the road or on the street. When such conditions are encountered the novice resorts to hotter mixtures and still less bitumen, all of which tends toward making a bad mixture worse.

The effect of the mixing temperature on the bituminous cement is of considerable importance, especially since many of the mixtures classified as highly stable are also low in aggregate voids and, in turn, low in total bitumen-carrying capacity. Reference to analyses of samples from existing pavements show conclusively that plant heat and agitation during mixing may lower the penetration of the asphalt as well as the percentage of bitumen so much as to destroy the self-healing properties entirely. As early as 1919, Roy M. Green, M. Am. Soc. C. E.,[10] reported numerous examples of pavements in which the aggregate was bonded with asphalt from 10 to 20 penetration and yet it was known that the material used was not as hard as the analyses indicated. These extremely low penetrations could not be chargeable entirely to a natural loss of the more volatile fractions by weathering.

[9] Prof. of Highway Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

[10] Bituminous Pavement Investigations, Pt. I and Pt. II, Texas Eng. Experiment Station, 1919 and 1921.

The writer has always been unable to find much good in the theory requiring the use of harder asphalts for increasing stability as measured by shearing tests. Shearing displacements are most likely to occur during periods of high temperature; and yet when the air temperature is 100° F the pavement temperature will often be 145° F, or so hot that any usable steam-refined asphalt cement will be in a liquid, or a very soft, condition. Obviously, the cementitiousness of two similar residues having slightly different degrees of fluidity cannot be measured as a large quantity. If most asphalt binders are in reality liquids or near liquids at summer pavement temperatures, then perhaps the real question to be answered is: What mixture design will serve both the summer conditions as well as the winter extremes? The author's investigations are interesting in that the results give some information on that question and cast suspicion on the theory sometimes advanced that harder asphalt cements produce better pavements.

If it is assumed that an asphalt surface is on an adequate foundation, low temperature failures of the surface are likely to occur as a result of mixtures that are too lean in asphalt cement, as a result of brittleness of the binder, or by raveling of the surface. Winter raveling may be due to the brittleness of the binder or it may be caused by freezing of impregnating water in the open mixtures. Brittleness in a pavement probably is more easily measured by rapidly applied loads than by slowly applied increments, and such a thought gives rise to the question: Why should not all stability tests on asphalt mixtures be made either with rapidly increasing loads or with loads applied suddenly? Regardless of what stability test is used on a bituminous paving mixture, the strength increases as the percentage of bituminous binder increases from a decided deficiency to some percentage that provides a maximum strength. After the maximum strength is reached, if the bituminous cement is further increased, the strength of the mixture decreases and continues to decrease upon the addition of bitumen until the samples are made of a preponderance of bituminous cement and little or no aggregate. The difficulty encountered in correlating the results of the different types of tests lies in the fact that the maximum strength does not occur for the same percentage of bitumen; for example, one testing procedure may indicate a maximum strength at about 8% bitumen, whereas another type of test will probably show a maximum strength for as high as 9½ per cent.

For a number of years the writer has been using a modified shear test made by forcing a frustum of a cone out of a cylindrical specimen of pavement under a gradually applied load, and has been able to verify conclusions of other investigators who used somewhat different tests to study the effects of different variables on the strength of mixtures. He has never been completely satisfied with the test as performed, however, because of the conviction that the manner of applying the load does not simulate the load application made by traffic; nor has he been able to propose such a loading device that is entirely satisfactory. Even the most rigid or stable asphalt pavements, as measured by the shearing strength tests, are in reality plastic mixtures that undergo movement on the street; and such movement does, to an appreciable extent, cause an internal re-arrangement of particles. Plasticity, then, is a property of a bituminous mixture that must be admitted and the most made of it as a quality of the mixture, because it cannot be eliminated entirely. A bituminous mixture may be plastic enough to flow gradually when subjected to a load of any kind for a long time and yet if the same mixture were loaded suddenly either in shear, compression, tension, or flexure, the plastic properties would not prevent failure.

As stated by the author, the ductility of the bituminous cement at low temperatures is of great importance. For that matter, any test for consistency at low temperatures is of value because plasticity is the desirable quality rather than brittleness in the lower ranges of temperature. It appears that the mixture which may be judged the strongest in shear at 140° F may be decidedly too brittle at 4° or 5° C.

In 1929, the writer undertook the direction of some research work on bituminous paving mixtures in the hope of developing certain modifications of test procedure that would detect properties of brittleness. Specimens were tested first by determining the intensity of load, applied gradually, that would be required to push a frustum of a cone out of a specimen 5 in. in diameter and 2 in. thick. From this test a strength curve could be plotted to show the effect of varying the bitumen. Later, another series of samples like the first was tested by knocking out the frustum of a cone of the same size by means of a hammer falling from a constant height. In this latter case the number of blows to cause failure was plotted as the ordinate against the percentage of bitumen as the abscissa. As was to be expected, the general shape of the strength bitumen curve was the same for the two tests, but the percentage of bitumen required for maximum strength was more for the impact test than for the shear test. In other words, the samples that were strongest under shear were not the strongest under impact. Of course, no one has proposed that the mixture which is strongest in shear should necessarily be the one chosen for the street; however, it has been a debatable question as to what variation from maximum results should be specified for the paving job. The writer is convinced that the foundation of a road must be able to withstand the traffic load before any surface will be capable of fulfilling its mission. If such a foundation is adequate, the function of the surface is to prevent wear, absorb impact, distribute load, and, in other ways, preserve the life of the load-carrying medium, regardless of weather. To fulfill that function the surface must be plastic enough to be either flexible or self-healing, stable enough to prevent waving, and designed so that it may be controlled as to uniformity in all the construction operations.

Since ground movement is also prevalent in winter months there appears to be every evidence to indicate that flexibility must be a quality of bituminous surfaces during winter extremes of temperature. It appears also that the mixture design, as well as the choice of all materials, must be predicated upon a proper evaluation of all demands to be made upon a surface, and not on the extremes of summer temperatures alone.

Roy M. Green,[11] M. Am. Soc. C. E. (by letter).—Engineers and asphalt technologists are indebted to the author for this contribution toward placing the design and performance of asphaltic mixtures upon a more sound and rational basis. He is to be particularly commended for his demonstration of the following facts: (1) A desirable design of an asphaltic mixture for cold climates is one in which the asphalt cement slightly over-fills the voids in the mineral; (2) in attempting to obtain high stability in a mixture there is grave danger of using a filler content which is too high; and (3) asphalt cements of higher penetration are desirable in the colder climates.

A reading of this paper and a study of the curves in Fig. 2 leaves the impression that the California cements (Specimens 1, 2, and 3) are undesirable in cooler climates. This is not a stated conclusion of the author, however. In the Cities of Omaha and Lincoln, Nebr., there are a number of sheet asphalt pavements which have been in service since 1905 and before. These pavements were laid with California cements, and have withstood the winter weather of this section of the country without the least distress and are in excellent condition to-day. However, the mixtures are rich and contain asphalt cement in excess of that necessary to fill the voids in the mineral.

It would have been very enlightening had the author made further mixtures with these cements, carrying the asphalt cement to 10% above normal, as he did the mixtures given in Fig. 5. Would this added asphalt cement produce a mixture such that the curve would not reverse itself at the lower temperatures? Is it possible, to a certain extent, to improve upon the performance of a given asphalt cement by altering the composition of the mixture from the standard conditions set up by the author's experiments?

W. W. Crosby,[12] M. Am. Soc. C. E. (by letter).—In the years since the writer first proposed a scientific research in the field of bituminous paving compositions[13], these analyses have been greatly developed and improved in many respects. Mr. Skidmore is to be complimented on having pursued a line of great importance, but one that has been too much neglected in the past.

In the beginning of the introduction of bituminous highways it was known that a higher percentage of "free carbon" was desirable in tars for roofing purposes or sidewalks in New Orleans, La., than would be the case in Bangor, Me., because of the lower temperatures in the latter place and their "brittling" or cracking effects. Furthermore, the higher temperatures of New Orleans seemed to render a higher percentage of inert material desirable in order to prevent "running" at those temperatures.

Similarly, when asphaltic oils were offered for road use, too much "middle oil" was recognized as undesirable because of the instability of these materials —which lack "free carbon"—under high temperatures. As the latter phase was of much wider observance for a long time, the researches have been mainly along the lines of perfecting bituminous materials for the warmer climates.

[12] Cons. Engr., Coronado, Calif.

[13] "Sampittic Surfacing", by W. W. Crosby, *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), p. 352.

Now that the roads of the colder climates are being regularly cleared of snow, and their surfaces exposed to traffic, the importance of researches along the lines suggested by Mr. Skidmore should be appreciated.

The writer has previously expressed[14] his opinion on the value of ductility at 77° F. He agrees in the main with the summary of this paper, although he feels that some of the "facts" stated therein may be expressed somewhat loosely and thereby possibly may permit of dangerous interpretations; for instance, under Items (1) and (4) material might be used that, from its characteristics or quantities, would result in 'bleeding" or "shoving" under traffic, in the hot suns of many localities.

JOSEPH ZAPATA,[15] ESQ. (by letter).—The author states that although the data reported in his paper pertain to sheet asphalt mixtures of the hot-mix type, sufficient work has been done with other compositions to demonstrate that typical characteristics disclosed by his studies are common to bituminous paving compositions in general. This conclusion does not agree with the results obtained by the writer in his experience and laboratory work.

In the first place, Mr. Skidmore gives no data on the stability characteristics of the aggregate mixture (sand-filler aggregate). Doubtless, this is due to the type of test that was used to evaluate the mixes discussed. During the last few years the writer has been working on the development of a stability test of wider range of application than either of the tests mentioned by Mr. Skidmore.[16] Under the conditions governing the test it was found that the addition of bitumen definitely lowers the resistance to displacement shown by the bare aggregate.

One of the conclusions reached by Mr. Skidmore is that the inherent characteristics and quantity of bitumen are much more important at low temperatures than at normal and higher temperatures in the pavement. The only characteristics given for the bitumens are penetration, ductility, cementation value, specific gravity, and the percentage soluble in carbon disulphide. The penetration has been limited to a range of 50 to 60; the available data are not sufficient to provide a clear understanding of the meaning of cementation values, (the test does not appear in standard reference texts); and the specific gravity and solubility values are not sufficient in themselves to establish inherent characteristics; therefore, the only characteristic available for making comparisons is the ductility. On the basis of the data shown in Table 1 the ductility seems to depend upon the origin of the petroleum. In view of the shear strengths shown on Fig. 2 is it possible, then, to assume that the choice of asphalts should be made on the basis of source?

Furthermore, Mr. Skidmore states that the ductility of the binders at the lower temperatures appears to be an important characteristic. His data do not confirm his statement inasmuch as the binder giving the highest shear strength is one that has no ductility at 41° F, 5 cm, 60 sec; also, in comparing the various binders it is noted that some show a difference of about 61% in ductility (41° F, 5 cm, 60 sec), with a difference of only 16% in shear strength. In making these comparisons, only data for temperatures of 41° F, 5 cm, 60 sec were considered for the following reasons: (1) A temperature of 41° F is practically that of the mean annual temperature for Wisconsin; (2) other ductility data available to the writer were obtained at a temperature of 39.2° F, 5 cm, 60 sec; (3) no data are given for ductilities at temperatures lower than 41° F, with a speed of 5 cm per min (although ductilities at 32° F are given, the conditions of test were changed, and thus an entirely new type of data are presented. What happens to the ductility, regardless of the method of test, when the temperature drops below 32° F?); and (4) in considering low temperatures, weather records were kept in mind; for example, in Wisconsin one finds the following temperature conditions: During approximately 5.5% of the year the temperature is 0° F, or below; for about 39% of the year it is 32° F, or below; and during the remainder of the year it is above 32° F.

[14] *Proceedings*, Am. Soc. for Testing Materials, Vol. XI (1911), p. 685.

[15] Asst. Materials Engr., State Highway Comm. of Wisconsin, Madison, Wis.

[16] *Journal of Industrial and Engineering Chemistry*, Vol. 6, No. 12, p. 976.

No proof has been furnished that the most destructive changes in pavements occur when the temperature is below 0° F, or between 0° F and 32° F. In an investigation conducted by the writer to determine the behavior of asphalts used as joint fillers, it was found that more damage was shown by the material during periods of alternate freezing and thawing than during periods of nearly zero weather.

Mr. Skidmore concludes that the ductility of the binder at the lower temperatures appears to be an important characteristic, and he recommends that the test for ductility be made at a standard rate of 5 cm per min and at a temperature of 4° C or 5° C. Making the safe assumption that by binder is meant a tar as well as an asphalt, Mr. Skidmore's data do not confirm his statement, especially if evaluations are to be made at 4° C or 5° C. The three binders showing high shear strengths at 4° C or 5° C have no ductility at those temperatures.

TABLE 4.—COMPARISON OF THE RATIONAL PERCENTAGE OF BITUMEN IN TWO BITUMINOUS MIXES

Material	Percentage by weight	Specific gravity	Rational proportion	Rational percentage
(*a*) MIX CONTAINING SPECIMEN 10				
Aggregate	90	2.662*	33.80	77.25
Bitumen	10	1.005	9.95	22.75
Total			43.75	100.00
(*b*) MIX CONTAINING SPECIMEN 5				
Aggregate	90	2.662	33.80	79.01
Bitumen	10	1.113	8.98	20.99
Total			42.78	100.00

* Computed from the specific gravity of the sand and the specific gravity of the mineral filler.

The design of the mixes was made on the basis of the voids theory; Mr. Skidmore does not indicate clearly, however, what steps were taken to balance differences in specific gravities. To illustrate the point, Table 4 offers a comparison. The question is raised in view of the statement that the common mixture was composed approximately of 10% bitumen, 18% filler, and 72% sand.

Mr. Skidmore fails to give data on the most important factor that should be considered in designing bituminous mixes, namely, the durability of asphalt cements. Without these data it is not possible to arrive at a complete understanding, or even to anticipate to a reasonable degree the possible behavior of mixes containing asphalts of various characteristics.

M. HIRSCHTHAL,[17] M. AM. SOC. C. E. (by letter).—The question raised by Mr. Skidmore in his analysis of bituminous mixtures as used for paving materials is also of great importance in the use of bitumens for water-proofing purposes where exposed to weather.

Unfortunately, it is a fact that although bitumens have been refined to develop qualities that will prevent "running" in high temperatures, the attempts at prevention of brittleness at low temperatures (at and below freezing) have been far from successful.

If a water-proofing material or a paving material is to be used in a location where it will be subjected to temperatures below freezing, the material should have some ductility at those temperatures to meet the contraction which is occurring and the expansion that is to follow with a future rise in temperature. It has been claimed that ductility tests on bitumens at 40° F are not reliable, as slight jars tend to crack the bitumen at that temperature before the test is completed. The claim itself indicates the necessity of ductility that is measurable. At the same time, it indicates the requirement of improved technique in making the test. Another claim frequently made is that a ductility test at 77° F, together with a melting point and penetration of the bitumen, will indicate the ductility at 40° F without the test at that temperature.

In 1921 and 1922 the writer required tests of quite a number of bitumens by the laboratory of the Delaware, Lackawanna and Western Railroad Company, at Scranton, Pa., for the purpose of obtaining results as a basis for writing a specification for water-proofing for the improvements on that road at East Orange, N. J. (at that time there was no water-proofing specification for railroad structures in existence). Some of the bitumens then tested and others submitted later to the laboratory showed melting points, penetrations, and ductility at 77° F, within the range of those found acceptable, but had no ductility at 40° F—a confutation of the claim that the other qualities of the bitumen will be sufficient to indicate a ductility of the material at 40° F. The writer feels strongly the necessity of knowing the quality of ductility at low temperatures, in a material that is known will be subjected to such temperatures on structures which are subject to movement due to such changes in temperature.

---

[17] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

Hugh W. Skidmore,[18] Assoc. M. Am. Soc. C. E. (by letter).—The reasoning of Professor McNew in connection with the fallacy of using hard asphalt in pavements, is very sound. It coincides perfectly with the ideas of the writer and his associates.

The displacement of paving mixtures under traffic during hot weather is the direct result of shearing action in the structure, induced by an applied force which is mainly compressive in nature. This compressive force is applied by means of the wheels of vehicles passing over the pavement. Fast-moving traffic ruts the pavement longitudinally in the direction of travel by displacing the composition laterally; the tendency, if any, toward forward displacement is converted apparently into lateral displacement due to the speed of the moving wheels. Vehicles coming to a stop on the pavement tend to displace the composition in a forward direction, creating humps across the line of travel. Very heavy, slow-moving traffic causes both types of failure.

In so far as hot-mix, filled, or dense, graded types are concerned, the problem of designing mixtures which will resist displacement successfully, has been readily solved, following the development of stability tests in which shear is involved. In the case of oil aggregate and some of the cold-lay mixtures, shear tests cannot be used at temperatures consistent with service conditions because these compositions possess little resistance to direct shear, except at very low temperatures; and yet many of the very soft and open-graded types of mixtures have shown satisfactory stability against displacement under traffic. This has led to the development of a new type of test as reported by Thomas E. Stanton, Jr., M. Am. Soc. C. E. and Mr. F. N. Hveem.[19]

Research in soil science is throwing much light upon the matter of the stability of cohesive masses subject to plastic flow, as well as upon the mechanics of stability of masses of non-cohesive, granular materials. Bituminous paving mixtures obviously are cohesive and subject to plastic flow. The stabilometer developed by Messrs. Stanton and Hveem appears to show much promise in the determination of the stability of all classes of bituminous paving mixtures as well as soils.

The low-temperature performance of bituminous paving mixtures, however, does not involve stability of the compositions. It has been shown clearly that the characteristics of bituminous cement are highly important with respect to low-temperature performance of the mixture. Cements that remain ductile at low temperatures unquestionably resist cracking. In this connection, Mr. Green points out that California asphalts have generally given good service in cold weather. The writer is entirely familiar with this fact. Although California cements of 50/60 penetration show no ductility at 0° C or 5° C, when elongated at a speed of 5 cm per min, they do show excellent ductility when a rate of $\frac{1}{4}$ cm per min is used; also, they show excellent elongation in the cementing value test, in which case the rate is 1 cm per min, whereas the tar and the highly cracked synthetic asphalt show no ductility at these low temperatures at either slow speed or fast speed.

---

[18] Pres., Chicago Paving Laboratory, Chicago, Ill.

[19] *Proceedings*, 14th Annual Meeting, Highway Research Board, Washington, D. C., December 6 and 7, 1934.

Mr. Zapata raises the point of the stability of the bitumen-free aggregate, although he does not describe the nature of the test which he uses for this purpose. Mr. Zapata's test measures the horizontal shear of a confined specimen of either coated or uncoated mineral aggregate, and he finds that the uncoated mineral always shows a higher value than the coated aggregate. Obviously, such a test does not measure stability as stability functions in the pavement or in the sub-grade; neither does it measure direct shear, because the specimen is confined laterally. Possibly, it is a measure of the mechanical interlocking of mineral grains, although it does not simulate service conditions. According to the Zapata test, uncoated, dry sand is more stable than a sand-bitumen or a sand-water mixture, and yet it is well known that dry sand will not support vehicular traffic, whereas wet sand will, as will also sand-asphalt mixtures.

With reference to Mr. Zapata's criticism of the lack of sufficient data concerning the characteristics of the bituminous cements, suffice it to state that the cements used in the studies were subjected to several tests not included in the general run of specifications for paving binder. No doubt others also could have been included as an after-thought. Most certainly the ductility test is one for quality and not for identification of source, as Mr. Zapata infers. The cementing-value test is well known to technologists and is described in detail in the reference given.[16]

Reference to Fig. 4 will show that binders of 44 to 175 penetration were studied. Surely this pretty well covers the range of cements suitable for hot-mix construction. Also, contrary, to Mr. Zapata's statement, the cement showing the highest shear strength at the low temperatures has good ductility at 41° F, even with its high mineral content present. Mineral-free Trinidad cement is unusually ductile at low temperatures unless an inferior flux is used.

There can be little question but that alternate freezing and thawing is destructive to any structure sufficiently porous to admit appreciable quantities of moisture. It is to avoid this difficulty, as well as to increase stability, that highway engineers generally are recommending closer grading and better filling of the aggregates used in low-cost road mixtures. Thermal contraction cracking unquestionably will be more severe at − 20° F than at 32° or 41° F. Bituminous pavements must not be confused with Portland cement concrete in this respect, since concrete slabs are generally high in moisture when cold weather comes, and are probably most susceptible at or near 32° F. The moisture content of a well designed and well built hot-mix asphalt paving mixture is very low, being usually less than 0.5% after total immersion of 3 to 5 days. Bituminous surfaces on concrete bases are compelled to follow the movement of the base irrespective of their own ability to resist contraction forces.

The writer fails to appreciate Mr. Zapata's analogy to the effect that since the tar mixture showed the highest shear strength at 41° F, the tar binder should have shown the highest ductility at that temperature. There is nothing in the data to indicate remotely that such a conclusion could be drawn. The fact remains demonstrated by these studies that those bitumens which showed the best ductilities at 41° F also produced the best shear strengths throughout the low temperature range, except the Bermudez cement, which reversed its curve in the sub-zero range.

The exact composition of the two mixtures which Mr. Zapata selected was:

	Specimen 5	Specimen 10
Bitumen (pure), by weight.......	10.6%	9.7%
Filler, by weight................	17.9%	18.1%
Sand, by weight.................	71.5%	72.2%

In every case adjustment was made to accommodate differences in specific gravity and purity of cement. Actual proportioning was by volume although the formula is based on weight.

It is not clear what Mr. Zapata means by "the durability of the asphalt cements." It was the writer's purpose in presenting the results of the study to try and throw additional light upon the matter of durability of bituminous pavements especially with respect to low temperatures.

It is quite possible that the ductility test will be supplanted by a better tool. Considerable can be said for the cementing value test. Neither of these tests seems to give all the information desired, but it must be remembered that several tests are required to establish the quality of a bituminous material and that some of the tests now being made are worse than useless since they may give fictitious information. A particularly culpable test which falls in the latter category is the reduction test at 500° F, made upon liquid binders to provide a so-called asphaltic residue of 100 penetration at 77° F.

FAILURE THEORIES OF MATERIALS SUBJECTED TO COMBINED STRESSES

BY JOSEPH MARIN,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. J. J. SLADE, JR., T. MCLEAN JASPER, I. K. SILVERMAN, W. P. ROOP, H. F. MOORE, A. A. EREMIN, A. FLORIS, AND JOSEPH MARIN.

SYNOPSIS

Several theories have been devised and tests made to determine the laws of failure of materials subjected to combined stresses. The main purpose of this paper is to extend the correlation of such theories and test results, representing them by a common set of co-ordinate axes. Without such a correlation, some test results on combined stresses have been interpreted incorrectly. In addition, some new theories are given. The graphical representation used is that of Mr. B. P. Haigh[2] and H. M. Westergaard,[3] M. Am. Soc. C. E.

Notation.—The symbols in this paper are summarized in the Appendix. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials,"[4] compiled by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

THEORIES OF FAILURE

The theories represented will be limited, for the present, to bi-axial stresses, isotropic materials, and gradually applied loads. The assumptions, limitations, and inconsistencies in each particular theory have been treated. The term, "failure," is subject to a variety of definitions. It implies a limiting value of change in shape, stress, sliding, energy, or a combination of these factors,

a point of failure being determined experimentally by a stress-strain curve.

Classification.—An element in a stressed member can be conceived as failing when a stress, deformation, sliding, or a combination of these three factors, reaches a limiting value. Based on these physical concepts, theories of failure are classified, as follows:

(*a*) General Stress Theories.—
  (1) Maximum Stress Theory (Rankine).
  (2) Maximum Normal-Stress Theory.
  (3) Maximum Stress-Normal Stress Theory.

(*b*) Deformation Theories.—
  (4) Maximum Strain Theory (St. Venant).
  (5) Maximum Distortion Theory.
  (6) Maximum Strain-Distortion Theory.

(*c*) Shear Stress Theories.—
  (7) Maximum Shear Theory (Coulomb and Guest).
  (8) Internal Friction Theory (Special Cases of Coulomb's Theory).
  (9) General Shear Theory (Special Cases of Mohr's Theory).

(*d*) Energy Theories.—
  (10) Maximum Strain-Energy Theory (Beltrami and Haigh).
  (11) Maximum Shear Strain-Energy Theory (von Mises, Hencky, and Huber).
  (12) Maximum Strain-Shear Strain-Energy Theory.
  (13) Maximum Volume-Energy Theory.

(*e*) Miscellaneous Theories.—
  (14) Wehage's Theory.
  (15) Maximum Change-in-Volume Theory.
  (16) Maximum Shear-Strain Theory (Becker).

It is possible that combinations of the aforementioned theories, depending on the signs of the principal stress, may be the true ones. Another approach to the problem is to consider the material as non-isotropic. Such a procedure has been followed by Brandtzaeg.[5]

For simplicity, the theories will be represented for the case of bi-axial stresses. In most cases they are easily extended to the case of tri-axial stress. In such cases, instead of a graphical representation in one plane, the theory is represented by a surface symmetrical about three planes at right angles. For brevity, the assumptions and limitations involved will be omitted.

Let s_1 and s_2 be the principal stresses at failure in a material subjected to bi-axial stress; s_t, the stress at failure in simple tension; and s_c, the stress at failure in simple compression. The theories are represented graphically by diagrams with co-ordinates, x and y, in which $+x = \frac{s_1}{s_t}$ and $+y = \frac{s_2}{s_t}$. The remaining quadrants are explained by the illustrations.

---

[5] "Failure of Materials Composed of Non-Isotropic Elements," by A. Brandtzaeg, Assoc. M. Am. Soc. C. E., Det Klg Norske Videnskabers, *Selskake Skrifter*, 1927, No. 2, Trondhjem, Norway.

GENERAL STRESS THEORIES

(*1*) *Maximum Stress Theory* (*Rankine*).—In Rankine's maximum stress theory, failure is defined as the condition of a material when one of the principal stresses equals the stress, at failure, in simple tension or compression. In other words, failure has occurred when $s_1 = s_t$; $s_2 = s_t$; $s_1 = s_c$; or, $s_2 = s_c$. Referring to Fig. 1, for the case, $s_c = s_t$, a material is defined as having failed when: $x = +1$; $y = +1$; $x = -\frac{s_c}{s_t}$; or $y = -\frac{s_c}{s_t}$. A more complete treatment of Theory (1) (and of Theories (4), (7), and (10), to follow), has been written by Professor S. Timoshenko.[6]

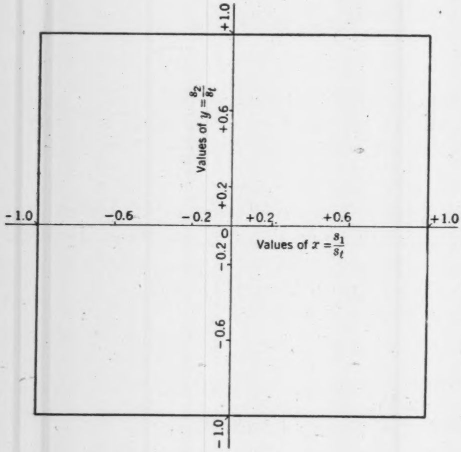

FIG. 1.—RANKINE'S MAXIMUM STRESS THEORY.

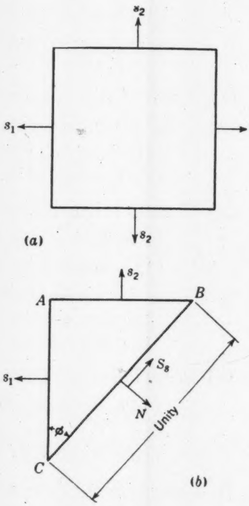

FIG. 2.

(*2*) *Maximum Normal-Stress Theory.*—Experimental evidence shows that materials do not fracture in a direction perpendicular to the greatest principal stress as required by the maximum stress theory. Consider the fracture to occur at right angles to some intermediate direction, and that the material in question has failed because the normal stress on this plane has reached a limiting value. Furthermore, let this limiting stress be composed of two parts: A normal component, N, of the principal stresses; and a normal component due to internal friction. Assuming the normal component due to friction to be proportional to the shearing stress, s_s, its value is $s_s f$, in which f equals a coefficient of internal friction. Fig. 2 represents the forces, s_s and N, acting on the plane of fracture, BC. Hence, the limiting normal stress, s, is:

$$s = N + s_s f \quad \text{.........................} \quad (1)$$

---

[6] "Strength of Materials," by S. Timoshenko Pt. II.

Substituting values of N and s_s in terms of the stresses, s_1 and s_2, and differentiating s with respect to ϕ, $\tan 2\phi = -f$ gives the condition for the maximum value of s. With $\tan 2\phi = -f$, the maximum or limiting value of s is expressed by:

$$s = \frac{s_1 + s_2}{2} + \frac{s_1 - s_2}{2} \sqrt{1 + f^2} \quad\ldots\ldots\ldots\ldots\ldots(2)$$

For the case of simple tension: $s_2 = 0$; $s_1 = s_t$; and,

$$s = \frac{s_t}{2} \left(1 + \sqrt{1 + f^2}\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

Combining Equations (2) and (3):

$$s_1 + \frac{s_2 \left(1 - \sqrt{1 + f^2}\right)}{1 + \sqrt{1 + f^2}} = s_t \quad\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

or, when s_1 and s_2 are positive, and $s_1 > s_2$:

$$x + \frac{y \left(1 - \sqrt{1 + f^2}\right)}{1 + \sqrt{1 + f^2}} = 1 \quad\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

Fig. 3 represents Equation (5) for values of f = 0.0, 0.3, and 1.0, in the four quadrants.

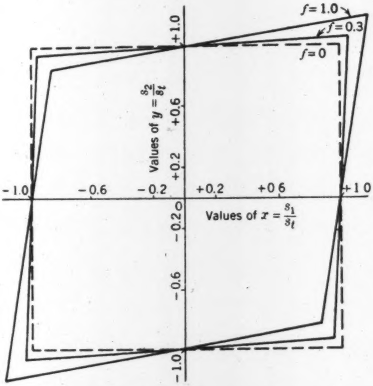

FIG. 3.—MAXIMUM NORMAL STRESS THEORY.

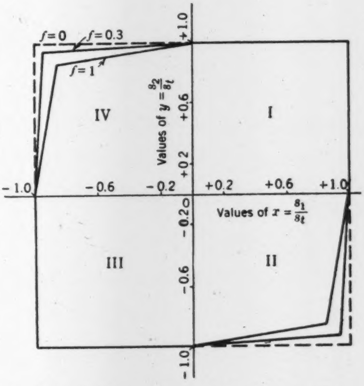

FIG. 4.—MAXIMUM STRESS-NORMAL STRESS THEORY.

(3) *Maximum Stress-Normal Stress Theory.*—Consider that the limiting stress is governed by either general stress or normal stress theories, depending on the signs of the principal stresses. Then, the limiting equations are:

$$x = \pm 1 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6a)$$

$$x + \frac{y \left(1 - \sqrt{1 + f^2}\right)}{1 + \sqrt{1 + f^2}} = 1 \quad\ldots\ldots\ldots\ldots\ldots(6b)$$

and,

$$y = \pm 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6c)$$

$$y + \frac{x\left(1 - \sqrt{1 + f^2}\right)}{1 + \sqrt{1 + f^2}} = 1 \ldots\ldots\ldots\ldots\ldots\ldots (6d)$$

Fig. 4 represents Equations (6) for values of $f = 0$, 0.3, and 1.0, and for $s_c = s_t$, in Quadrants II and IV.

DEFORMATION THEORIES

(*4*) *Maximum Strain Theory* (*St. Venant*).—In the maximum strain theory failure is assumed to occur when the elongation or contraction in the direction of one principal stress reaches a limiting value equal to the deformation at failure in simple tension. Expressed algebraically, this is equivalent to stating that failure occurs when:

$$x - \sigma y = \pm 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7a)$$

or,

$$y - \sigma x = \pm 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7b)$$

in which σ = Poisson's ratio. Fig. 5 represents Equations (7) for $s_c = s_t$ and $\sigma = 0.25$ and 0.35.

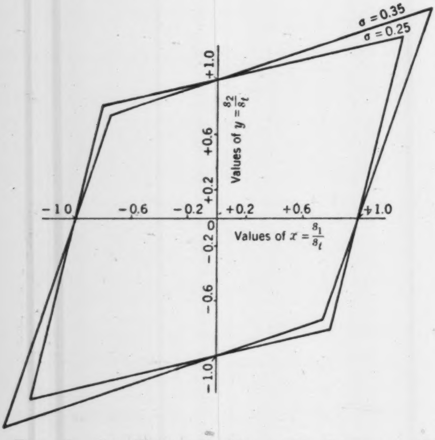

FIG. 5.—ST. VENANT'S MAXIMUM STRAIN THEORY.

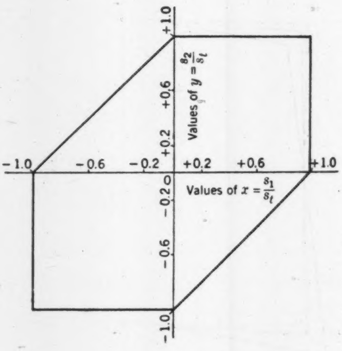

FIG. 6.—MAXIMUM DISTORTION THEORY.

(*5*) *Maximum Distortion Theory.*—A distortion theory is based on the assumption that a limiting angular deformation or shear distortion is the factor that produces failure. By equating the angular distortion in the case of bi-axial stresses to that for the case of simple tension, the following limiting equations are obtained: $x = \pm 1$; $x - y = \pm 1$; $y = \pm 1$; or $y - x = \pm 1$ (see Fig. 6). As might be expected, this theory reduces to the maximum shear theory (Theory (7)), the discussion of which follows.

(6) *Maximum Strain-Distortion Theory.*—Consider failure as being governed by a limiting elongation, contraction, or angular distortion, equal to the values in simple tension, but depending on the signs of s_1 and s_2. Then the equations defining failure are (see Fig. 7): $x - \sigma y = \pm 1$; $x - y = \pm 1$; $y - \sigma x = \pm 1$; or, $y - x = \pm 1$.

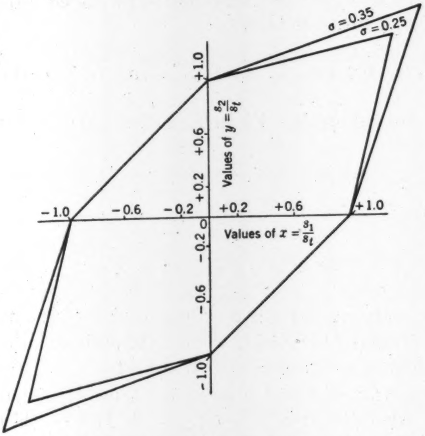

FIG. 7.—MAXIMUM STRAIN-DISTORTION THEORY.

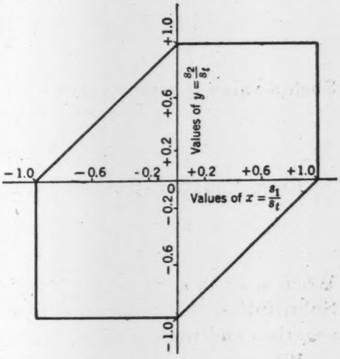

FIG. 8.—COULOMB AND GUEST'S MAXIMUM SHEAR THEORY.

SHEAR STRESS THEORIES

Shear theories are based on the assumption that failure results along some plane as a result of shear stress on the plane having reached a value equal to the limiting value of the shear stress in simple tension. Several theories are rooted in this concept, by defining the direction of the plane of the limiting shear or the value of the shear stress.

(7) *Maximum Shear Theory (Coulomb and Guest).*—In this theory, the plane of sliding or limiting shear is considered to be the plane of theoretical maximum shear, and may be expressed algebraically as follows (see Fig. 8): $x = \pm 1$; $y = \pm 1$; $x - y = \pm 1$; or, $y - x = \pm 1$.

(8) *Internal Friction Theory (Special Cases of Coulomb's Theory).*—Assume the plane of failure or sliding to be at an angle different from that of the theoretical maximum shear. For example, in Fig. 2, consider that the resistance to sliding, or the limiting stress, s_L, on the limiting plane, *BC*, is equal to the sum of a shearing stress, s_s, which is due to s_1 and s_2, and a frictional force proportional to the normal stress, *N*, equal to fN. Then:

$$s_L = s_S + fN \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Coulomb showed that, by substituting values of s_1 and s_2 for s_L and N:

For $s_1 \neq s_2$.

$$s_s = \frac{1}{2 \cos \alpha} [s_1 - s_2 + (s_1 + s_2) \sin \alpha] \quad \ldots\ldots\ldots\ldots (9)$$

and, for $s_1 = s_2 = s_T$,

$$s_s = \frac{s_T}{\cos\alpha} \quad \text{.........................} (10)$$

in which $\alpha = \tan^{-1} f$; and s_T = shear stress in torsion.

Special cases of this theory can be obtained and represented by the co-ordinates used for Theories (1) to (7). Thus, consider,

$$s_T = 0.6\ s_t \quad \text{.........................} (11)$$

Such a value is representative for several steels. From Equation (9):

$$s_1 - s_2 + (s_1 + s_2) \sin\alpha = 2\, s_T \quad \text{...............} (12)$$

From Equations (11) and (12):

$$s_1 - s_2 + (s_1 + s_2) \sin\alpha = 1.2\ s_t \quad \text{...............} (13)$$

When $s_2 = 0$, $s_1 = s_t$ and from Equation (13) $\sin\alpha = 0.2$, or $\alpha = 11° \ 30'$. Substituting this value of α in Equation (13) (and, when s_1 is positive, s_2 is negative, and when $s_1 > s_2$), $s_1 - 0.67\ s_2 = s_t$, or $x - 0.67\ y = 1$.

When s_1 and s_2 are both positive, $x = +1$ and $y = +1$. Considering all quadrants the theory requires that, for failure: $x = +1$; $y = +1$; $x - 0.67y = 1$; or, $y - 0.67x = 1$. Fig. 9 represents this special case of Coulomb's theory for $s_T = 0.6\ s_t$.

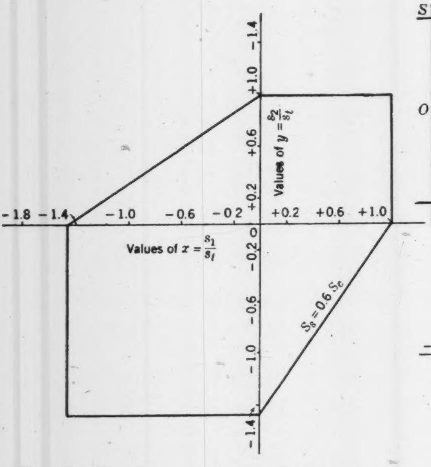

FIG. 9.—INTERNAL FRICTION THEORY, SPECIAL CASES OF COULOMB'S THEORY.

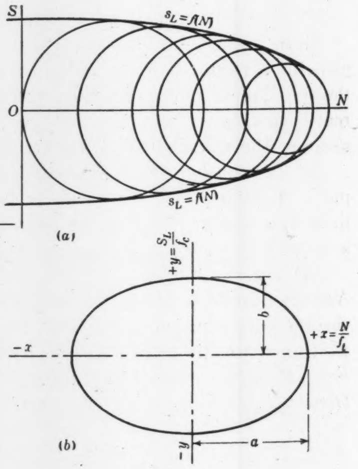

FIG. 10.

(9) *General Shear Theory (Special Cases of Mohr's Theory).*—Assuming that the plane of limiting shear or sliding is dependent in direction on the

relative values of the combined stresses, Mohr stated a general shear theory. It is assumed that the limiting stress, s_L, is equal to a constant stress plus a frictional stress produced by the normal stress, N, on the plane of sliding. The value of s_L is thus a function of N, or,

$$s_L = f(N) \qquad (14)$$

Referring to Fig. 2, in which ϕ defines the direction of sliding, by statics:

$$N = \frac{s_1 + s_2}{2} \times \frac{s_1 - s_2}{2} \cos 2\,\phi \qquad (15)$$

and,

$$s_L = \frac{s_1 - s_2}{2} \sin 2\,\phi \qquad (16)$$

Mohr represents the values of s_1 and s_2 graphically as shown in Fig. 10(a) for different values of s_1 and s_2 as represented by a series of circles. The lines drawn tangent to the circles represent Equation (14) and the co-ordinates of the points of tangency are given by Equations (15) and (16). The envelopes to the circle, therefore, represent the limiting values of N and s_L that define failure.

An empirical correlation between Mohr's theory and other theories is desirable. For this purpose, test results of several experimenters were plotted on the co-ordinate axes as indicated in Fig. 10(a), and the average envelopes to the circles were drawn. It was found that the experimental data could best be expressed by the equation of an ellipse. Actual values are given subsequently in Equations (21) and (22). Fig. 10(b) represents the relation between N and s_L—the envelope to the circles shown in Fig. 10(a). Then $N^2 + \frac{a^2}{b^2} s^2_L = a^2 s^2_t$; or,

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \qquad (17)$$

in which, $x = \frac{N}{s_t}$; and $y = \frac{s_L}{s_t}$. Substituting Equations (15) and (16) in Equation (17):

$$(y + x)^2 + (y - x)^2 \cos^2 2\,\phi - 2\,(y^2 - x^2) \cos 2\,\phi$$
$$+ \frac{a^2}{b^2} (y - x)^2 \sin^2 2\,\phi = 4\,a^2 \qquad (18)$$

For Equation (18) to be consistent for simple tension, let $x = 1$ and $y = 0$. Therefore,

$$1 + \cos^2 2\,\phi + 2 \cos 2\,\phi + \frac{a^2}{b^2} \sin^2 2\,\phi - 4\,a^2 = 0 \qquad (19)$$

Assuming $\phi = 45°$ for the case of simple tension, Equation (19) becomes:

$$b^2 = \frac{a^2}{4\,a^2 - 1} \qquad (20)$$

From the plotted experimental data and for average limiting values of the envelopes, the values of a and b, consistent with Equation (20) and the test data, are: For $a = 1.30$, $b = 0.54$; and, for $a = 1.00$, $b = 0.58$. Substituting these values in Equation (17):

For $a = 1.30$,

$$N^2 + 5.80\, s_L^2 = 1.69\, s_t^2 \qquad (21)$$

and for $a = 1.00$,

$$N^2 + 3.02\, s_L^2 = s_s^2 \qquad (22)$$

Substituting the values of N and s_L from Equations (15) and (16) in Equation (12) and assuming that $\phi = 45°$:

For $a = 1.0$,

$$y^2 - x\,y + x^2 - 1 = 0 \qquad (23)$$

and, for $a = 1.3$,

$$y^2 - 1.41\, x\,y + x^2 - 1 = 0 \qquad (24)$$

Fig. 11 represents Equations (23) and (24) for values of $a = 1.00$ and $a = 1.30$.

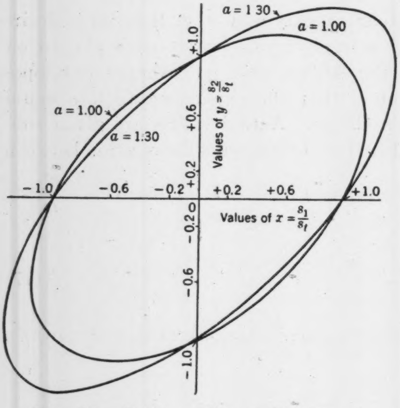

FIG. 11.—GENERAL SHEAR THEORY: SPECIAL CASES OF MOHR'S THEORY.

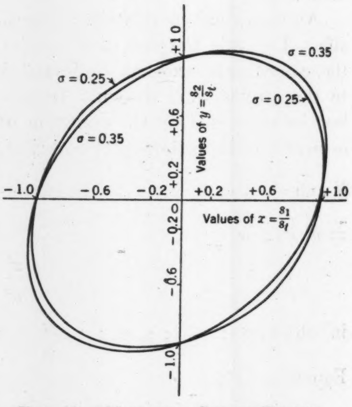

FIG. 12.—MAXIMUM STRAIN-ENERGY THEORY: BELTRAMI AND HAIGH.

ENERGY THEORIES

(*10*) *Maximum Strain-Energy Theory* (*Beltrami and Haigh*).—This theory is based on the assumption that the strain energy at failure for combined stresses equals the value of the energy at failure in the case of simple tension. In other words, failure occurs when,

$$x^2 + y^2 - 2\,\sigma\,x\,y = 1 \qquad (25)$$

Fig. 12 shows Equation (25) for $\sigma = 0.25$ and 0.35.

(*11*) *Maximum Shear Strain-Energy Theory* (*von Mises, Hencky, and Huber*).—Assuming that the energy due to shear distortion at failure for combined stress equals the value of shear energy of distortion for simple tension, this theory reduces to:

$$x^2 - x\,y + y^2 = 1 \quad\text{.....................(26)}$$

This was obtained by subtracting from the total strain energy the energy due to change in volume, which yields the resulting energy due to change in shape.

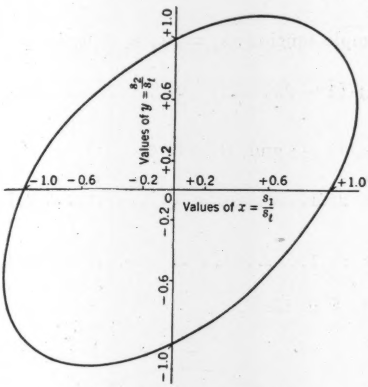

FIG. 13.—MAXIMUM SHEAR-STRAIN THEORY: VON MISES, HENCKY, AND HUBER.

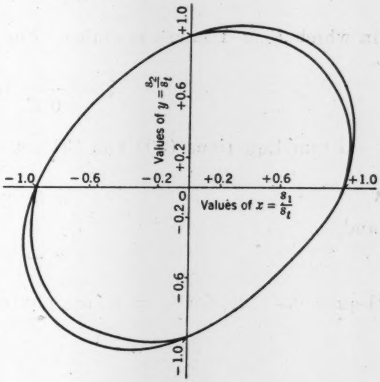

FIG. 14.—MAXIMUM STRAIN-SHEAR STRAIN-ENERGY THEORY.

Equation (26) (see Fig. 13) is identical with the special case of Mohr's theory for $a = 1.0$. Theory (11) and other theories have been written by A. Nadai.[7]

(*12*) *Maximum Strain-Shear Strain-Energy Theory.*—Consider that the energy due to either the normal strains or the angular distortions are the limiting factors. The equations defining failure are then expressed as:

$$x^2 + y^2 - 2\,\sigma\,x\,y = 1 \quad\text{..................(27)}$$

or,

$$x^2 - x\,y + y^2 = 1 \quad\text{.....................(28)}$$

The equation which defines failure in Equations (27) and (28) depends on the value of σ. Equations (27) and (28) are represented in Fig. 14 for $\sigma = 0.25$ and $\sigma = 0.35$.

(*13*) *Maximum Volume-Energy Theory.*—Let the energy to produce change in volume be the limiting factor. In addition, let the volume energy at failure for simple tension equal the volume energy at failure for combined stress.

---

[7] "Plasticity," by A. Nadai, 1931.

The energy required to change the volume of an element subjected to the principal stresses, s_1 and s_2, is:

$$\xi = \frac{1}{2}\left(\frac{s_1 + s_2}{3}\right)(\epsilon_1 + \epsilon_2 + \epsilon_3) \ldots\ldots\ldots\ldots\ldots (29)$$

in which, ϵ_1, ϵ_2, and ϵ_3 are the principal strains and $\epsilon_1 + \epsilon_2 + \epsilon_3 =$ change in volume. Substituting for stresses in terms of strains in Equation (29):

$$\xi = \frac{1}{6\,E}\,(s_1 + s_2)^2\,(1 - 2\sigma) \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

in which $E =$ Young's modulus. For simple tension: $s_1 = s_t$; $s_2 = 0$; and,

$$\xi = \frac{1}{6\,E}\,(s_t^2)\,(1 - 2\sigma) \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

From Equations (30) and (31), $s_1 + s_2 = s_t$; and, therefore;

$$x + y = \pm\, 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32a)$$

and,

$$x - y = \pm\, 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32b)$$

Equations (32), for $s_c = s_t$, are plotted in Fig. 15.

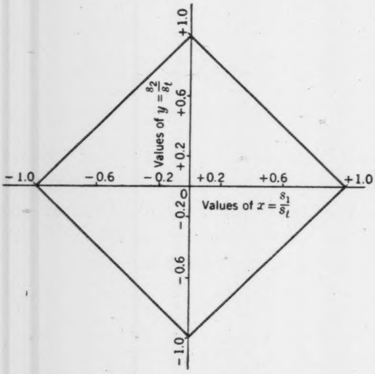

FIG. 15.—MAXIMUM VOLUME ENERGY THEORY.

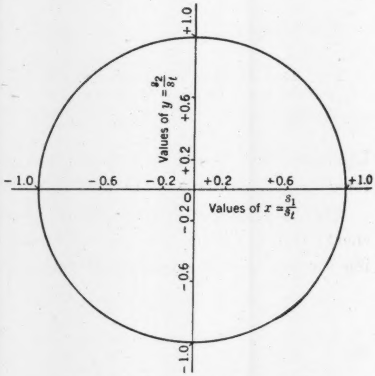

FIG. 16.—WEHAGE'S THEORY.

MISCELLANEOUS THEORIES

(*14*) *Wehage's Theory.*—This theory is empirical and is based on experiments made with pieces of paper submitted to tension in two directions at right angles. Algebraically, the theory reduces to:

$$x^2 + \frac{a^2\,y^2}{b^2} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

in which a and b are the "yield" point stresses in the two directions. For $a = b$, the theory becomes:

$$x^2 + y^2 = 1 \qquad (34)$$

Equation (34) is represented in Fig. 16 for $a = b$.

(*15*) *Maximum Change in Volume Theory.*—Consider that the volume change is the limiting factor and that the change in volume to the point of failure in simple tension is equal to the change in volume for combined stresses. Let the change in volume $= \Delta V$. For the case of an element subjected to the principal stresses, s_1 and s_2:

When s_1 and s_2 are both positive:

$$\Delta V = \epsilon_1 + \epsilon_2 + \epsilon_3 = \frac{1}{E} (1 - 2\sigma)\ (s_1 + s_2) \qquad (35)$$

When s_1 and s_2 are both negative:

$$\Delta V = -\frac{1}{E} (1 - 2\sigma)\ (s_1 + s_2) \qquad (36)$$

When s_1 is positive, s_2 is negative, and $s_1 > s_2$:

$$\Delta V = \frac{1}{E} (1 - 2\sigma)\ (s_1 - s_2) \qquad (37)$$

When s_1 is negative, s_2 is positive, and $s_2 > s_1$:

$$\Delta V = \frac{1}{E} (1 - 2\sigma)\ (s_2 - s_1) \qquad (38)$$

When (in the case of simple tension), $s_1 = s_t$, and $s_2 = 0$:

$$\Delta V = \frac{1}{E} (1 - 2\sigma)\ s_t \qquad (39)$$

and, when (in the case of simple compression), $s_1 = s_c$, and $s_2 = 0$:

$$\Delta V = \frac{1}{E} (1 - 2\sigma)\ s_c \qquad (40)$$

Equating the formulas, (35) to (38), inclusive, to Equation (39), and letting $s_c = s_t$, the following equations are obtained, defining failure as a limiting volume change; thus:

For $s_c = s_t$,

$$x + y = \pm 1 \qquad (41a)$$

and,

$$x - y = \pm 1 \qquad \text{(41b)}$$

and, for $s_c \neq s_t$,

$$x + y = \frac{s_c}{s_t} \qquad \text{(42a)}$$

and,

$$x - y = \frac{s_c}{s_t} \qquad \text{(42b)}$$

Equations (41) and (42) are represented in Fig. 17.

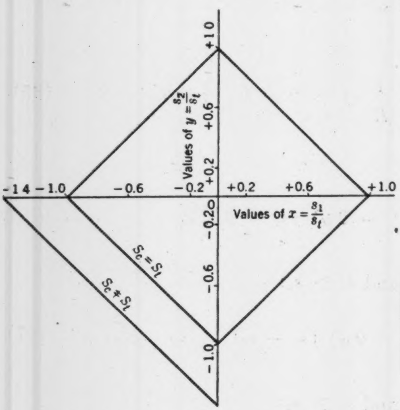

FIG. 17.—MAXIMUM CHANGE IN VOLUME THEORY.

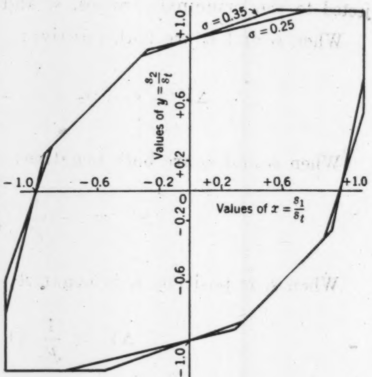

FIG. 18.—BECKER'S MAXIMUM SHEAR-STRAIN THEORY.

(16) Maximum Shear-Strain Theory (Becker's Theory).—Consider that the limiting condition for failure is either a maximum strain or a maximum shear. Then from the formulas of Theory (4) Equations (7), and Theory (7), the conditions defining failure are: $x - \sigma y = \pm 1$; $x - y = 1$; $x = \pm 1$; $y - \sigma x = \pm 1$; $y - x = 1$; and $y = \pm 1$.

Becker introduces an experimental constant in the foregoing equations by assuming that $\frac{s_s}{s_t} = 0.6$ instead of 0.5. Using this value the corresponding formulas become: $x - \sigma y = \pm 1$; $x = \pm 1.2$; $x - y = + 1.2$; $y - \sigma x = \pm 1$; $y = \pm 1.2$; and $y - x = 1.2$. These formulas, for values of $\sigma = 0.25$ and 0.35, are shown graphically in Fig. 18. A number of theories of this type can obviously be obtained by the superposition of others, as seen from Fig. 19.

COMPARISON OF THEORIES

The differences in the dimensions of machine and structural members as a result of designing by the various theories are of interest, if not of importance. The importance is evidently reduced because of the indeterminate factors involved in the selection of a working stress. The theories are compared graphically in Fig. 19 for the values of the mechanical properties given. From this graphical representation, a numerical comparison can be obtained between the limiting stresses as required by the various theories and the resulting differences in design.

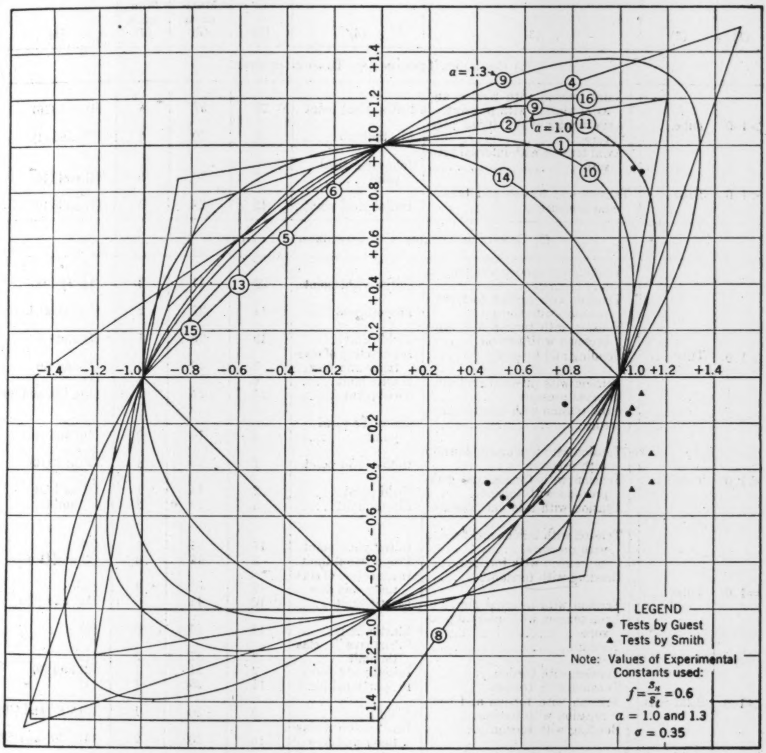

FIG. 19.—COMPARISON OF MEASURED AND THEORETICAL STRENGTH FOR BRASS TUBES.

COMPARISON OF THEORIES AND TESTS

Numerous tests were conducted on specimens of cast iron, steel, copper, and brass, to study the relation between the measured and the theoretical strengths in each case. The specimens were subjected to combined stresses and the results plotted with the corresponding theoretical curve in the manner demonstrated in Fig. 19 for brass tubes. The numerical comparison given in Table 1 is obtained from these plotted results. The percentage values for the discrepancies between the test results and all the theories are approximate. These values for the percentage difference between theoretical and actual

stresses were obtained by arithmetical averages. The values in Column (8), Table 1, are based on these results.

A study of the test data and test procedure shows that in some cases the discrepancies between theories and tests may be due to inaccurate test data. Computations were made showing that the errors in the stresses, due to errors in measurement or errors in the values of experimental constants used, may be appreciable. Another source of error is in the computation of the stresses, s_1 and s_2, from the applied loads and the dimensions of the member.

CONCLUSION

The foregoing comparison shows that no one theory now in use agrees exactly with test results. The precisely correct theory of failure is probably a combination of a number of these theories, depending upon the ratio, $\frac{s_1}{s_2}$. Fig. 19 indicates a number of such cases. Furthermore, there may be several theories equally well supported for one material and the correct theories may vary with the material. Obviously, an ultimate solution will depend on the results of further study in this field.

ACKNOWLEDGMENT

This paper is based in part on a research[8] sponsored by the Engineering Experiment Station, University of Illinois, and the Chicago Bridge and Iron Works. The study was made under the direction of Wilbur M. Wilson, M. Am. Soc. C. E.

[8] Presented as a thesis to the University of Illinois in 1930 in partial fulfillment of the requirements for the degree of Master of Science in Engineering.

APPENDIX

NOTATION

The following symbols have been adopted for use in this paper:

a = major axis of an ellipse; also, a = major yield point stress.
b = breadth; minor axis of an ellipse; also, b = minor yield point stress.
c = a subscript denoting "compression."
f = coefficient of internal friction.
s = unit stress in general; s_L = limiting normal stress; s_1 and s_2 = principal stresses at failure; s_t = stress at failure in simple tension; s_c = stress at failure in simple compression; s_s = unit shearing stress; and s_T = shear stress in torsion.
t = a subscript denoting "simple tension."
x = variable distances measured parallel to the X-axis.
y = deflection; variable distances measured parallel to the Y-axis.
E = modulus of elasticity; Young's modulus; E_s = modulus of elasticity in shear.
L = length; as a subscript, L, denotes "limiting."
M = moment of force.
N = normal component of principal unit stress.
T = a subscript denoting "shearing torsion."
V = volume; ΔV = change in volume.
α = $\tan^{-1} f$.
Δ = "change in."
ξ = energy of distortion on an element subjected to the principal stresses, s_1 and s_2.
σ = Poisson's ratio.
ϕ = angle between planes of stress.

DISCUSSION

J. J. SLADE,[9] JR., ESQ. (by letter).—The interpretation of the results presented by Professor Marin offers some serious difficulties, the principal of which is due to the large radial scatter of the representative points. It is apparent, however, that none of the theories outlined by the author is adequate to represent the phenomenon throughout the range of values of $\frac{s_2}{s_1}$. In noting this the author states (see "Conclusion") that "the precisely correct theory of failure is probably a combination of a number of these theories, depending upon the ratio, $\frac{s_1}{s_2}$."

Assuming a material essentially homogeneous, such as steel, it is not likely that the failure values, s_1 and s_2, of the principal stresses would jump, at some ratio, $\frac{s^2}{s_1}$, from those given by one theory to those given by another; that is, it is more conformable with experience that the transition should be gradual. Such transitions, then, would most likely occur close to the points of intersection of the representative curves. Tracing the various possibilities it is seen that, although one may obtain a locus much closer to the average of the test data than any of those given by the simple theories, still there are serious discrepancies. For instance, near the ratio, $\frac{s^2}{s_1} = 1$, the average of the tests falls between loci of the general shear and the maximum strain-energy theories. These observations do not rule out any of the simple theories presented, however, but only their mathematical form; most of these expressions have been obtained on the assumption that Hooke's stress-strain relation holds, and failure, by any reasonable definition, occurs beyond the linear relation.

In view of this the writer proposes a different approach to the problem. Considering sufficient homogeneity of the material and accuracy of tests to determine the failure point, it will be assumed: (*a*) That there is a law of failure; (*b*) that the curve representing this law is continuous and continuously changing; and (*c*) that, for a given value of the ratio, $\frac{s_2}{s_1}$, the resultant of the principal stresses is single valued. As was stated, Assumption (*b*) is a requirement that conforms with experience. Requirement (*c*) states, in other words, that, if two identical samples are subjected to identical conditions, the values of the principal stresses at failure will be identical for the two. It is important to notice that the test results will not generally be identical, but these results are subject to errors of interpretation and mechanical errors which cannot be avoided. The scatter of the points representing the tests presented by Professor Marin will be considered later.

---

[9] Assoc. Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

In order to develop the present analysis it will be convenient to adopt the polar co-ordinates, ρ and θ, which are connected with the co-ordinates, x and y, by the relations $x = \rho \cos \theta$; and $y = \rho \sin \theta$; or,

$$\rho = \sqrt{x^2 + y^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

and,

$$\theta = \text{arc tan} \left(\frac{y}{x}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

It is thus seen that ρ is the resultant of the principal stresses divided by s_t. For brevity, ρ will be called the resultant and x and y, the principal stresses. In terms of these co-ordinates the law of failure embodying the foregoing three requirements will be given by a functional relation,

$$\rho = F\ (\theta) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

Besides the aforementioned requirements, it is seen that $F(\theta)$ is periodic in θ (this is so by the very nature of the representation of the law; for instance, the value of ρ cannot change by adding 360° to θ). Therefore, $F(\theta)$ is ideally suited to be expanded in a Fourier series:

$$F(\theta) = b_o + \sum_{k=1}^{\infty} a_k \sin k\ \theta + \sum_{k=1}^{\infty} b_k \cos k\ \theta \ldots\ldots (46)$$

With very extensive data the coefficients of this expansion may be determined readily by the method of least squares. A number of the terms of the series may be discarded *a priori* by Requirement (*d*) that the curve must pass through points, ± 1, on the axes, and Requirement (*e*) that the curve must be symmetrical about the two lines, $\theta = \pm 45$ degrees. The number of the remaining terms of the expansion, Equation (46), that may be retained, will depend on the completeness of the available data. In another connection, the writer has discussed the significant flexibility of curves,[10] particularly of curves represented by a series in which the coefficients are adjusted by the method of least squares or related procedures. It is sufficient to state that, depending on the data, there is a point beyond which added terms of the series will give a poorer representation of the function than will be given by the series with these terms omitted. The first two terms of the series, Equation (46), that satisfy Requirements (*d*) and (*e*) are:

$$F(\theta) = 1 + a \sin 2\,\theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

Equation (47) will be tried as a first approximation to the law of failure. There is only the constant, a, to be determined, so that the method of least squares leads to the simple formula:

$$a = \frac{1}{n} \sum_{k=1}^{n} \frac{\rho_k - 1}{\sin 2\,\theta_k} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

---

[10] See p. 94.

for the best value of a. In Equation (48) ρ_k is the resultant of the recorded tests; θ_k, the corresponding angle in the polar representation; and n, the number of items. Equation (45) has been used to substitute ρ for F. To every experimental result there corresponds a definite set of co-ordinates, ρ_k and θ_k, which may be readily obtained from the data made available to the writer by Professor Marin; but instead of computing each term of the series,

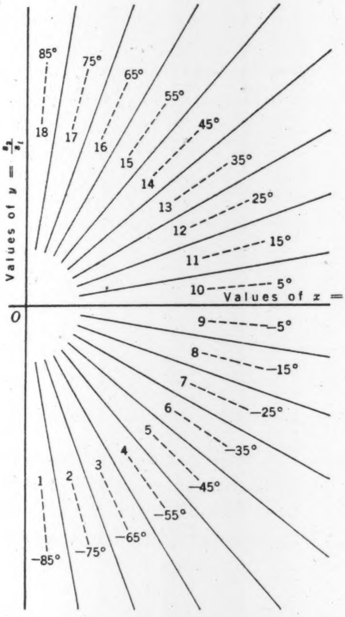

FIG. 20.—CLASS SECTOR DIVISION OF THE STRESS PLANE

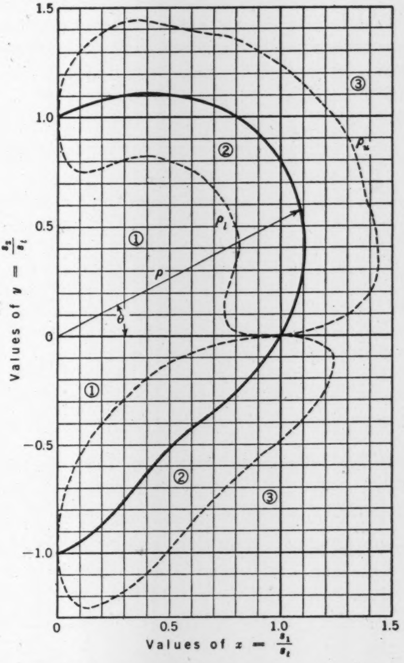

FIG. 21.—FAILURE CURVE WITH REGIONS OF ACCIDENTAL VARIATION

Equation (48), separately, the data will be grouped as follows: The right half of the stress plane (where all the experimental data fall) will be subdivided into eighteen 10° sectors numbered as shown in Fig. 20, and to the points falling within each sector will be assigned the angle of the sector midline, as shown in the same diagram. This subdivision is not only convenient but necessary for the statistical analysis of the problem. The magnitude of the angular opening of the class sectors adopted, has been dictated by personal judgment; it is desirable to make this magnitude small, but if it is made too small, the classes into which the data are thereby grouped will not contain a sufficient number of items with which to compute their statistical elements.

Adopting this class subdivision and inserting the values in Equation (48), obtained from the data on steel tubes presented by Professor Marin (which is the most extensive), the magnitude, 0.278, is obtained for the best value of a. Thus, the best two-term Fourier approximation to the failure law for steel tubes is:

$$\rho = 1 + 0.278 \sin 2\,\theta \quad \text{.....................(49)}$$

Before discussing Equation (49) to determine its meaning as a mathematical expression for the theory of failure under bi-axial stresses, it is well to test its adequacy to represent the given data. For this purpose Table 2 has been constructed. The first column of this table lists the class numbers given in Fig. 20. The second column gives the number of experiments with representative points falling within the corresponding sectors. The third lists the corresponding sector mid-angles, also shown in Fig. 20. The mean resultant of the observed points for each class is given in Column (4). The standard radial deviation was computed for each class about the class mean and the results listed in Column (5), Table 2. Column (6) gives the values of ρ computed for the values of θ listed in Column (3). In Column (7) are listed the differences, Column (4)—Column (6); these, then, are the deviations of the sector means from the failure curve, Equation (49). For every sector, from the number of items in the class and the corresponding standard deviation, the standard error of the mean was computed and the results are listed in Column (8).

In the first place, it should be noted that the deviations from the failure curve of the sector means do not show any marked trend; their distribution is not incompatible with one of a random nature. Now, of the thirteen classes for which the statistical elements can be computed, the deviations from the curve of the means of five of them are less than the standard errors in the mean, and five others come well within three times the standard errors. Of the remaining three, two may be disposed of by the following arguments: In Sector 6, ten of the fourteen items represent experiments by Cook and Robertson, which, it will be noticed, show consistently high values for the resultant—as compared with tests by Scoble, for instance, which show consistently low results. This sector, therefore, is not a fair sample, and the high value of the deviation cannot be given full weight. Sector 16, with a high negative deviation, has only two items, from which a standard deviation of 0.039 was computed. Two items, however, cannot give a fair estimate of the dispersion, which is consistently high for the entire range of tests, averaging 0.091 for the thirteen classes and being 0.107 for Sector 5 which has sixty items. With such high dispersion it is not beyond the bounds of reasonable probability that the average of two experiments, particularly when performed by the same person (Guest), should deviate − 0.120 from the curve. The remaining class, Sector 15 with seven items, might be considered in like manner, but it is quite probable that one in thirteen classes should deviate from the norm by more than three times the standard error. Of the two classes with a single item each (Sectors 2 and 4) one deviates less than the average standard deviation, the other less than three times this deviation—a reasonable variation for single items.

Altogether, this analysis seems to show a high probability that Equation (49) is a close first approximation to the law of failure under bi-axial stresses for steel tubes.

The writer believes that it is important to make explicit recognition of the fact that the scatter of the experimental points is doubtless due more to errors of observation and faults of technique than to variations in the strength of the material, provided, of course, that the strength is kept within certain specification bounds. For the purpose of design it is desirable to set limits to the actual variation in the strength of the material, but there are no data available to the writer from which to make such an estimate. However, a rough estimate of the observational variation limits may be made from the data presented by Professor Marin. In the octant included between Line $\theta = 0°$ and Line $\theta = -45°$, where most of the experimental points fall, the circle of radius = 1 and the center at the point (1, − 1) follows quite well the trend of the lower limit of variation. The equation of this circle referred to the origin is:

$$r = \sin \theta' + \cos \theta' - \sqrt{\sin 2\theta'} \ldots\ldots\ldots\ldots\ldots (50)$$

in which r is the radius vector and θ' equals θ in the fourth quadrant taken with a positive sign. The lower limits of experimental variation from Equation (49) will thus be given, in the fourth quadrant, by,

$$l = \rho - r \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (51)$$

Assuming an essential symmetry in the accidental variations two curves may be constructed in the four quadrants:

$$\rho_1 = \rho - l \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

and,

$$\rho_u = \rho + l \dots\dots\dots\dots\dots\dots\dots\dots (53)$$

where, for all quadrants, l is computed from the fourth quadrant by Equations (50) and (51). The values for the limits of variation thus determined are given in Column (9) of Table 2. Columns (10) and (11) give ordinates of ρ_1 and ρ_u. In Fig. 21 are given the graphs of Equations (49), (52), and (53) in the right half of the stress plane. These loci divide the plane into three regions. Assuming material essentially homogeneous, and reasonably accurate laboratory technique, then one can state that in Region 1 no sample will be found to fail, all samples will be observed to fail somewhere in Region 2, and no samples will be found to persist in Region 3. These limits, no doubt, can be greatly narrowed when more is known regarding the differences between observed results and actual failures. It may be noted that three results of experiments by Becker (Sector 14) fall beyond the tentatively assigned upper limit.

From the available data little can be said about the distribution of failures throughout Region 2; but taking as typical the limits, ±0.315, and a standard deviation of 0.105 (this value, which is close to the average of the standard deviations, is taken so as to make the ratio, $\frac{0.315}{0.105} = 3$, an even number), one may construct a distribution curve from Table 22 of the closing discussion of the writer's paper.[11] From the first section of Table 22, for the symmetric distribution function, for the value, $\lambda = 3$, the quantities listed in Table 3 are obtained.

TABLE 3.—DISTRIBUTION OF OBSERVATIONAL VARIATIONS

Percentage of samples...	1	5	10	15	20	30	40	50	60	70	80	85	90	95	99
Deviation...	—0.233	—0.184	—0.151	—0.126	—0.104	—0.066	—0.031	0.0	0.031	0.066	0.104	0.126	0.151	0.184	0.233

The meaning of Table 3 is that, in testing a large number of samples, 5% of them, for instance, will be observed as weak or weaker than the value given by Equation (49), less 0.184; or, that 70% of samples will be observed as weak or weaker than the value given by Equation (49), plus 0.066.

Fig. 22 shows this distribution function. For comparison the actual distribution is given of the tests in Sector 5 about the class mean. The two are not strictly comparable because neither the means nor the standard deviations coincide; but the comparison is made, nevertheless, to show that, in general, the distribution of observed failures in Region 2 follows that required by theory.

The present statistical analysis of the problem has led to Equation (49) as a first approximation to the law of failure for steel tubes under bi-axial stresses. The available statistics do not warrant a closer approximation, but they seem to give to this equation a high probability of approximating closely the true law. It remains to discuss this law from the point of view of a possible theory of failure that might give rise to it.

---

[11] "An Asymmetric Probability Function", see p. 95 *et seq.*

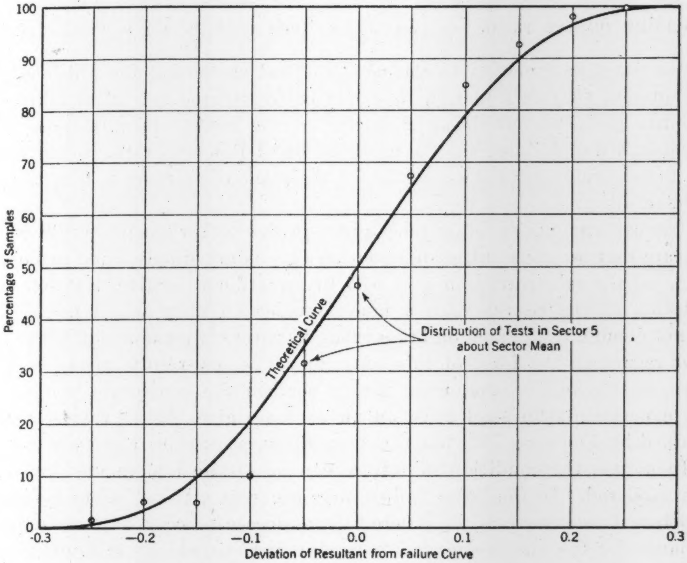

FIG. 22.— DISTRIBUTION OF FAILURES ABOUT FAILURE CURVE

The value, $a = 0.278$, found for the constant of Equation (47) suggests strongly that this constant might be Poisson's ratio; or, perhaps (as will appear subsequently in the discussion of the failure of brass tubes), some function of this ratio. One might indeed expect, *a priori*, to find this important constant included in the law of combined stress failure. Assuming $a = \sigma$ for the moment, and using the relation, $\sin 2\theta = 2 \sin \theta \cos \theta$, and the co-ordinate transformations, Equations (43) and (44), then the law of failure, Equation (49), becomes,

$$\sqrt{x^2 + y^2} = 1 + \frac{2 \sigma x y}{x^2 + y^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

or, more compactly (using the value for ρ given by Equation (43)),

$$x^2 + y^2 - \left(\frac{2\sigma}{\rho}\right) x y = \rho \ldots\ldots\ldots\ldots\ldots\ldots (55)$$

In this form the law is seen to bear a striking resemblance to the expressions for several of the theories presented by the author. Equation (55), in fact, may be considered as the equation of a continuously varying ellipse.

In Sectors 9 and 10 this curve coincides closely with the maximum strain-energy theory, but elsewhere it intersects or parallels the curves representing the other theories and thus does not seem to bear out the author's conjecture that the correct theory may be a combination of several of these theories depending on the ratio, $\frac{y}{x}$. In the writer's opinion the correct theory of failure, an approximation to the mathematical expression for which is given by Equation (49) or Equation (55), can be formulated only after taking into account: (*a*) The non-linear character of the stress-strain relation in the neighborhood of failure; (*b*) the modification of Poisson's ratio in that region; and (*c*) the relation of the direction of the plane of fracture to θ in the polar representation.

The experiments on brass tubes given in the author's paper would seem to indicate that the constant, a, of Equation (49) is not simply equal to Poisson's ratio, for the substitution of $\sigma = 0.35$ in Equation (55) gives a poorer representation of the results than a much smaller quantity would give. There are not enough tests given on brass tubes, however, to make a significant statement regarding the form of this constant. The few results given on copper tubes, on the other hand, more nearly confirm the conjecture that $a = \sigma$. The experiments on steel rods, on an average, give higher values than are obtained by Equation (49) but this is, perhaps, what should be expected.

In a tube the condition of failure can be attained more uniformly than in a solid rod. In the latter failure may occur at a point before failure can be detected experimentally. Where failure does not occur uniformly there is a chance for the phenomenon of "wire-drawing" to add its reinforcing effect to the test rod. In this case Equation (49) would give the first failure, or "point" failure, and whether this can be detected depends on the achievement of very exact laboratory technique. Cast iron presents characteristics of failure that seem to be definitely different from those of the more elastic and homogeneous materials. Experiments on this material show a scatter of the representative points which is smaller than that for tests on steel, so that a few careful experiments that plot in the first quadrant of the stress plane would no doubt give a good indication of the failure characteristics of this material. A negative value of the constant, a, of Equation (47) is necessary to represent the cast-iron data properly, but the law thus determined might not follow through into other quadrants. Another term in the Fourier series may be necessary to approximate closely enough the law of failure for this material, a term which becomes insignificant in the case of the failure of steel tubes. This case illustrates the importance of formulating carefully the correct theory of failure.

In conclusion, the writer wishes to express his appreciation of Professor Marin's work of unifying and presenting this valuable information collected from such wide sources; his paper is a great step toward the correlation of theory with experiment in this interesting branch of mechanics, which marks the way to greater efficiency in design.

T. McLean Jasper,[12] M. Am. Soc. C. E. (by letter).—In discussing the paper by Professor Marin it is well to point out two fundamental differences which might cause confusion in the discussion of theories of failures. It is believed, that the general testing methods adopted to discover the theories of material failure have not been given proper differentiation as between the failure of a structure because of its shape and the failure of a material based on its fundamental strength qualities.

When buckling is introduced into the test sample as a possible method of failure of a structure, it is obvious that failure can occur at values of stress that are much below the elastic limit or yield point of the material. Such a failure depends on the shape and on the elastic properties of the test pieces, rather than on the yield or general break-down of the material.

Examples of structure failure, in which buckling occurs at varying values of stress depending on the relative slenderness of the test samples, are contained in the column problem, the tube collapse problem, and the thin tube torsion problem. Many of the theories of material failure are based on test samples in which buckling, as a method of failure, enters, and the confusion which has associated itself with various theories, as shown in the author's Fig. 19, is largely attributable to lack of appreciation of this fact. The writer's experience with testing has brought to light failure of slender steel columns at less than one-third the yield strength of the material. The slender tube has collapsed at less than one-third the yield strength of the steel, and the slender torsion tube has collapsed at less than two-thirds of the torsional yield strength of the steel. In each case as the slenderness of the test sample has been reduced, the failure point of the various aforementioned structures has increased progressively.

Many of the experimenters have applied as experimental test samples one or more of the aforementioned methods which are associated with this buckling and as different investigators have varied the relative slenderness of test shapes, they do not check even within large percentages with each other.

A good example of what the writer wishes to convey is contained in the experimental work of Guest,[13] who is responsible for the maximum shear theory of failure. The record of his work shows that great care was taken in his experimentation, and since it was recorded in such detail, it allows a careful study of the test procedure. In his experimental work, Guest used thin cylinders and performed as many as twenty tests on a single test sample. He used a combination of torsion, internal pressure, and tension or compression, or various combinations of these testing methods. In certain cases, he repeated the combinations of stress application more than once on a single test sample. For instance, the first test might be that of simple shear, and after various other tests were made on the same sample, he again resorted to simple shear. Invariably, when he repeated identical tests on the same sample he obtained the same results.

The point the writer wishes to make is this; Since his standard of measurement depended on the stress-strain diagram and the deviation from proportionality, it is obvious, that if this point is exceeded in terms of yielding of the metal, then with each test a new yield point is established. If, on the other hand, elastic buckling only is responsible for the phenomena, the limit of proportionality of the structure can be exceeded without interfering with the yield of the metal and such elastic buckling will repeat itself indefinitely. If Guest had changed the slenderness of his test sample appreciably, he would have obtained quite different results.

---

[12] Research Dept., A. O. Smith Corporation, Milwaukee, Wis.

[13] "On the Strength of Ductile Materials under Combined Stress", by J. J. Guest, *Philosophical Magazine*, July, 1900, p. 69.

There is exceeding good evidence that elastic structures fail very nearly according to the mathematical theory of elasticity, especially in the zone in which the elastic properties of the materials impose the controlling factor. The failure of materials, such as separation into two parts can occur only in tension or in shear according to the strict interpretation of these terms. The writer has obtained fatigue fractures from different samples of the same bar of steel which occurred separately as tension and as shear.

It is very probable, that neither the maximum shear theory nor the maximum stress theory can explain the break-down of the steel or other materials in bi-axial or tri-axial loading. The writer leans toward the idea that some form of maximum energy will yield the most reliable answer to the problem of the theory of failure of a material.

This discussion is not presented with the idea that the answer to the problem of material failure is known definitely. The method of determining the answer must be disassociated from buckling. It is possible that different materials may yield to different solutions; for instance, glass probably will produce a different result than steel. Steel will possibly have a different solution than aluminum. On the other hand, the failure of structures has yielded to consistent ideas, so that the service problem of the application of materials has not suffered because the various theories of material failure do not coincide.

I. K. SILVERMAN,[14] JUN. AM. SOC. C. E. (by letter).—The conditions causing plasticity have been of great interest not only to physicists but also to engineers, since the limiting states of stress are intimately bound up with working stresses and factors of safety.[15] Civil engineers use the Rankine or maximum stress theory almost exclusively, whereas mechanical engineers favor the maximum shear theory, especially for ductile materials.

The author lists sixteen theories. The best known of these are Theories (1), (4), (7) to (11), (14), and (16). Theory (5) reduces to that of Theory (7); Theory (12) reduces to Theories (10) and (11); and, Theories (6), (13), (14), and (15) seem to have very little experimental support. By comparing the hypotheses of Theories (11) and (13) it is seen that the fundamental ideas thus expressed are diametrically opposed. The statement of Theory (11) is based upon the experimental fact that materials can withstand large hydrostatic pressures without failing. What is the basis for the statement expressed in Theory (13)?

[15] "Factor of Safety and Working Stress," by C. R. Soderberg, *Transactions*, Am. Soc. Mech. Engrs., APM 52-2.

These various theories can be compared by examining the case of pure shear, in which $s_1 = -s_2$, and from which a relation between the yield stress in shear and that in uni-axial stress may be obtained. Writing this relation as,

$$s_T = k\ s_t \text{ ....} (56)$$

the values of k for the various theories mentioned by the author, are given in Table 4.

TABLE 4.—COMPARISON OF k-VALUES

Theory No. (1)	Special condition (2)	Value of constant, k (3)	Theory No. (1)	Special condition (2)	Value of constant, k (3)	Theory No. (1)	Special condition (2)	Value of constant, k (3)

Experiments by Becker[16] have shown that k is approximately 0.6, and that, apparently, for the state of stress expressed by $s_1 = s_2$ failure occurs when $s_1 = s_2 = 1.2\,s_t$. This value may have been influenced by the fact that the tests were not purely bi-axial. More recent experiments[17] seem to support the theory of Huber-Hencky-von Mises.

W. P. ROOP,[18] M. AM. SOC. C. E. (by letter).—The need for a "failure theory" is not immediately apparent; it is a rather naive but widespread idea that a safety factor, taken as the ratio of ultimate to working stress, represents the margin provided to prevent failure in spite of the designer's mistakes. In point of fact "there is a considerable number of variables outside of magnitude of stress, involved in the problem of strength"[19]; the burden thrown on the safety factor by uncertainty as to what determines failure under combined stresses is not responsible for a large share of the margins of strength found necessary.

Nevertheless, some sort of criterion by which to allow for combination of stress is necessary, and as the other variables in the problem of strength are subjected to more searching analysis, it is right that this one should also be re-examined. For this purpose sixteen different theories are reduced to forms suitable for comparison, both analytical and graphical. It is understood that the curves shown represent boundaries beyond which plotted points indicate failure. Although it is not clearly so stated, it is understood furthermore, that the co-ordinate of these points are the relative values of the principal stresses. Each such point thus represents a certain proportion between the two principal stresses, the scales being such that the ultimate strengths in simple tension and compression are correctly indicated, so that all curves (except that for Theory (8)) pass through all the four points $x = \pm 1$, $y = \pm 1$.

It appears in Table 1 that "failure" may mean anything from rupture to exceeding the proportional limit. In the graphic study, these differences are ignored and only the effect of combining stresses is considered, with no reference to characteristics of the material.

The stress at a point in a homogeneous elastic medium is a condition that can be specified exactly, regardless of the combination of loads, each with its contribution to stress, by which the actual result is produced. The real questions thus appear to be: (*a*) Considering the stress at the point at which "failure" begins, what feature of the stress is it that determines the failure; or, in a word, what constitutes equivalence of stresses in causing failure? and (*b*) in strength calculations involving combined loads, how shall the effective feature of the resultant stress be estimated?

Fig. 19 indicates that the graphs generally agree in showing an elongation along the axis of half past one. Does this mean that a combination of principal stresses of the same sign is more easily withstood than a combination of opposite signs? If so, that would confirm the idea that somehow shear plays a special part in causing failure.

It appears that no more definite conclusion than this is possible from the data presented, since the spots in Fig. 19 and the data in Columns (6) and (7), of Table 1, show that the spread of observations exceeds the differences between the theories.

H. F. MOORE,[20] ESQ. (by letter).—An interesting summary of the present-day knowledge of theories of failure of materials subjected to combined stress, is presented in this paper. Table 1 is a very convenient statistical summary of the evidence. It is to be noted that, with the exception of the tests with solid cast-iron rods under combined tension and compression (at right angles), Professor Marin has used the criterion of elastic strength in all cases. He quotes the strength of a tube of cast iron as judged by "yield point". This reporting of a yield point in cast iron would seem to call for further explanation, as cast iron ordinarily does not have a yield point. At first sight, the various criteria used for elastic failure would rather confuse the evaluation of results, but a closer examination shows that for each comparison of theory with experimental results the same criterion is used, so that tests may be compared fairly satisfactorily. It would be of interest if Professor Marin had given references for the particular experiments in each case listed in Table 1; in fact his paper would be distinctly more valuable if references to original sources of data were given more fully.

---

[20] Research Prof. of Eng. Materials, Univ. of Illinois, Urbana, Ill.

Two points are not covered by the paper. The first is the failure of materials by other than elastic failure. Professor Marin has, indeed, quoted tests on cast iron in which theory was judged by the strength at fracture. These tests seem to indicate that the maximum strain theory fitted test results more closely than the other theories. This result is checked by tests obtained by Matsumura and Hamabe[21] on tests of cast iron under combined bending and torsion. In the 1933 Marburg Lecture before the American Society for Testing Materials, Dr. H. J. Gough, of the British National Physical Laboratory, quoted fatigue tests of mild steel under combined stresses[22] which indicated that, using fatigue fracture as a criterion of strength, the maximum shear strain-energy theory (Theory (11) in the paper) fitted results best; and the maximum shear theory (Theory (7), in the paper) showed fairly close agreement with test results and was slightly on the "safe" side. It is quite possible that different theories hold for ductile and for brittle materials, and also for failure by fracture as opposed to failure by plastic action. This raises the question of failure by continued flow or creep, which has become important at high temperatures. No data on creep under combined stresses are available, so far as the writer knows.

Another point not covered by Professor Marin is the question of failure by "tri-axial" stress, especially a failure under equal tensile stresses along three axes of reference. So far, no effective experimental study of this phenomenon has been made. Under equal tensile stresses in three directions the shearing stress in a metal would be zero, and it is a matter of dispute whether this would strengthen the metal by preventing shearing failure, or weaken it by inhibiting the occurrence of slight localized plastic action which usually is found in metals even under light stresses, and which tends to reduce the "peaks" of localized stress which, without this plastic action, would be developed on minute areas. The writer does not know any more intriguing problem than the study of this "triple tension", which has been discussed so vigorously by Professor B. P. Haigh, of the Greenwich Naval Academy Laboratories, at Greenwich, England.

A. A. Eremin,[23] Assoc. M. Am. Soc. C. E. (by letter).—Tests of materials are not sufficient on which to base conclusions as to the validity of the theories of failure treated in this paper. Under "Conclusions", Professor Marin states that, "the precisely correct theory of failure is probably a combination of a number of these theories, depending upon the ratio, $\frac{s_1}{s_2}$".

Each theory with its basic assumptions and limitations has its individual historical and practical value. The theory of the strength of materials has always been a favorite subject of scientific research among mathematicians. In the first part of the Seventeenth Century the theories of elasticity were based on empirical values of either twenty-one or fifteen unknown constants.

Discussion of some of these theories continues to the present.[24] Theorists and mathematicians have contributed numerous equations for computing ultimate forces sustained by various elastic members. It is an imposing task to apply some of these equations and theories in practice. The Euler formula for a column sustaining direct force was considered erroneous for a number of years. Only recently have the practical limitations of Euler's equations been understood. His equations have found wide application in the theory of the strength of materials.[25]

An interesting practical application of the theory of maximum shear stress failure has been made by Professor J. Fritsche.[26] He has developed the equations for computing the relation between direct stresses in a concrete test prism and ultimate stresses in concrete under combined stresses. Furthermore, in the equations for computing the limiting stresses in concrete, Professor Fritsche introduced an exponential expression for variation of strain and stresses in concrete. However, as stated[27] correctly by the late George F. Swain, Past-President and Hon. M. Am. Soc. C. E., no one has yet proposed a reliable instrument for measuring the variation in stresses in material sustaining combined forces in space in such a manner as to verify the theories of failure.

A. FLORIS,[28] ESQ. (by letter).—The critical examination of the existing theories of failure advanced by various investigators, and their correlation by means of a common set of co-ordinate axes, is the subject of this interesting paper. To the theories of failure treated, the writer wishes to add one more, proposed by Professor G. D. Sandel.[29]

The change in shape of a body under the influence of external forces, caused by the change in position of its particles relative to each other, can be considered as the measure of ultimate strength of the material. Consequently, the deformation of a body is determined by the slip of its particles along principal shearing planes and also by its volume change. The theory proposed by Sandel is based upon this reasoning. It is identical with the maximum shear theory when the influence of the intermediate principal normal stress is equal to zero. In general, however, this influence can be explained only if it is assumed that the volume change contributes also to the rupture of the material. At the limiting state of stress, therefore, the greatest sliding reaches a limiting value which afterward decreases linearly with the positive volume change (increase) of the body. Evidently, Sandel's theory of failure is a generalized maximum shear theory.

In the case of a bi-axial state of stress and with the author's notation, Sandel's theory of failure is expressed by,

$$(n + 1)\, s_1 + (n - 1)\, s_2 = 2\, s_s \ldots\ldots\ldots\ldots\ldots (57)$$

in which, s_s is the shearing stress at failure; and $n = \frac{s_c - s_t}{s_c + s_t}$ denotes the degree of brittleness of the material. For structural steel, $n = 0.04$; for cast iron, $n = 0.60$; and for concrete, $n = 0.88$.

For $n = 0$, Equation (57) expresses the maximum shear theory and for $n = 1$, the maximum stress theory of failure.

The bi-axial state of stress is easily extended to that of tri-axial stress by adding the term, $n\, s_3$ of the intermediate principal normal stress to the left-hand side of Equation (57).

The author is to be commended for bringing this important subject to the attention of engineers who, in practice, are accustomed to deal with allowable stresses.

Joseph Marin,[30] Jun. Am. Soc. C. E. (by letter).—The interpretation of the test results for materials subjected to combined stresses as given by Professor Slade offers an interesting method of attack. It is essentially the same as the method used in the modified Mohr theory (Theory (9)), since in both cases an average value of the test results is used. As might be expected, both these semi-empirical methods give approximately the same results. It is apparent that Professor Slade's interpretation is more flexible and basic in its application. However, the usefulness of his method in this particular problem, is reduced in view of the new data presented in this closure.

Mr. Jasper has revealed a significant factor in referring to the error introduced in some experiments due to a buckling type of failure. This danger, however, can be avoided by a preliminary analysis in which the size of the specimen can be determined in such a manner that failure by buckling is avoided.

The writer wishes to thank Mr. Silverman for referring to the work of Lode and that of Ros and Eichinger. Later work by these investigators has been reported.[31] In addition, the recent experimental work of Taylor and Quinney[32] should be mentioned. A further study by the writer, of the experimental results obtained by these investigators and others, shows that for ductile metals the maximum shear energy theory (Theory (11)) gives decidedly the best agreement with the experimental results, whereas, for a brittle material, such as cast iron, the few test results available show that the maximum stress theory agrees best with the experiment. The basis for the formulation of the maximum volume energy theory as requested by Mr. Silverman, is that failure in the case of an element subjected to combined stresses is assumed when these stresses have reached such values that the volume change produced as a result of deformation reaches the value of the volume change produced in the case of simple tension at failure.

H. in Zurich, Versuche zur Klarung der Frage der Bruchgefahr", by M. Ros and A. Eichinger, *Diskussionsbericht*, Nr. 28 (1928) and Nr. 34 (1929).

[32] "Plastic Distortion of Metals", by G. I. Taylor and H. Quinney, *Philosophical Transactions*, Royal Soc. of London, Series A, Vol. 23, 1931, p. 323.

The writer does not understand the statement made by Lieut. Comdr. Roop that "the need for a 'failure theory' is not immediately apparent." The ultimate strengths in simple stress are not always denoted by the points, $x = \pm 1$, $y = \pm 1$. It is the practice usually to define failure for a ductile material such as steel by the lower yield point (if such exists), or a proof stress, while for a brittle material such as cast iron it is the practice to use the ultimate stress. The more definite conclusion requested by Lieut. Comdr. Roop is given in the foregoing paragraphs.

Professor Moore mentions the tests on cast iron subjected to combined stresses made by Matsumura and Hamabe as supporting the maximum strain theory. However, tests on cast iron subjected to combined stresses made by Ros and Eichinger[31] and others made by Cook and Robertson[33] show that the maximum stress theory is in closer agreement with the test results. Regarding fluctuating stresses, tests by Gough[34] more recent than those mentioned by Professor Moore verify that, for the two kinds of steel tested, the maximum shear energy theory is a good approximation. The writer agrees with Professor Moore that there is sufficient evidence to show that different theories hold for ductile and brittle materials. Some recent work has been done on the subject of creep under combined stresses, both experimentally and analytically, principally by Bailey.[35]

The problem of the failure of materials subjected to tri-axial static stresses was intentionally omitted from the paper in order to present first the simplest case. In answer to Professor Moore's comment about tri-axial stresses, the researches of von Kármán[36] and Boker[37] on brittle materials, and more recently that of Cook[38] on steel, should be mentioned. There are apparently many problems yet to be investigated regarding the failure of materials subjected to static and fluctuating combined stresses at both normal and elevated temperatures.

ADAPTATION OF VENTURI FLUMES TO FLOW MEASUREMENTS IN CONDUITS

By Harold K. Palmer[1], M. Am. Soc. C. E., and Fred D. Bowlus[2], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. N. F. Hopkins, Hunter Rouse, F. V. A. E. Engel, J. C. Stevens, Filippo Arredi, and Harold K. Palmer and Fred D. Bowlus.

Synopsis

A weir can be considered as a control section through which water flows at critical depth. The sharp angle at the face and the fact that the flow is convex where it passes the critical section introduce energy losses between the point of measurement and the control section, the amount of these losses depending upon the setting of the weir in the channel. The ordinary weir formula is an empirical equation that is accurate only as long as the fundamental conditions upon which it was developed can be duplicated. These conditions can rarely be complied with in a confined channel, such as a sewer or an irrigation canal.

This paper presents the theoretical hydraulic principles involved, and the results of special tests made, in the adaptation and construction of various Venturi flumes for measuring flow in conduits of uniform cross-section, where weirs have proved unsatisfactory.

Since the uncertainties or variations in weir coefficients are due to indeterminable energy losses, it is reasonable to suppose that if these losses can be eliminated or reduced to a negligible amount by the use of some other device, the uncertainties in the rating curve will be eliminated. Such conditions are found in the so-called Venturi flume which, in this paper, includes any streamlined device placed in an open channel, or a closed channel partly full, having a sufficient constriction to cause water to flow at critical depth with parallel filaments.

Note.—Published in September, 1935, *Proceedings*.

[1] Chf. Draftsman, Los Angeles County Sanitation Dists., Los Angeles, Calif.

[2] Res. Engr., Los Angeles County Sanitation Dist. No. 2, Whittier, Calif.

Any shape of throat may be used, and the flow can be determined from a single depth measurement, using a rating curve drawn from rational formulas. Several of these Venturi flumes have been constructed, including one that was simply a flat slab on the bottom, and had no side contractions; one that was rectangular in cross-section; and several with trapezodial-shaped throats, all of which have given good results.

The writers show how the rating curve may be drawn, and give graphs for use with circular conduits.

Introduction

Weirs have long been considered the standard devices for measuring running water, but their use involves empirical formulas, and they must be built under restricted conditions, unattainable in many classes of conduits. The ponding effect of the water up stream from the weir causes deposits of suspended matter which often alter the hydraulic conditions so that the empirical formula fails to give the correct flow. In the case of sewers, sludge deposited in this manner will decompose in time and become an added source of trouble. Another objection to the use of weirs in a closed conduit is the relatively large loss of head.

Many factors affect the proper installation of weirs as shown by Schoder and Turner[3] in an able discussion of precise weir measurements. The United States Bureau of Reclamation has found from experiments[4] that the ordinary sharp-crested Cipolletti or rectangular type of weir must have certain very definite requirements for a fair degree of accuracy; for instance, the distances from the bottom and sides of the channel to the edges of the weir must not be less than twice the depth of water over the weir, and the channel above the weir for a distance of 20 or 30 ft must have a cross-sectional area at least six times that of the over-flowing sheet of water at the weir crest. When the depth of the water passing over a weir exceeds three-tenths of its width, the engineers of the Reclamation Bureau have found that the standard formulas indicate quantities that are too small. The error ranges from zero at three-tenths to 30% when the depth equals its width. These restrictions limit the capacity of the weir to about 40% of the capacity of a closed conduit.

Occasionally, the true Venturi flume has been used to advantage because it gives a minimum of ponding and the frictional losses, being small, result in little loss of head. However, it has the disadvantage of requiring the measurement of the area of cross-section as well as the velocity of the water flowing in the throat. This has only been possible in the past by making two simultaneous depth measurements.

Use of the Parshall meter,[5] which is one form of a Venturi flume, obviates some of the difficulties previously mentioned, but it is not readily installed in conduits already constructed because of the required 3-in. drop in the invert grade at the throat. It could scarcely be adapted to an existing, standard sewer manhole, say, 4 ft in diameter. In the design of a new system of conduits for which the desired points of flow determinations might be predetermined and a few inches of grade sacrificed, Parshall meters could be (and have been) installed to advantage. They have certain disadvantages in the continuous measurement of sewage, requiring daily inspection when a week or more of record is required, because the orifice between the channel and the wet-well often becomes clogged and the formation of sludge after a day or two in the wet-well tends to raise the float, thereby causing an error in the stage recorder reading.

---

[3] "Precise Weir Measurements," by E. W. Schoder, M. Am. Soc. C. E., and the late Kenneth B. Turner, Esq., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 999.

[4] "Measurement of Irrigation Water", U. S. Dept. of Interior, Bureau of Reclamation. Third Edition, 1925.

[5] "The Improved Venturi Flume", by R. L. Parshall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 841.

Ordinary Venturi tubes may also be used for liquid flow measurement, but larger structures are required for their installation. Such a tube must be entirely submerged and in sewers this is likely to prevent the proper handling of light floating material. Its efficiency is often impaired by clogging of the pressure recording pipes and, including the recorders, the initial installation is more costly than the weir and stage recorder units.

In 1920, Hinds[6] suggested placing a sufficient constriction in a channel to cause the water to flow at critical depth, on the assumption that in this case the energy head is fixed, whereas the depth is uncertain. He presented experiments made by the U. S. Bureau of Reclamation,[7] on a flume similar in many respects to one type considered by the writers and showed an error of less than 5% in measurement of flow, assuming no transition losses.

The following analysis of the adaptation of the Venturi flume to flow measurements in conduits of regular cross-section is applicable not only to clear water, but also to any liquid carrying suspended matter. Among the latter are included silt-laden irrigation water, storm water, and sewage. The investigations herein reported were made in connection with a sanitary sewerage system and as sewage presents most of the difficulties encountered in the other classes of water, the word, "sewage," will be used subsequently to denote water that carries settleable solids.

In passing, it may be stated that an accurate measurement of sewage flows in various parts of a sewerage system is quite important in order to be able to predict with reasonable accuracy the need of future works, relief sewers, additional pump capacity where pumping is required, etc. In joint sewerage works an accurate measurement of sewage is necessary to apportion costs to respective participants. Furthermore, as a check on pumping efficiency and power requirements, knowledge of the actual sewage flow is necessary. An accurate gauge of the flow is required for efficient and economical operation, where pre-chlorination[8] is practiced since the chlorine feed depends on both the strength and the quantity of the sewage. One difficulty encountered in an accurate measurement of sewage flow in new sewerage works is the fact that a sewer is usually constructed of a greater capacity than is required at the time it is first placed in operation. The flow in the line is then relatively shallow. Furthermore, in a new system of any large extent, the increase in sewage from month to month or year to year is relatively large and many measuring devices which might be satisfactory at one time would prove totally inadequate at a later date. Sewage flows range from a minimum in the early morning to a maximum of as much as two or three times the minimum amount later in the day; it will also vary from day to day, and any meter used for the purpose must be adaptable to such variations.

[7] "The Improved Venturi Flume", by R. L. Parshall, Assoc. M. Am. Soc. C. E., discussion by Julian Hinds, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 864.

[8] "Control of Sewage Condition by Chlorination", by F. D. Bowlus, and A. P. Banta, Assoc. Members, Am. Soc. C. E., *Water Works and Sewerage*, November, 1932, Vol. 79, p. 369.

Difficulties encountered with ordinary weirs and other similar devices in the measurement of sewage indicate that the most satisfactory meter would incorporate the use of a stream-lined flume, with minimum head loss, preventing deposits of sludge above it; without sharp edges to catch rags and other floating refuse; and with sufficient capacity to measure the entire designed flow and yet be sensitive enough to record low flows in the first years of its use. The flume must be adaptable to the use of a simple float mechanism for water-stage recording, and must be designed so as to be readily installed in an existing conduit with minimum interference to the sewage flow. This paper deals with a measuring flume designed so that the flow may pass without objectionable ponding up stream; which offers no obstruction to floating or suspended solids; and which affords an opportunity to measure the flow from a continuous record of the water-surface elevation at a single point in the channel up stream from the flume.

The formulas developed for the flume are not empirical but are based entirely on theory and can be applied to conduits of any regular size or shape. Irregular channels would require regulation for a short distance up stream by lining of some kind. Uniformity of shape rather than factors affecting friction are important. The method has been developed especially for sewers, but is equally applicable to other channels, irrigation canals, storm drains, etc.

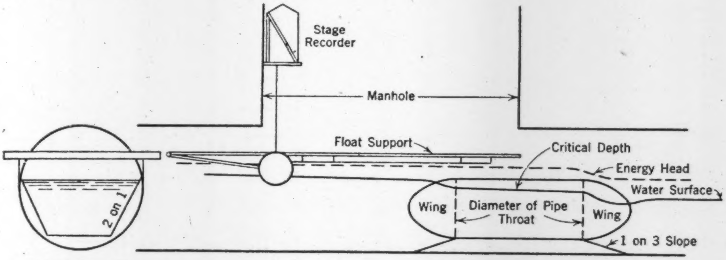
NOTATION

The symbols introduced in this paper are defined as follows:

b = a bottom width.
c = a subscript denoting "a critical depth."
d = depth of flow.
f = "function of."
g = acceleration due to gravity.
n = Kutter's coefficient of roughness.
v = a subscript denoting "velocity."
A = area.
B = surface width; width of water surface.
C = Chezy's coefficient.
D = diameter.
H = head; H_v = velocity head.
K = a constant in Kutter's formula = $A\,C\,\sqrt{R}$.
Q = rate of flow, or discharge.
R = hydraulic radius.
S = hydraulic slope; slope of a conduit, expressed as a percentage.
V = average velocity in a section.
Δ = "difference in;" ΔH_v = difference in velocity heads in throat and conduit.
ϵ = energy head; ϵ_c = energy head at critical depth.
ϕ = "function of."

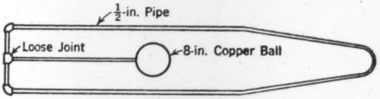
THEORY OF DESIGN

According to Bernoulli's theorem, the energy head of each pound of water in a conduit is the height of the water surface above a given datum plane, plus the velocity head. In passing from one section of a conduit to another, frictional and other losses are measured by the decrease in the total energy head regardless of changes in depths and velocities at the two places. Therefore, measurement of the total energy head is the logical basis for the development of any theory in the design of a Venturi flume of the general type illustrated in Fig. 1.



(a) SECTION AT CENTER OF THROAT

(b) LONGITUDINAL SECTION OF METER IN 24-IN. PIPE



(c) PLAN OF FLOAT SUPPORT

FIG. 1.

Under certain conditions a calculation of the flow may be made by simply measuring the depth of the water flowing in a conduit of regular cross-section at any convenient point immediately above the throat of the measuring flume. This is only possible when the throat is designed to cause the water to flow through it at critical depth. For any given quantity of water, and size and shape of conduit, Fig. 2 shows that the energy head has a minimum value when the water is flowing at critical depth in the throat. For a given channel this critical depth is a function of the quantity of water, and attempts have been made by Woodburn[9] to use a broad-crested weir as a measuring device recording the critical depth. However, in this case, it was found impossible to locate the section of critical depth accurately as it changed position with different quantities of flow. Near the section of critical depth in the throat of the Venturi flume, the depth is uncertain, but the energy head is fixed; therefore, if the throat is designed so as to cause the water to flow at critical depth the depth in the conduit of the regular cross-section above will be the average energy head less the velocity head at that point, except for frictional losses, which will be discussed subsequently.

---

[9] "Tests of Broad-Crested Weirs", by James G. Woodburn, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 387.

The proposed method of measurement is best illustrated by reference to Fig. 2. For simplicity, consider that a rectangular conduit is contracted on the sides only, forming a rectangular throat one-half the width of the conduit.

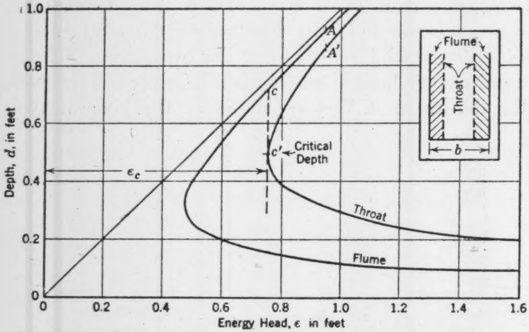


FIG. 2.—ENERGY HEAD CURVES IN A VENTURI FLUME.

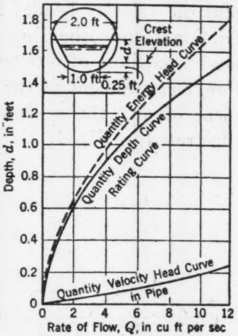

FIG. 3.—DERIVATION OF RATING CURVE, VENTURI FLUME.

For any given quantity of water, according to Bernoulli's theorem,

$$\epsilon = d + \frac{V^2}{2g} \quad \text{(1)}$$

in which ϵ = energy head; d = depth of flow; V = average velocity in a section; and g = acceleration due to gravity.

Since $V = \frac{Q}{A}$,

$$\epsilon = d + \left(\frac{Q}{A}\right)^2 \frac{1}{2g} \quad \text{(2)}$$

in which Q = rate of discharge; and A = area of cross-section. For a rectangular cross-section:

$$A = bd \quad \text{(3a)}$$

$$V = \frac{Q}{bd} \quad \text{(3b)}$$

and,

$$\epsilon = d + \left(\frac{Q}{bd}\right)^2 \frac{1}{2g} \quad \text{(4)}$$

in which b = the bottom width of a channel; and ϵ and d are the variables. In Fig. 2, the curves represent Equation (4) for the conduit and throat, respectively, Q being the same in both cases. Neglecting frictional losses there would be no loss of energy in or through the Venturi flume, and if Q cu ft per sec flowed at a depth, A, in the conduit, it would flow at a depth, A', in the throat. Theoretically, Q could be determined by measuring these two depths, A and A'. The necessity in the past for the two measurements has been an inconvenience in the use of the Venturi flume. If Q, in cubic feet per second, flowed at the critical depth in the throat (Point C'), its depth in the conduit would be represented by Point C which would be its minimum depth above the throat, because for shallower depths the energy is insufficient to force Q through the throat.

By drawing similar pairs of curves for other values of Q, a rating curve showing the relationship between Q and d could be drawn, but in practice this requires an unnecessary amount of labor.

For a given size and shape of throat, the value of ϵ_c is a definite function of Q, or to write the inverse case:

$$Q = f(\epsilon_c) \dots\dots (5)$$

When ϵ and Q are known, H_v in the conduit can be found by trial, and subtracting this H_v from ϵ gives d (Fig. 3).

For rectangular throats, Equation (5) takes a simple form which will be evaluated from the general formula, but for other throat shapes, this becomes a transcendental function too complicated to be considered, and it is easier to compute a few points on the curve and prepare the rating curve graphically. It has been found from practice in computing these points that the best procedure is to assume various critical depths in the throat and compute Q and ϵ by the following formulas:

At critical depth, $\frac{d\epsilon}{dd} = 0$; differentiating Equation (2):

$$\frac{d\epsilon}{dd} = 1 - \frac{Q^2}{g} \times \frac{1}{A^3} + \frac{dA}{dd} \dots\dots (6)$$

Equating this formula to zero, and substituting B for its equivalent[10], $\frac{dA}{dd}$, Equation (6) becomes:

$$1 - \frac{Q^2}{g} \times \frac{B}{A^3} = 0 \dots\dots (7)$$

and, therefore,

$$Q = A \sqrt{\frac{A}{B} g} \dots\dots (8)$$

Equation (8) is the accepted formula for the quantity flowing at a critical depth in a channel of any shape. Since $Q = A\,V$, by substituting the value of Q in Equation (8):

$$\frac{V^2}{2g} = \frac{A}{2B} \dots\dots (9)$$

and Bernoulli's equation becomes,

$$\epsilon = d_c + \frac{A}{2B} \dots\dots (10)$$

---

[10] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., p. 31, Equation (19).

In a rectangular throat in which $A = B\,d_c$, Equation (8) becomes,

$$Q = B\sqrt{g}\,d_c^{\frac{3}{2}} \quad \text{(11)}$$

$$\frac{V^2}{2g} = \frac{d_c}{2} \quad \text{(12)}$$

and,

$$\epsilon = \frac{3}{2}\,d_c \quad \text{(13)}$$

Substituting the value of d_c obtained from Equation (13) in Equation (11):

$$Q = 3.09\,B\,\epsilon^{\frac{3}{2}} \quad \text{(14)}$$

which is the form taken by Equation (5) for a rectangular throat. For all other shapes it is necessary to use Equations (8) and (10).

Having drawn the quantity-energy head curve for a given throat (see Fig. 3), it is necessary to compute and draw the quantity-velocity head curve for the conduit section. If the conduit is circular this may be done by means of Fig. 4, which gives for various depths the velocity and velocity head for 1 cu ft per sec on a logarithmic scale, and, for other quantities, by merely adding log Q graphically. The intersection of the velocity abscissa with the "guide" line falls on the ordinate of the velocity head. The procedure is best

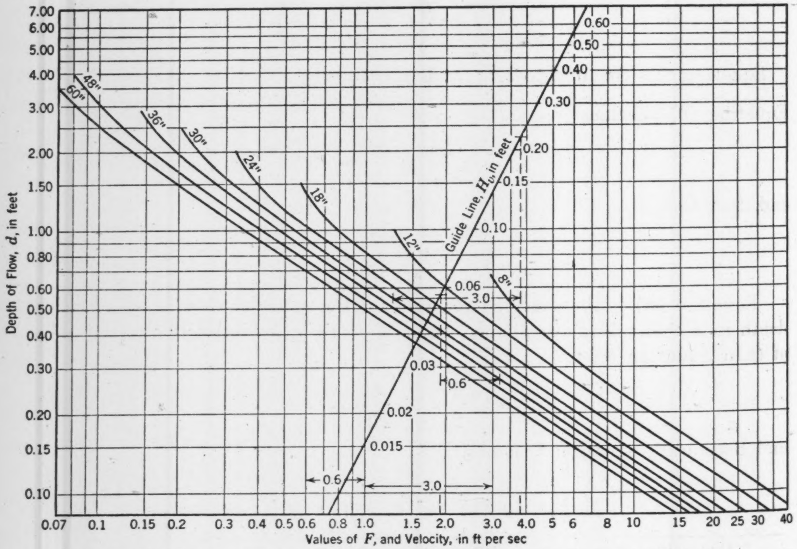

FIG. 4.—VELOCITY IN PIPES WITH WATER FLOWING AT VARIOUS DEPTHS.

explained by two examples: First, when $Q > 1$; and, second, when $Q < 1$. For example, let $Q = 3$ cu ft per sec with water flowing 0.55 ft deep in a 30-in. pipe. Set a pair of dividers to the distance from 1 to 3 and measure this distance to the right from the intersection of the 30-in. pipe with $d = 0.55$ ft, giving $v = 3.8$ ft per sec. The vertical line for $v = 3.8$ intersects the "guide line" at $H_v = 0.225$. In the second case let $Q = 0.6$ cu ft per sec, with water flowing 0.27 ft deep in a 36-in. pipe. Set the dividers for the distance 1.0 to the left to 0.6 and measure this distance to the left from the intersection of the 36-in. pipe with the $d = 0.27$ horizontal line, finding $v = 1.86$ ft per sec. The vertical line for $v = 1.86$ intersects the guide line at $H_v = 0.056$ ft.

To find the velocity head for any value of Q, first assume an approximate value of the velocity head, subtract it from the quantity-energy head, and note the assumed depth. Enter Fig. 4 with these values of Q and d and read the velocity head. If this differs materially from the assumed value, a second approximation should be made. To draw the velocity-head curve it is obviously better to begin with a small value of Q because the error in the assumed value of the velocity head is correspondingly small and one or two approximations are usually sufficient. It will be found that only a few points are required to draw in the quantity-velocity head curve. Ordinates on the quantity-depth curve are merely the differences between the ordinates of the quantity-energy head curve and the quantity-velocity head curve. This quantity-depth curve is the required rating curve.

As an illustration of the method of computing a rating curve, consider a Venturi flume with trapezodial throat cross-section as in Fig. 1(*a*), 12 in. wide at the base with side slopes of 2 on 1 and a flat slab base 3 in. above the invert of a 24-in. pipe. All measurements are in feet and quantities in cubic feet per second. As previously recommended, various critical depths will be assumed and Q and ϵ computed. In this case the formulas for the cross-sectional area and water-surface width in the throat are:

$$A = \left(1 + \frac{d_c}{2}\right) d_c \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

and,

$$B = 1 + d_c \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The computations for energy heads are arranged in Table 1. In computing the velocity heads (see Table 2), it must be remembered that the crest of the throat is 0.25 ft above the invert; hence, the depth in the conduit must be increased by that amount. The velocity head in the conduit can be obtained only by trials preferably starting with the small values of Q. In Table 2 when $Q = 2$ cu ft per sec, the depth in the conduit will be somewhat less than $\epsilon + 0.25 = 0.908$. For 2 cu ft per sec, at a depth of 0.9 ft in a 24-in. pipe, Fig. 4 gives $H_v > 0.03$. Assuming $H_v = 0.03$, the depth becomes 0.88 with a resultant value of $H_v = 0.035$. This is not a sufficient change to effect the result so 0.035 can be assumed as the final value. Since the crest of the throat is taken as the datum, this 0.035 is to be subtracted from the value of ϵ. The velocity heads for other values of Q are found in the same way, except that after two or more have been computed an assumed value for the next one may be obtained by extending the curve drawn through the known points.

TABLE 1.—QUANTITY-ENERGY HEAD CURVE

d_c	0.2	0.4	0.6	0.8	1.0	1.2
$0.5\ d_c$	0.1	0.2	0.3	0.4	0.5	....
$b + 0.5\ d_c$	1.1	1.2	1.3	1.4	1.5	....
A	0.22	0.48	0.78	1.12	1.50	1.88*
B	1.2	1.4	1.6	1.8	1.93*	1.79*
$\frac{A}{B}$	0.183	0.343	0.487	0.622	0.777	1.050
Q	0.53	1.60	3.09	5.02	7.50	11.00
H_v	0.092	0.172	0.244	0.311	0.389	0.525
ϵ	0.292	0.572	0.844	1.111	1.389	1.725

* By scale and planimeter (see Fig. 1).

Table 1 is extended to a value, $Q = 11.0$. The energy head was so regular that it was extended by eye to $Q = 12$, and Table 2 is computed to this limit although it is subject to some suspicion for $Q > 11.0$. These curves are all shown in Fig. 3.

TABLE 2.—QUANTITY-VELOCITY HEAD CURVE.

Q =	2	4	6	8	10	12
ϵ =	0.658	0.978	1.225	1.438	1.630	1.812
$\epsilon + 0.25$ =	0.908	1.23	1.48	1.69	1.88	2.06
Assumed H_v =	0.03	0.07	0.09	0.14	0.19	0.25
$\epsilon + 0.25 - H_v$ =	0.88	1.16	1.39	1.55	1.69	1.81
H_v (final) =	0.035	0.064	0.100	0.145	0.198	0.256
$d = \epsilon - H_v$ =	0.623	0.914	1.125	1.293	1.432	1.556

An exponential formula may be written for some small sections of the final rating curve, but it is not advisable. The inaccuracies of such a formula can be appreciated by equating the value of ϵ in Equation (2) for both the throat and conduit sections; thus,

$$d_c + \left(\frac{Q}{A_c}\right)^2 \frac{1}{2\,g} = d + \left(\frac{Q}{A}\right)^2 \frac{1}{2\,g} \quad \text{..............} (17)$$

which reduces to,

$$Q = \sqrt{2\,g\,\frac{(d - d_c)\,A\,A_c}{A - A_c}} \quad \text{..................} (18)$$

Writing $A = f(d)$ and $A_c = \phi\ (d_c)$:

$$Q = \sqrt{2\,g\,\frac{(d - d_c)\,f\,(d)\,\phi\,(d_c)}{f\,(d) - \phi\,(d_c)}} \quad \text{................} (19)$$

Since $f(d)$ is not a simple function in a circular pipe, it is evident that the use of an exponential formula is generally inadvisable because of the many different combinations depending on the relative size of the pipe and throat, and the height of the crest of the throat above the invert.

ENERGY LOSSES

One of the chief disadvantages of water measurement with a weir is the relatively large and uncertain loss of energy. Schoder and Turner[3] show how the so-called constant of a weir is subject to wide changes depending on the size and setting. This change in the constant can be interpreted as a variation in the energy loss, and it follows that if such variations can be limited by the use of other devices, the change in so-called constants will likewise be restricted. In the case of the weir such control is difficult and at times impossible; with a Venturi flume it may be accomplished easily.

In the adaptation of the Venturi flume, to the writers' ideas, considerable attention was given to the design of the transitions to minimize loss of energy. In the hydraulic design of flume transitions Hinds[11] found, in making twenty-nine tests on ten flume inlets, that only three had losses amounting to more than $0.1 \Delta H_v$. In a number of cases no measurable loss occurred and the average was about $0.04 \Delta H_v$. The 4-ft diameter of a standard sewer manhole limits the length of the transition that can be built readily in an existing sewer. In the sewerage system of the Los Angeles County Sanitation Districts, a ratio of three longitudinally to one transversely has been adopted as a compromise. To determine the energy losses through Venturi flumes constructed by the Districts, a differential meter acting on the principle of a Pitot meter was devised. This is shown in Fig. 5.

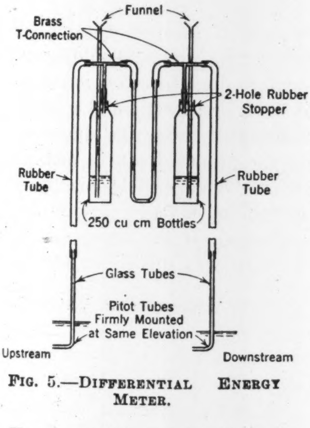

FIG. 5.—DIFFERENTIAL ENERGY METER.

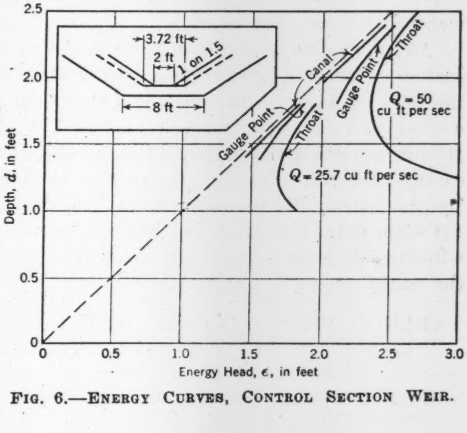

FIG. 6.—ENERGY CURVES, CONTROL SECTION WEIR.

Two bent tubes are set at two points in the stream with orifices at the same elevation and pointing up stream, one in the throat and one above the inlet transition. These two tubes are connected by means of air tubes to a manometer filled with colored water; the displacement of the water column in the manometer after all water is blown out of the bent tubes measures the difference in energy head at the two points. To allow for any compression of the air which might occur in the tubes it was found advisable to blow air into each from time to time during the test. This was accomplished by pouring water into the two bottles, forcing air out through the orifice tubes. In sewage, one or the other of the orifice tubes may become clogged by floating matter, throwing the manometer out of balance. The manometer resumes its balance when the obstruction has been cleared away and a little more air forced into the tubes. Any type of meter in which water is drawn into the tubes will be clogged by sewage. This simple, head-differential apparatus has been found to be accurate and sensitive.

---

[11] "The Hydraulic Design of Flume and Siphon Transitions", by Julian Hinds, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1423.

Several tests with the differential-energy meter (Fig. 5) integrated over the entire cross-section have shown that no energy losses greater than 0.005 ft occur in any of the meter throats thus far installed, and as many stage recorders are not sensitive to such small changes this energy loss is practically negligible. Should an appreciable loss be found in a given installation for high velocities it can be added to the quantity-energy head curve.

In sewage measurement, the mean daily flow is usually required. This may be calculated with sufficient accuracy by using a planimeter on a water-stage record to get the mean depth. If it is suspected that there are energy losses through the Venturi flume at higher flows the differential energy meter can be used at various stages, including the maximum, to correct the curve; and if the flow is increasing from year to year, the corrections may be determined beforehand, as the maximum flow of to-day will be the mean flow some months or some years hence.

Another possible source of error seems to be that in an open conduit the surface velocity is about 25% greater than the mean, which should cause the velocity head at the surface (where the float is installed for measurements), to vary as the ratio of 1.00^2 to 1.25^2, or 56% greater than the mean. If this condition existed, 1.56 H_v should be subtracted from the quantity-energy head instead of 1.0 H_v, in order to obtain the proper depth in making a rating curve. This condition was tested at one meter formed by placing a flat slab, 6 in. thick (at the invert), on the bottom of a 54-in. sewer pipe without side contractions. In the regular pipe channel, at the upper end of the transition section and at mid-stream, a Pitot tube was turned up stream and then at right angles to the current. The difference between these two measurements was the true velocity head, which, added to the measured depth, gave the total-energy head. Applying this energy head to the previously computed quantity-energy head curve gave the quantity. Readings taken at various depths between the center and sides of the stream showed substantially

TABLE 3.—RELATION BETWEEN THE MEASURED AND THE THEORETICAL VELOCITY HEADS AT MID-STREAM.

Quantity, Q, in cubic feet per second	Calculated velocity, V, in feet per second	Theoretical head, H_v, in feet	Measured head, H_v, in feet
8.2	2.18	0.074	0.076
10.25	2.50	0.097	0.096
17.5	3.15	0.153	0.142

the same velocity head at all points. Table 3 shows the relation between the measured and the theoretical velocity heads at mid-stream. These results indicate that within the accuracy of the measurements the velocity head in the conduit may be assumed to be the mean velocity head.

An investigation of the velocity-head correction for hydraulic flow by O'Brien and Johnson[12] indicates that, in this case, such a correction might amount to from 4 to 10% of the velocity head. As this is less than the limit of accuracy for a stage recorder with a float set in the main stream it may be neglected. For measurements in clear water, using a float-well for more accurate measurements, it should be determined experimentally.

When the velocity above the meter is less than 2 ft per sec the water surface is usually smooth, but above this velocity waves begin to form, probably caused by the difference in velocity heads in the region adjacent to the sides of the conduit. The waves are too small to affect the ball-float, but would affect very precise measurements made with a hook-gauge. Where they are usable float wet-wells would obviate this trouble, but in sewers the floats are affected by the accumulation of decomposing sludge.

One question that may be raised is the effect on the energy head of different velocities at various points in the cross-section of the throat. It was found that the energy head was the same at all points in a transverse plane. As another check, small floats were dropped simultaneously into the upper end of the throat in pairs, one being near the side and the other nearer the center. Every time, both floats reached the lower end together. As another test a string was dropped into the throat transversely to the flow line and reached the lower end straight. The explanation of this phenomenon is that at, and near, the critical velocity in a short flume the side friction is not an appreciable factor.

Efforts were made to find a coefficient to be applied to H_v in the conduit. The flow was determined by measuring the energy head in the throat with a Pitot tube. Using this value of Q, the measured depth was subtracted from the energy head to give $C\,H_v$. Within the accuracy of measurements, flows of 10.3 cu ft per sec, at a velocity of 2.4 ft per sec, and 17.5 cu ft per sec, at a velocity of 3 ft per sec, in the conduit both gave $C = 1$. These were the largest flows and velocities available.

EXPERIMENTAL VERIFICATION

In the experiments made by the U. S. Bureau of Reclamation,[7] a wooden throat with a bottom width of 2 ft and side slopes of 1 on $1\frac{1}{2}$ was installed in an earthen canal with a bottom width of 8 ft and similar side slopes. The bottom of the throat was 8 in. above the base of the canal and the downstream apron end of the throat sloped downward to a point 8 in. below the elevation of the canal base, similar to the Parshall meter. The gauge-point was placed in the upper transition where the bottom width was approximately

---

[12] "Velocity Head Correction for Hydraulic Flow", by M. P. O'Brien, Assoc. M. Am. Soc. C. E., and J. W. Johnson, Jun. Am. Soc. C. E., *Engineering News-Record*, Vol. 113, 1934, p. 214.

3.72 ft. It was placed only 0.4 ft down stream from the upper end of the wooden flume section where it was certain no silt deposit would occur. The writers have drawn energy curves for the flume (Fig. 6) at the control, or throat section, the gauge-point, and in the main canal for 50 and 25.7 cu ft per sec, respectively.

Had the gauge-point been moved back into the main canal, the measured depth would have been greater by about 0.1 ft in the case when $Q = 50$ cu ft per sec, but the main argument in favor of moving up stream is that the drop in the water surface indicates convexity, especially as it increases rapidly with the tapering of the channel, and it is in the convex water surfaces that the relation of the water surface to energy head is not correctly given by the Bernoulli theorem. Had the gauging-point been placed in the regular channel above as suggested, and the sides and bottom lined for a few feet to maintain a uniform cross-section, the stream filaments would have been parallel and the calculated flow would have followed more closely the volumetric measurements. Friction due to the longer distance between the point of measurement and the throat could have been measured by means of the differential energy-head meter (Fig. 5) and the energy head increased by this amount.

With this change in the point of measurement the recorded tests would have shown closer agreement with the calculated rating curve. Since the quantity of water flowing through this Venturi flume tested by the Bureau of Reclamation was carefully measured volumetrically the data are considered most reliable. From the known dimensions a quantity-depth or rating curve was readily constructed by the writers using the method previously outlined. As stated by Hinds the difference between the quantities taken from this curve for given depths and the actual measurements in no case exceeded 5 per cent. Since the writers have pointed out that greater accuracy could have been attained by the selection of a better place for measuring the depths, and by measurement of frictional losses, this test is sufficient proof that all forms of the Venturi flume will give accurate measurements when it is possible to measure the depth in the conduit of a regular cross-section immediately above the throat and where the throat is properly designed to insure that the water reaches critical depth.

In the absence of an experimental laboratory the writers have had to make use of active sanitary sewers in the development and adaptation of the Venturi flume designs. Standard weirs were set in adjacent manholes, but comparative results were poor except where the flow was small in comparison with the capacity of the sewer, since the weir coefficients were uncertain. Therefore, these measurements were not considered sufficiently accurate to verify those obtained from the Venturi flumes.

The experiments made by the U. S. Bureau of Reclamation, previously referred to, were considered a positive check on the accuracy of the method outlined herein. Furthermore, a field test, comparing measurements of a temporarily installed Venturi flume with a permanent Parshall meter (made through the co-operation of the Cities of Los Angeles and Beverly Hills), supplied added proof of the accuracy of the adapted Venturi flume.

At the point selected for the test an elaborate underground structure was constructed on a 21-in. sewer line which included a standard 12-in. Parshall meter and an indicating and recording register, showing the depth of flow through the flume and the rate of flow, in cubic feet per second. Water continuously running into the float-well prevented the accumulation of sludge which otherwise would affect the float results. The wooden throat of the temporary Venturi flume was installed in an ordinary standard manhole about 1 000 ft above the permanent gauging station, where the grade of the 21-in. sewer was 0.70 per cent. The bottom of the throat with a width of 10 in. was placed 2 in. above the invert. Although the boards forming the side slopes were intended to be set at a slope of 2 on 1, the irregularities of the pipe caused them actually to be placed on a slope of 2.1 on 1.

Tin transitions for stream-lining the upper end were attached to the boards, but could not be set in exact position due to the roughness of the channel through the manholes. Some caulking had to be done with oakum. The entire apparatus was quickly installed in the sewer during the low early morning flow and readily withdrawn a few hours later when the flow was at its peak of about 6 cu ft per sec. The elevation of the bottom of the throat was referred to a straight-edge placed across the manhole rim in the street pavement and measurements to the water surface above the flume were made with a steel tape.

Readings were taken simultaneously at the Venturi flume and the Parshall meter, a correction in time being made between the two stations as determined by passing floats occasionally from one to the other. A correction was also required for the small flow entering the sewer from a side branch at a point between the two testing stations. Occasional depth measurements over a V-notch gave this correction with sufficient accuracy.

Table 4 gives the results of tests when the flow was within the capacity of the Venturi flume. In Table 4(*a*) the average discrepancy between the two methods of measurement was 4.2%, with a probable error of ± 0.4 per cent.

During the period of high flow (8:28 to 8:58) it was found that the critical depth in the throat exceeded the depth of the Venturi flume. These results are shown in Table 4(*b*). In this second group the discrepancy was + 6% ± 0.7%, showing that even when poorly adapted it was still comparatively correct. The 4% error in the first group could be corrected by allowing a head loss of 0.25 H_v, or by subtracting 0.75 H_v instead of H_v from the energy head. Doubtless the discrepancy could be reduced materially by carefully installing a permanent concrete Venturi flume instead of the temporary wooden one which was used. Any obstruction placed in this sewer laid on a slope greater than the critical causes the water to jump immediately to the conjugate depth on the energy-head curve (Fig. 2) and unless allowance is made for this effect, the capacity of the sewer would be curtailed seriously. Therefore, it was necessary to use a large throat with a consequent rather high velocity of approach. It has been found that the slower the velocity of approach the greater the accuracy. This is limited by the capacity of the conduit and the possibility of forming deposits in the approach channel which would affect the rating curve.

DESIGN OF VENTURI FLUME

The proper design of a Venturi flume requires that parallel flow occur in the channel[13] above the flume and in the throat. The necessary critical velocity is obtained only when a drop in the energy head occurs just below the throat. A small jump in the water surface at this point (see Fig. 1) is positive evidence that critical velocity is occurring. In addition, the throat section must have sufficient length or the water will not be flowing in parallel filaments at the point of critical depth. The first meter stations installed by the Sanitation Districts of Los Angeles (Calif.) County had short throats which gave good results only on the small flows. Lengthening the throat to 3 ft insured parallel flow through more of the length, and tests with a Pitot tube showed no apparent change in energy head except at the ends. Data are lacking to formulate a rule as to the proper length, but experience indicates that the throat should be at least as long as the diameter of the pipe. A comparison of flow through two Venturi flumes in consecutive manholes, with 36-in. and 6-in. throat lengths, respectively, showed a ratio of 1.0 to 0.8, the longer throat indicating the larger flow.

The important features of the Venturi flume are its adaptation to stream-flow measurement in all shapes of conduits not flowing under pressure and its ready installation in lines to which access is much restricted. The device can always be installed in an existing line and often without serious interruption to the flow.

The size of the flume throat depends upon the size and grade of the conduit and the range of flow it is desired to measure. The ideal flume throat would have such a size and shape that the ratio of the cross-section of the water in the throat to that in the conduit would be the same for all quantities; but such a throat would be impossible to design and build because the ratio of the critical depth to the depth in the conduit is not a constant.

For a flow that is only a small percentage of the designed capacity of a conduit, a throat, V-shaped, or narrow at the bottom, with sloping sides, is satisfactory. However, such side walls are difficult to hold in place. A rectangular narrow throat may contract the flow so much as to give inadequate capacities for larger flows.

For circular pipes it has generally been found advisable to install a bottom slab in addition to the two sides, a feature which helps to support the side walls. The slab acts as a broad-crested weir when flows are only a small percentage of the designed capacity. Since a thin bottom slab properly stream-lined by approach transitions causes no deposition of solids except possibly at the very lowest velocities, such a slab is recommended, especially on the lighter grades, to offset any possible chance of back-water from an unforeseen obstruction below that might otherwise prevent critical velocity from being attained. In general, the flatter the slope, the more necessary is this precaution and the greater the slab thickness needed.

A throat of rectangular cross-section with proper transitions may be adaptable in some cases, as in the instance of a semi-elliptical section, or a rectangular-shaped conduit, where its use is recommended. Lack of accuracy in very low flows and inability always to pass the full design capacity, however, are restricting limitations to its general use.

---

[13] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., 1932, p. 28.

Where a large flow in either rectangular or circular-shaped conduits prevents the placing of forms for building the side walls, a simple device to create critical velocity consists of placing on the invert a pre-cast flat slab with transitions. Deposition can only occur above this type at extremely low velocities. In similar cases involving large flows critical velocity may be produced by simply inserting vertical side walls with the proper transitions.

The important factor in the construction and installation of any form of Venturi device is that a constriction of some sort be placed in the channel to produce critical velocity with the least loss of energy, and that the shape, size, and dimensions of the device are important only in so far as they meet the specific problem at hand in a practical manner.

The correct size and shape of throat for use in a given conduit is that one for which the energy head is greater than the normal energy head in the free flowing conduit at all values of Q, and with a bottom slab thin enough to prevent deposition of sludge at low flow. A practical method of making this selection is first to prepare quantity-energy head curves for several sizes of Venturi flume throats (Fig. 7) on tracing cloth. Table 5 can be used for constructing these curves for trapezoidal throats having side slopes of 2 on 1. Next, on the same scale, but on a separate piece of paper, a quantity-energy head curve is drawn for the conduit under consideration, assuming unobstructed flow. Any formula for flow in open channels may be used for first constructing a quantity-depth curve, but the following procedure is suggested. Bakhmeteff[14] expresses the Chezy formula, as follows,

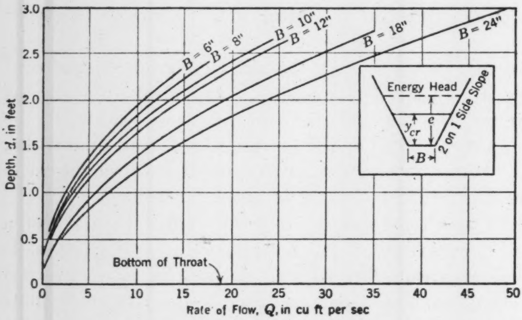

FIG. 7.—QUANTITY-ENERGY HEAD CURVE FOR VARIOUS THROAT SIZES WITH SIDE SLOPES OF 2 ON 1.

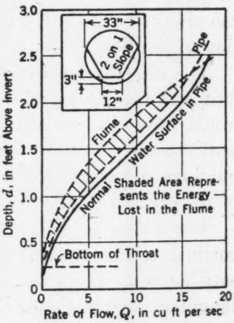

FIG. 8.—ENERGY HEAD CURVE, VARIOUS THROAT SIZES.

$$Q = K \sqrt{S} \qquad (20)$$

in which,

$$K = A\,C \sqrt{R} \qquad (21)$$

---

[14] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., 1932, p. 13.

Computing K as a function of the depth in a pipe is rather tedious. Values of K are shown for several pipe sizes in Fig. 9 which has been computed for $n = 0.013$ and $S = 0.01$ in Kutter's formula. Drawn to a logarithmic scale, it is merely necessary to add one-half the logarithm of the slope (expressed as a percentage) to obtain the quantity for any depth in the pipe. Velocity heads are obtained from Fig. 4 in the manner previously described. Adding these velocity heads to the depths shown on the quantity-depth curve gives the quantity-energy head curve. Fig. 8 shows a typical diagram.

Referring to Fig. 9, the capacity, Q, of a pipe is given by Equation (20) when S = the slope, expressed as a percentage; $K = A \times \frac{C}{10} \sqrt{R}$ for any given depth; and C = Chezy's coefficient. The curves are drawn for a 1% slope. For values of S less than 1% the flow for any depth will be to the left of the curve and for more than 1% to the right. To find the value of $\sqrt{S}$ measure from the slope guide to the right 10-line for $S < 1\%$ and to the left for $S > 1$ per cent. For example: Let $S = 0.25\%$; D = 8-in. pipe; and, $Q = 0.1$ cu ft per sec. In this case $S < 1$ per cent. Set the dividers for the distance between the inclined slope line in percentage line and the right 1.0-line of the diagram at $S = 0.25$. Transfer this distance to the $Q = 0.1$-line, measuring to the right and intersect the 8-in. curve at $d = 0.20$ ft. If Q is given in million gallons daily, set the dividers for the distance between the inclined line and the million-gallon-daily guide line on the extreme right. For $S = 0.25\%$ and $Q = 0.1$ mgd, $d = 0.25$ ft in an 8-in. pipe.

On the other hand, let $S = 2.25$; D = 60-in. pipe; and $Q = 15$ cu ft per sec. In this case $S > 1$ per cent. Set the dividers for the distance from the inclined slope line to the 0.1-line to the left at $S = 2.25$. Transfer this distance to the $Q = 15$-line, measuring to the left and intersect the D = 60-in. line at $d = 0.66$ ft.

By superimposing the quantity-energy head curves for the throat upon that for the pipe and then moving the throat tracing up or down, it is possible to decide quickly which throat size should be used and how high it should be set above the invert. The difference in the two energy heads shows the

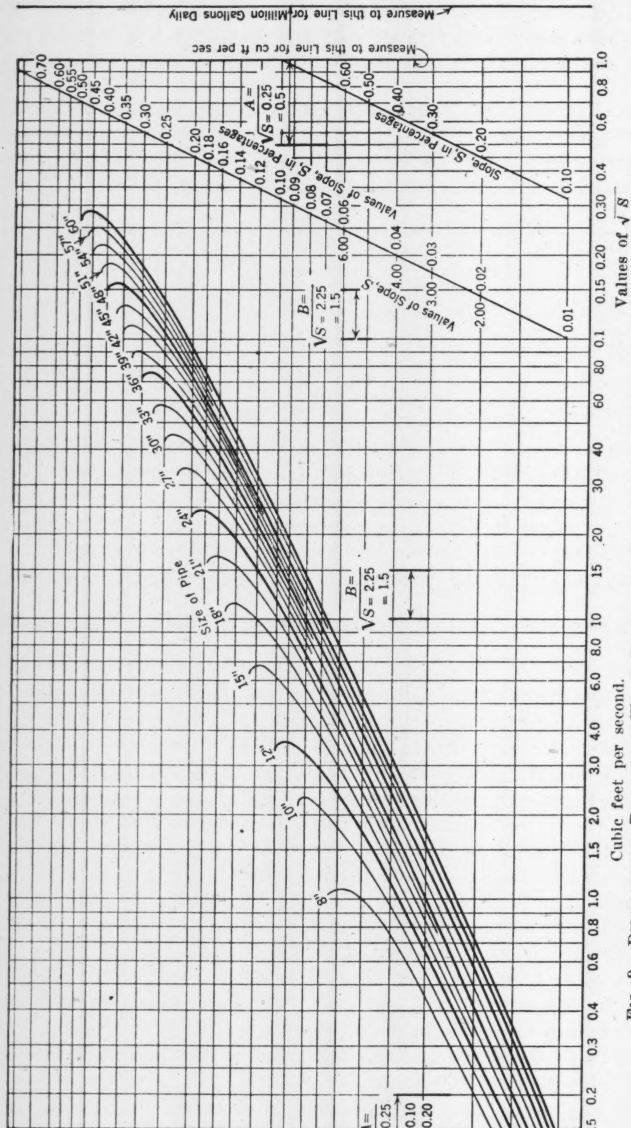

FIG. 9.—DISCHARGE OF PIPES WITH WATER FLOWING AT VARIOUS DEPTHS WHEN KUTTER'S $n = 0.013$.

loss caused by the Venturi flume for all quantities. Fig. 10 shows typical quantity-energy head curves for both a trapezoidal and a rectangular throat superimposed upon a quantity-energy head curve for a 33-in. circular pipe,

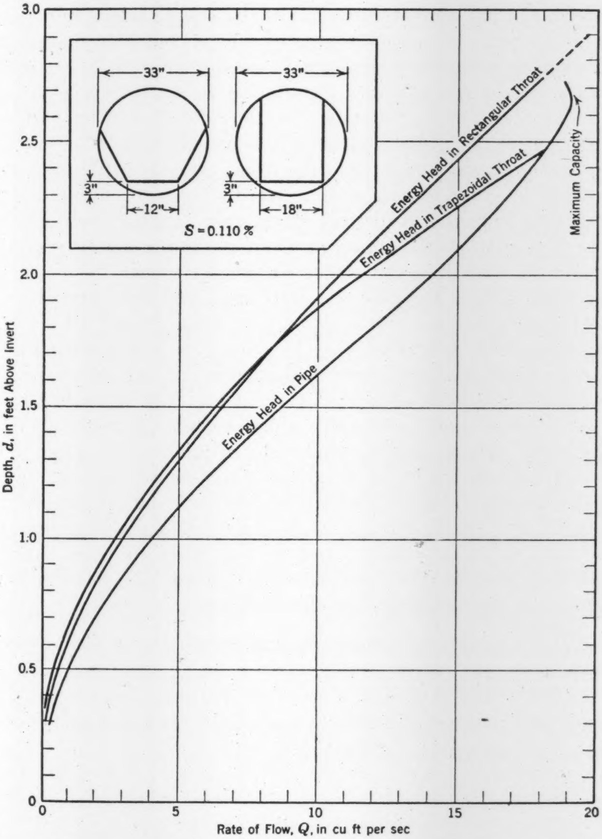

FIG. 10.—COMPARATIVE ENERGY HEAD IN TRAPEZOIDAL AND RECTANGULAR FLUMES.

and it is easily seen that the trapezoidal section can be used as a meter for flows as great as 18 cu ft per sec and that at 19 cu ft per sec, which is the maximum capacity of the pipe (there being no loss in energy through the flume), the carrying capacity of the pipe is not curtailed. The quantity-energy head curve of the rectangular flume (Fig. 10) being always above the energy head for the pipe, shows loss of energy through the flume at maximum designed capacity. This type of Venturi flume would interfere with the use of the sewer at full capacity. It is more accurate to compute the rating or quantity-depth curve from actual measurements of the flume as constructed than to base it upon the design curves. Figs 4 and 9 are for use with circular pipes, but similar curves may be computed for conduits of any shape.

For permanent installation in sewers of the Los Angeles County Sanitation Districts the Venturi flumes were readily constructed of concrete directly in the sewer manhole without interruption to sewage flow. A layout sketch of the meter was prepared for a single installation in a circular pipe and, using the plan as a pattern, forms for other sizes were obtained by proportion. When possible the entire form for the flume was assembled in the sewer manhole invert and concrete was poured into the forms from one side until the bottom slab was filled in order to assure complete displacement of the sewage. Use of a fast-setting cement had distinct advantages in such installations.

Placing the center of the throat at about the lower side of a manhole gave proper space for installing the stage-recorder float near the upper side at a point where the flow in the pipe was uniform. The float consists of an 8-in. copper ball fastened to a 2-ft length of $\frac{1}{2}$-in. pipe, hinged loosely up stream to a pipe framework (see Fig. 1). The latter is attached to the top of a plank placed cross-wise to the sewer and supported by the shelves of the manhole. Without some such apparatus to hold the ball, it tends to float down stream and disturb the record. The stage recorder is suspended on a specially built steel seat immediately under the manhole cover where it is readily accessible. Repeated checks of indicated stage records against actual measured depths show no appreciable error during the daily range of velocities. Braided, insulated, copper wire connects the float to the recorder. Considerable difficulty was experienced in keeping the stage recorder clocks running for a week at a time in the damp, gas-laden, sewer air, but the purchase of sealed clocks has practically solved this problem.

ACKNOWLEDGMENTS

The writers are particularly indebted to A. K. Warren, Assoc. M. Am. Soc. C. E., and A. M. Rawn, M. Am. Soc. C. E., for the opportunity to make the experiments and studies for this investigation, and for their constructive criticism in the preparation of the paper.

DISCUSSION

N. F. HOPKINS,[15] M. AM. SOC. C. E. (by letter).—The experiments reported by the authors are interesting as confirming the formulas. Especially interesting are the experiments showing that the velocity is uniform throughout the cross-section of the flume at such comparatively low velocities.

It would seem as if the theory could have been set forth in a more simple manner. The velocity increases with the drop in the surface from the back-water to the flume, whereas the area of the cross-section decreases with the drop. The quantity is the product of the area and the velocity. If there is no drop, there would be no velocity and quantity; and, if the drop is a maximum, there would be no area and no quantity. At some point, the product of the velocity and the area is a maximum.

For example, in addition to the notation of the paper, let p = the pitch of the sides of the flume; Z = the elevation of the back-water above the bottom of the flume plus the velocity head at back-water, minus the friction loss in entering the flume; H_v = the velocity head in the flume; d = the depth of water in the flume = $Z - H_v$ (see Fig. 11); V = the velocity in the flume = $\sqrt{2\,g\,H_v}$; and A = the area of the water section in the flume. Furthermore, let $a = B\,d - A$, then;

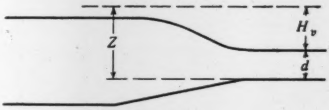

FIG. 11.

$$A = B\,d - a = B\,Z - B\,H_v - a \qquad (22)$$

$$Q = \sqrt{2\,g\,H_v}\,(B\,Z - B\,H_v - a) = \sqrt{2\,g}\,(B\,Z\,H_v^{0.5} - B\,H_v^{1.5} - a\,H_v^{0.5}) \qquad (23)$$

and for a maximum value of Q:

$$\frac{dQ}{dH_v} = \sqrt{2\,g}\left(\frac{B\,Z}{2\,H_v^{0.5}} - \frac{3\,B\,H_v^{0.5}}{2} - \frac{a}{2\,H_v^{0.5}}\right) = 0 \qquad (24)$$

In Equation (24), the quantity in parenthesis equals zero, and, consequently, $B\,Z - 3\,B\,H_v - a = 0$; that is:

$$H_v = \frac{Z}{3} - \frac{a}{3\,B} \qquad (25)$$

For a rectangular flume, $a = 0$ and Equation (25) becomes $H_v = \dfrac{Z}{3}$ and Equation (23) becomes:

$$Q = 3.09\;B\,Z^{1.5} \qquad (26)$$

---

[15] Civ. and Min. Engr. (Harrop & Hopkins), Pittsburgh, Pa.

For a V-shaped flume, in which $a = \frac{B(Z - H_v)}{2}$, Equation (25) is:

$$H_v = 0.2\,Z \ldots\ldots\ldots\ldots (27)$$

and, Equation (23) is,

$$Q = 2.297\ p\,Z^{2.5} \ldots\ldots\ldots\ldots (28)$$

For a trapezoidal flume, in which $a = (Z - H_v)^2\ p$, Equation (25) becomes:

$$H_v = \frac{0.3\,b}{p} + 0.6\,Z - \sqrt{\left(\frac{0.3\,b}{p} + 0.6\,Z\right)^2 - \frac{Z}{5}\left(\frac{b}{p} + Z\right)} \ldots (29)$$

and Equation (22) becomes:

$$A = b\ (Z - H_v) + p\ (Z - H_v)^2 \ldots\ldots\ldots\ldots (30)$$

Substitute the value of H_v found by Equation (29) in Equation (30) to find A; and in Equation (23) to find Q. An approximate expression for the flow is:

$$Q = 3.06\ (b + 0.72\ p\,Z)\ Z^{1.5} \ldots\ldots\ldots\ldots (31)$$

For a parabolic flume, in which $a = \frac{B}{3}\ (Z - H_v)$, Equation (25) becomes:

$$H_v = 0.25\,Z \ldots\ldots\ldots\ldots (32)$$

Equation (22) becomes:

$$A = \frac{B\,Z}{2} \ldots\ldots\ldots\ldots (33)$$

and Equation (23) becomes:

$$Q = 2\ B\,Z^{1.5} \ldots\ldots\ldots\ldots (34)$$

Finally, it is necessary to find the value of B for $d = 0.75\,Z$.

For a circular flume (or, in fact, for a flume of any cross-section), it is sufficiently exact to assume that,

$$Q = 4\,A\,\sqrt{Z} \ldots\ldots\ldots\ldots (35)$$

in which A is the area of a section of the flume, the depth of which is $0.75\,Z$.

HUNTER ROUSE,[16] ESQ. (by letter).—In so far as the subject-matter specified in the title of this paper is concerned, the writer must commend the authors for their able solution of a practical hydraulic problem. The fact is not to be disputed that any appropriate measuring device may be expected to yield satisfactory results once its rating curve has been determined directly or indirectly by volumetric measurement. Hence, the authors were fully justified in choosing a measuring device which eliminated every possible objectionable feature, in adapting it to the needs of the situation, and then rating it in place through comparison with a device of known characteristics. In view of the accuracy required (an allowable error of perhaps 5%, or more), it was not amiss to apply certain empirical checks upon the characteristics of flow encountered, and to express the flow equations in simplified form through several common approximations.

---

[16] California Inst. of Technology, Pasadena, Calif. Mr. Rouse was elected Assoc. M. Am. Soc. C. E., on January 13, 1936.

Approximate methods, however, are truly justifiable only if the investigator realizes the fact that the assumptions made do not fully describe the actual state of flow. When the authors claim that their paper "presents the theoretical hydraulic principles involved" in the performance of the Venturi flume, the writer believes that certain supplementary remarks have a definite place in this discussion. For although the authors state that "the formulas developed for the flume are not empirical but are based entirely on theory", the analysis of flow which they have presented is really only the first page of a long and complex story.

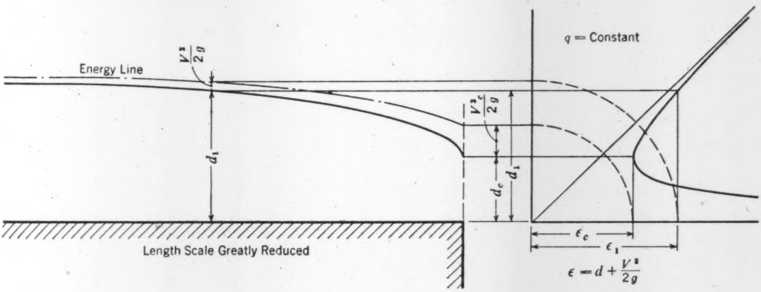

FIG. 12.

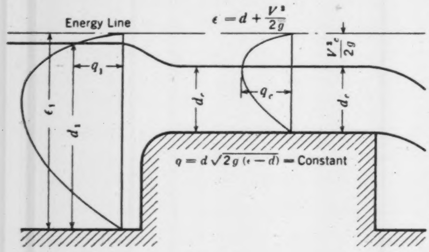
The specific energy diagram used by the authors applies correctly only to flow in long open channels in which the gradual change in surface profile is entirely the result of energy loss, and not of horizontal or vertical contraction of the flow section. Thus, in Fig. 12 is shown the surface curve in a long channel of mild slope ending in an abrupt fall, the specific energy of flow, and hence, also, the depth of flow, decreasing in the direction of motion; the specific energy must reach a minimum value, for the given rate of discharge, in the vicinity of the fall, in which region the depth is equal to the critical. It must be remembered that such an energy diagram is constructed on the assumption that the flow at every section is so nearly parallel that accelerative forces can be ignored; that is, the pressure distribution is considered static throughout, so that the sum of pressure head, $\frac{p}{\gamma}$, and elevation, z, must always equal the depth of flow. The vertical distance between the energy line and the free surface must then be equal to the velocity head.



Energy Line
$\epsilon = d + \frac{V^2}{2g}$
$\frac{V_c^2}{2g}$
q_1
q_c
ϵ_1
d_1
d_c
d_c
$q = d\sqrt{2g(\epsilon - d)}$ = Constant

Fig. 13.

The authors' equations for flow through the Venturi flume, however, are practically identical with those used in the customary treatment of the broad-crested weir, in which the change in surface profile is entirely the result of contraction of the flow section (see Fig. 13). Not only is the flow assumed parallel throughout, but the further assumption is made that no energy loss occurs. Hence, instead of the specific energy diagram, recourse must be taken to the discharge curve, which considers the discharge per unit width as a function of the depth for a given energy line elevation. In the case of two-dimensional motion over the broad-crested weir, since $\epsilon = \frac{V^2}{2\,g} + d$, the unit discharge may then be expressed as:

$$q = \frac{Q}{b} = V\,d = d\,\sqrt{2\,g\,(\epsilon - d)} \quad \ldots\ldots\ldots\ldots\ldots (36)$$

Taking the derivative of q with respect to d,

$$\frac{\delta q}{\delta d} = \sqrt{2\,g}\left(\sqrt{\epsilon - d} - \frac{d}{2\,\sqrt{\epsilon - d}}\right)$$

and setting this equal to zero $\left(\frac{2\,\epsilon - 3\,d}{2\,\sqrt{\epsilon - d}} = 0\right)$; and:

$$d_c = \frac{2}{3}\,\epsilon = \sqrt[3]{\frac{q^2}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Obviously, the critical depth, d_c, derived by this method must be identical with that used by the authors, although the original premises are quite different.

From Equation (36) it is apparent that q must be zero when $d = 0$ and when $d = \epsilon$, and will attain its maximum value when $d = d_c$. Two such q-curves are plotted in Fig. 13, the water surface over the entire length of the weir coinciding with the point of maximum discharge on the smaller q-curve. For any other depth of flow the rate of discharge must be less than the maximum on the corresponding q-curve as shown in the region of approach.

As stated by the authors, a single measurement of depth in the throat should suffice for the determination of the discharge under these conditions, according to Equation (37). As also pointed out by the authors, a definite relationship must exist between the critical depth and the depth of approach, so that once this relationship is known a single measurement of the latter depth would also be sufficient.

A slightly different use may be made of the discharge curve in a procedure that is more directly applicable to the Venturi flume. As suggested to the writer by B. A. Bakhmeteff, M. Am. Soc. C. E., the surface curve for flow in either converging or diverging channels may be approximated in the following manner: Again assuming parallel flow at constant specific energy over a horizontal floor (the velocity then being normal at all points to horizontal concentric arcs of circles), the depth of flow at any section may be expressed in terms of the radius, or horizontal distance, r, from the fixed center, the total head, ϵ, and the rate of discharge per unit width, q. If the angle of convergence or divergence of the vertical walls is designated by θ, from the law of continuity the total discharge will be:

$$Q = \theta\, r\, V\, d = \theta\, r\, q = \text{constant} \qquad (38)$$

Introducing the discharge per unit width at the critical section (where q must again be a maximum):

$$\theta\, r\, q = \theta\, r_c\, q_c \text{ and } \frac{q}{q_c} = \frac{r_c}{r} \qquad (39)$$

Since,

$$\epsilon = \frac{V^2}{2\,g} + d = \frac{3}{2}\, d_c = \text{constant} \qquad (40)$$

$$q = V\, d = d \sqrt{2\, g\, (\epsilon - d)} \qquad (41)$$

and at the critical section,

$$q_c = \sqrt{g}\; d_c^{\frac{3}{2}} = \sqrt{g} \left(\frac{2}{3}\, \epsilon \right)^{\frac{3}{2}} \qquad (42)$$

Substituting Equations (41) and (42) in Equation (39):

$$2.6\, \frac{d}{\epsilon} \sqrt{1 - \frac{d}{\epsilon}} = \frac{r_c}{r} = \frac{q}{q_c} \qquad (43)$$

Equation (43) is thus a dimensionless relationship between the ratio of depth to total head and either the ratio of the critical radius to the radius at any section or the ratio of the unit discharge at any section to the critical unit discharge. This equation will yield the q-curve and the two surface curves shown in Fig. 14. It will be noted that in the region between $r = 0$ and $r = r_c$ no flow can occur under the assumed conditions, this region being known in hydrodynamics as a "singular" zone which does not belong to the region in which the function is continuous.

These relationships may be applied to the Venturi flume having vertical side contractions by assuming, as in the case of the broad-crested weir, that the critical depth occurs over the entire parallel section of the throat. Choosing arbitrarily the throat proportions shown in Fig. 15, this method would yield the profile given in the illustration. It is clear, as noted by the authors, that the hydraulic jump may form at any section beyond the throat, if the tail-water level is raised, for in this region the flow is in the rapid state. Thus, the Froude number, identical with Bakhmeteff's kinetic flow factor, λ, will be:

$$\lambda = 2\,\frac{\dfrac{V^2}{2\,g}}{d} = 2\,\frac{\dfrac{2\,g\,(\epsilon - d)\,d^2}{2\,g\,d^2}}{d} = 2\,\frac{1 - \dfrac{d}{\epsilon}}{\dfrac{d}{\epsilon}} \qquad (44)$$

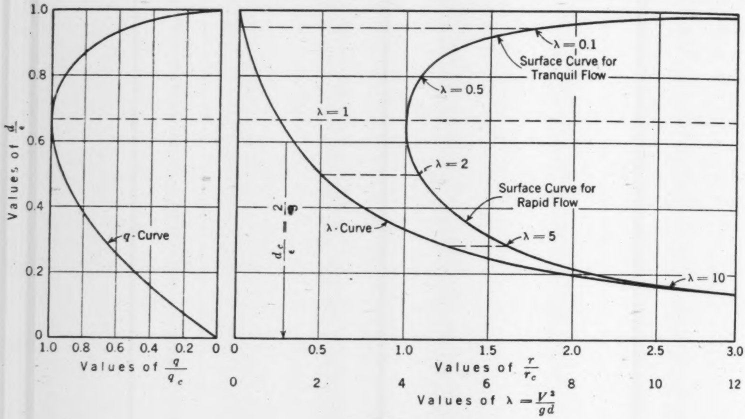


FIG. 14.

The characteristics of the jump at any section will then depend upon the magnitude of λ and of θ at that section; λ, of course, must have a value greater than unity before the jump can form. The curve of $\frac{d}{\epsilon}$ against λ is also shown in Fig. 14.

FIG. 15.

It should be apparent that a single measurement of the depth in the approach channel would suffice to determine the rate of discharge, the relationship between the depth at this point and the magnitude of q being given by Equation (43). Although this method has been applied only to straight contractions in the horizontal plane, a slight modification would permit simultaneous treatment of the vertical contraction of the lower boundary and even a study of any curvature of the converging and diverging boundaries. It is presumed, however, that the foregoing example will suffice to illustrate the point in question.

Although this procedure is fully as justifiable as the customary elementary treatment of flow over the broad-crested weir, the resulting picture of flow in the throat region is, to say the least, quite hypothetical. Actually, neither of the two basic assumptions made is completely fulfilled in the case of either weir or flume, and two major errors are thereby introduced by this elementary line of attack:

1.—The energy line is not horizontal, but slopes at a rate which varies with the discharge through a given flume or over a given weir. At any given discharge, the longer the meter the greater will be the discrepancy in total head between the channel of approach and the critical region. Since the energy line slopes, there can really be no critical "region" but only a critical section; and according to the energy diagram, which must now be used in addition to the q-curve, this critical section should be near the end of the parallel throat or horizontal crest.

2.—The flow is not even approximately parallel if the contracted section is short, and hence the calculations based upon assumed static pressure distribution cannot be correct. The shorter the contraction the greater will be the error introduced by this assumption. If parallel flow does not exist, surely the expression for critical depth based on this assumption cannot apply. Thus, the authors' statement that the sharp-crested weir is a "control section through which water flows at critical depth" is a fallacy, since the sharp-crested weir is the shortest possible contraction one can imagine and hence involves an extreme degree of departure from the basic assumption of parallel flow.

In order to clarify the error introduced by this assumption, consider the region of the fall shown in distorted scale in Fig. 12. If the length scale is given its correct proportion to the vertical scale, the profile of flow will be that shown in Fig. 16. As the flow approaches the abrupt drop, vertical acceleration will begin, and the nappe will be deflected in the downward direction. Since curvature of the filaments requires the action of centripetal forces, the pressure will no longer be statically distributed, and the pressure head will be less than the depth below the free surface by an amount depending upon the elevation and curvature of the filaments. Although the computed critical depth for parallel flow may still be found some distance up stream from the fall (a distance varying with the unit discharge, with the slope and roughness of the channel, and with the degree of ventilation of the space below the nappe), the fact that the energy line still slopes signifies that the true critical section—that is, that of minimum energy—exists at the fall itself, where the flow is highly curvilinear. Unfortunately, the treatment of critical flow under conditions of non-static pressure distribution has not yet been mastered by the hydraulician.

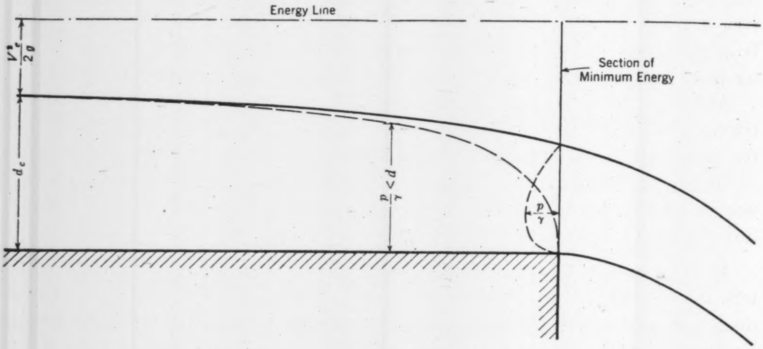

FIG. 16.

The situation at the free over-fall is closely parallel with that at the end of a broad-crested weir and is also an indication of what may be expected in the Venturi flume. Furthermore, the convergence of the boundaries between the channel of approach and the contracted section itself introduces another region of curvilinear flow which by no means can be neglected. If the meter is short these two transition regions partly overlap so that at no point throughout the contraction can parallel flow be assumed to exist. If the meter is long, reaction waves are likely to occur over the entire length of the contracted section, thereby introducing further curvature of the filaments.

These two basic fallacies in the customary elementary presentation thus present a combination of difficulties which can be ignored only in an approximate analysis, for it is almost impossible to devise a meter which, for a large discharge range, will be both short enough to make the energy loss inappreciable and long enough to insure nearly parallel flow at some definite section of the contraction. Not only will the true relationship between the actual depth of approach and the theoretical critical depth have to be determined by laboratory or field calibration, but the critical section for parallel flow—if it exists at all—will shift in position along the crest or throat with change in discharge.

The actual surface profile in a meter similar to that shown in Fig. 15 may be approximated by sketching in by eye a smooth reverse curve connecting the two computed portions, as shown. Obviously, no one profile can be established which will hold for every discharge, for the section at which this surface line intersects the line of critical depth for parallel flow will move in one direction or the other as the discharge varies. Its form will depend upon the proportions of the meter and upon the slope of the energy line, each of which geometrical relationships must be considered to change with the depth of the approaching flow.

FIG. 17.

As an illustration of the actual energy distribution in the throat of the meter, reference is made to Fig. 17, in which it is assumed, for the time being, that the total head is the same at all depths of flow. Although the depth at this section happens to be exactly equal to the computed critical depth, this really has no significance whatsoever, since the pressure distribution is not static; on the contrary, the pressure head, $\left(\frac{p}{\gamma}\right)$, at any elevation, z, above the floor, is considerably less than the distance, $(d - z)$, below the free surface, as a result of the vertical acceleration of the fluid particles at this section. Although the average velocity of flow as found from the equation of continuity, $V = \frac{q}{d} = \frac{1}{d}\int^{d} v_x \, \delta d$, is commonly used in the Bernoulli theorem, the latter may be written properly only in terms of the velocity vector, v, at any point and not its component, v_x, in the direction of flow; thus the true velocity head at any elevation, for the conditions shown, is everywhere greater than the assumed mean value, with the sole exception of the point at the water surface itself. In general, it may be said that in curvilinear flow both $\frac{v^2}{2g}$ and $\frac{p}{\gamma}$ will vary with z, so that the correct form of the Bernoulli theorem must be the following:

$$\epsilon = \frac{v^2}{2g} + \frac{p}{\gamma} + z \qquad (45)$$

To the foregoing discrepancies in the assumptions traditionally made in dealing with such basic types of flow, there must be added further errors arising from variation in total head from floor to surface; from additional curvature due to vertical as well as horizontal contraction; from separation (change of actual flow section) and eddy formation due to abrupt inlet and excessive angle of divergence; and, finally, from partial drowning of the throat because of back-water. Even if many of these difficulties could be avoided through the use of a carefully constructed flume, attempts to produce a "critical-depth" meter of this kind with a constant theoretical coefficient under all passable discharges are quite futile; no meter of this type will yield a flow that is dynamically similar under different heads, for the geometrical relationship of the meter profile, water surface, and energy line cannot remain constant with changing depth.

When an attempt is made to analyze the physical state of flow, as undertaken by the authors, it is impossible to remain content with approximate methods; furthermore, it is not at all justifiable to claim theoretical completeness when it has not been attained. If the essential accuracy of the authors' experimental work is indicated by their practice of measuring static pressure closely enough simply by turning a Pitot tube sidewise, it is obvious that further refinement is quite needless; but if hydraulicians intend to use the Venturi flume in the future for more fundamental research, it is to be hoped that they will not follow blindly such approximate and empirical paths.

One must not conclude from these pages that the simple methods of attack are without value. On the contrary, if the full significance of the elementary facts contained in this discussion were more fully realized, the Boussinesq number would not have appeared in hydraulic literature on Venturi flumes, nor would much of the search for a true critical depth meter have been undertaken.

DR. ING. F. V. A. E. ENGEL[17] (by letter).—In comparison with other measuring devices, such as weirs, for example, the investigation of the Venturi flume meter extends over only a short period of about twenty years. This paper, therefore, is welcome as a further contribution on the subject. It certainly merits the careful study of hydraulic engineers who are confronted by problems relating to the measurement of large quantities of fluid flow.

The writer has been engaged for several years in investigating and designing Venturi flume meters and would like to offer the following comments. In connection with Equation (14), for a free discharging Venturi flume with a rectangular throat, reference should have been made to the investigations by Mr. A. H. Jameson. In 1925, Jameson[18] published equations relating to throat sections of different shapes; that is, a rectangle, triangle, parabola, and a trapezium. Definite progress was made by Jameson[19] in a paper published in 1930, but this work does not seem to have become generally known. The equations developed make it possible to determine the dimensions of a Venturi flume of rectangular section by a direct method, which seems to be much simpler than to solve Equation (14) graphically. Particularly in the case of a rectangular section of both the throat of the flume and the channel, the Jameson method for obtaining the various dimensions is so straightforward that it is the only one to be recommended.

Possibly the accuracy obtained by the authors with their method of calibration would have been greater had they been able to conduct the tests on the Venturi flume in a hydraulic laboratory. The results they obtained by comparing their flume with the Parshall meter are not very convincing, as an accuracy of the order of 5% would appear rather unsatisfactory.

[18] "The Venturi Flume and the Effect of Contractions in Open Channels", by A. H. Jameson, *Transactions*, Inst. of Water Engrs., Vol. 30 (1925).

[19] "The Development of the Venturi Flume", by A. H. Jameson, *Water and Water Engineering*, Vol. 32 (1930), pp. 105 to 107.

To the writer's knowledge, the Parshall meter has not been tested in a hydraulic laboratory and, therefore, its discharge coefficient is not known with sufficient accuracy. The discharge coefficients of the Parshall meter and the design by Messrs. Palmer and Bowlus may have quite different characteristics and it seems a rather doubtful method, therefore, to calibrate one Venturi flume meter against another. The only reliable method of calibration would appear to be either by weighing or by the determination of water-volume passing through the flume in a measured time.

A further point which does not seem very satisfactory is that the calibration only covered a range of Q-values equal to about 1 to 5, whereas a range of about 1 to 8 or 1 to 10 is usually demanded.

* 100 liters per sec = 3.54 cu ft per sec. † 1 cm = 0.3937 in.

It is the opinion of the writer that the Venturi flume meter, if correctly designed, is one of the most accurate of measuring devices, and that it has great advantage in comparison with the weir method.

Table 6 contains some test results on Venturi flume meters obtained during previous investigations[20] in the hydraulic laboratory of the City and Guilds (Engineering) College, in London, England, in 1932. Both the Venturi flumes were installed in a rectangular channel and had a rectangular throat section. The discharge equations used were:

$$Q = \left(\frac{2}{3}\right)^{\frac{3}{2}} C_f \sqrt{g}\; b_3 \left(d_2 + \frac{V_2^2}{2g}\right)^{\frac{3}{2}} \qquad \text{.............(46)}$$

and,

$$Q = \left(\frac{2}{3}\right)^{\frac{3}{2}} C'_f \sqrt{g}\; b_3 d_2^{\frac{3}{2}} \qquad \text{..................(47)}$$

in which C'_f is the product of C_f and the velocity-of-approach factor. Further data may be obtained from the previous publications by the writer[21] on the subject. For the flume with a width ratio of 0.294 (Table 6(*a*)), the average coefficient of discharge is 0.9482 (see Column (6)). The rate of flow was varied over a measuring range of about 1 to 8. It is of interest to note that there is only one test for which the discharge coefficient is more than 0.5% from the average. All the other test results are within the limits of ± 0.5 per cent. For a width ratio of 0.533, the test results of which are given in Table 6(*b*), there are only two test points outside the limit of ± 1%, whereas 19 of the total of 24 were within the limits of ± 0.5%, the average coefficient being 0.9574. Seldom under actual working conditions could an accuracy like this be obtained, but one can assume that the accuracy of a Venturi flume meter in a rectangular channel and using dimensions similar to those used in the writer's investigations, would be in the order of ± 1.5 per cent.

The section entitled "Energy Losses", seems rather misleading. The problem treated only refers to the dissipation of energy in the convergent entrance section and the authors' conclusion is that there is practically no dissipation of energy—a point which is evident from previous research. The more important point regarding the head losses due to the Venturi flume was totally neglected by the authors, whereas this is of the greatest practical value.

In designing Venturi flume meters, it is absolutely necessary to ascertain whether free discharge conditions prevail for certain down-stream conditions. There is a minimum head loss for which the flume will discharge without banking up the up-stream level for a given rate of flow. For a Venturi flume with a width ratio of 0.533, the writer found that in a channel with a horizontal bottom, it was possible to increase the down-stream depth without changing the state of free discharge, to a level corresponding to 92% of the up-stream depth. In a flume of a width ratio of 0.294, however, the down-stream depth was between 74% and 90% of the up-stream depth for the limit of free discharge conditions.

---

[20] "Non-Uniform Flow of Water: Problems and Phenomena in Open Channels with Side Contractions", by F. V. A. Engel, *The Engineer*, Vol. 155 (1933), pp. 392 to 394, 429–430, and 456–457.

[21] "The Venturi Flume", by F. V. A. E. Engel, *The Engineer*, Vol. 158 (1934), pp. 104 to 107 and 131 to 133.

In order to determine head losses, the writer has developed a certain criterion based on the Boussinesq number[21, 22]. The critical Boussinesq number determines the head loss, which may be about 8%, or a value between 10 and 30 per cent. The critical Boussinesq number for the second flume is 0.358, and from this it will be seen that only for Test No. 22 (Table 6(*b*)) will the head loss be greater than 8 per cent. In the case of the flume with the narrow throat, the critical Boussinesq number is 0.147 and from Column (9), Table 6(*a*), it is evident that in all cases, except the last line, the head losses will be greater than 8 per cent.

The critical Froude number determines whether the flume is discharging freely, and the test results are quite in accordance with the critical numbers obtained by calculation. The critical Froude number for the flume with the width ratio of 0.294 is 0.154, referred to the up-stream section, whereas for the second flume, the critical Froude number is 0.296. The last columns of Table 6 show also a characterizing feature of both the Froude and Boussinesq numbers, namely a constant value of the Froude number and a comparatively large variation in the Boussinesq number.

J. C. Stevens,[23] M. Am. Soc. C. E. (by letter).—A very practical application of the use of critical flow for measuring the discharge in conduits is demonstrated in this paper. If critical flow can be produced in a conduit by any kind of constriction whatever, the depth above that constriction immediately becomes a stable index of discharge.

Caution must be observed, however, in designing the control so that it is not submerged for the range of discharges that may obtain. Whenever the tail-water level is more than about 65% of that of the head-water over the crest of the control, the head-water rises with the tail-water and loses its stability as an index of flow. Two depths must then be observed and discharge determination from them becomes more complex and uncertain. Recorders with totalizing equipment also lose their efficacy at this point of submergence.

In circular conduits the writer has used a "hump" control on the bed of the conduit to produce critical flow over it. The flow is readily computed from the criterion that for critical flow the velocity head equals one-half the mean depth. This applies to any shape of conduit whatever as long as width is a continuous function of the depth.

Fig. 18 shows the type of control used in a circular conduit, which is believed to have some advantages over the trapezoidal control used by the authors and certainly involves less energy losses. It is readily constructed of concrete without forms; it may even be pre-cast and placed while the conduit is in service. Fig. 18 also shows the rating curves for five heights of the con-

*A_c = area corresponding to ϵ_c.

the head of each column. A table of areas and chord lengths of circular segments is all that is required. Supplementing the notation used by the authors, let z = maximum height of the control "hump"; Z = area of the control hump at maximum height; $x = 1 - (y_c + z)$; X = area of a segment with a rise of x; y = depths (y_c, critical depth; y_m, mean depth, etc.); Y = area corresponding to depths, y; t = top width of water surface = chord of a segment with a rise of $z + y_c$; h = velocity head (h_c for critical flow, etc.); ε = energy head above the pipe invert; and A = area above the control corresponding to energy head, ϵ. All symbols are expressed in terms of the pipe diameter, D.

The depth, y_1 (see Fig. 18), is obtained by deducting the velocity head at this point from the energy head. The trial method used by the authors can be eliminated by dividing the discharge by the area corresponding to the energy head, to obtain the pipe velocity, V_1. This is shown in the last four columns of Table 7. The error involved from assuming no energy loss from y_1 to y_c and that from using the area corresponding to the energy head, ϵ, tend to compensate each other.

The method of computing the rating curve directly illustrated in Table 7 is equally effective for the trapezoidal control described by the authors.

In large sewers in which only the sanitary flow is to be measured, or at manholes over smaller ones, the equipment illustrated in Fig. 19 has been used very effectively. Two screw struts are held in the sewer by expanding them against the sides of the pipe or the manhole. One strut carries a small platform on which the recorder is mounted. The other supports an adjustable pivot from which trails a float that can be adjusted both up stream and down stream and laterally until it is properly adjusted to connect with the style of the recorder.

A scow-shaped float with a rudder was found to have decided advantages over other types. One advantage of this equipment is the ease with which it can be moved from place to place.

PROF. ING. FILIPPO ARREDI[24] (by letter).—The sole purpose of this discussion is to suggest a variation in the authors' method of calculating discharge for the given case, which is a little different from that described in the paper and, possibly, slightly more practical.

Equations (8) and (10) of the paper apply to the throat section, if the water is assumed to flow at critical velocity. For the section of the channel above the throat Equation (2) applies, in which ϵ and Q have the same values as in the throat, and d and A are the depth of water and the area of the wetted section of the channel, respectively.

The method of calculating the Venturi flume which the authors propose is as follows: Taking a value for d_c, the values of A and B are calculated for the throat, and the values of Q and ϵ are then obtained from Equations (8) and (10). Then, from Equation (2), substituting these values of Q and ϵ, d can be obtained by trial, taking account of the relations between A and d.

---

[24] Asst., Cattedra di Costruzioni Idrauliche, Facoltà d'Ingegneria, R. Univ. di Roma, Rome, Italy.

As it will usually be necessary to study throats of various types in order to make a choice among them, it will also be necessary to make calculations for many values of Q, and considerable work, requiring a large amount of time, may be needed. For this reason, it may perhaps be useful to supplement the authors' method by a graphical device which may prove more rapid in that it does not require "trial-and-error." The relation,

$$\frac{V^2}{2\,g} = \frac{Q^2}{2\,g}\,\frac{1}{A^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(48)$$

applies for both the channel and the throat. If a value is assumed for $\frac{Q^2}{2\,g}$ and arbitrary values are taken for A, the corresponding values of $\frac{V^2}{2\,g}$ may be obtained easily from Equation (48). The computation is repeated for various values of $\frac{Q^2}{2\,g}$. Curves corresponding to each value assumed for $\frac{Q^2}{2\,g}$ are then drawn in a diagram (see Fig. 20) in which the values of $\frac{V^2}{2\,g}$ are ordinates and those of A are abscissas.

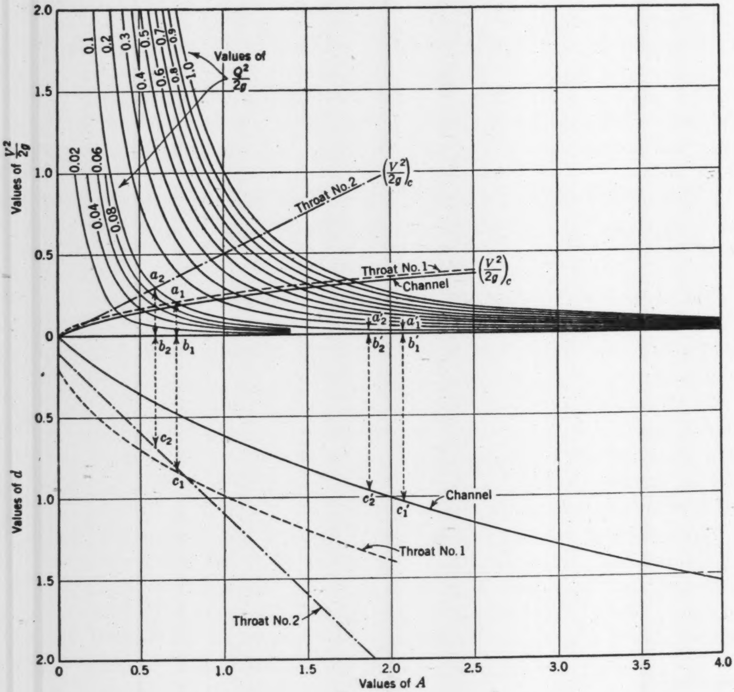

FIG. 20.

Knowing the section of the canal, and assuming the sections of one or more throats, the relation between the values of A and the depth, d, becomes known for each case, d being taken with respect to a common datum. In Fig. 20 the curve that expresses A in terms of d, for either channel or throat, is drawn downward from the zero line.

For critical conditions, the relation,

$$\left(\frac{V^2}{2\,g}\right)_c = \frac{A}{2\,B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49)$$

applies. Assuming values of d_c in the throat, corresponding values of A and B are calculated, and $\left(\frac{V^2}{2g}\right)_c$ is computed by means of Equation (49), and the curve showing $\left(\frac{V^2}{2\,g}\right)_c$ as a function of A can be drawn intersecting the curves already drawn. It may be useful, although not necessary, to draw a similar curve for the channel also (see Fig. 20).

FIG. 21.

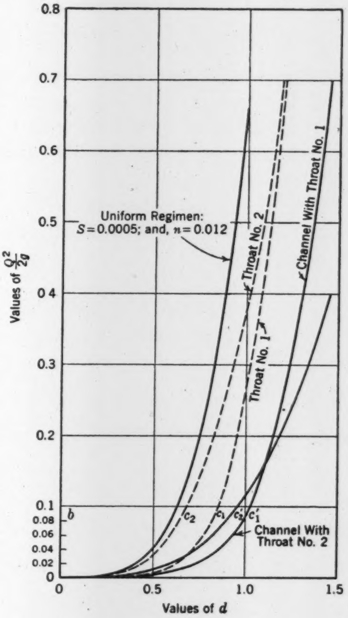

FIG. 22.

Assuming, for example, that a discharge, Q, such that $\frac{Q^2}{2\,g} = 0.1$, flows through Throat No. 1 in the critical condition, it is then easy to see that the ordinate, $a_1\,b_1$, represents the velocity head. In Fig. 20, a_1 is the point of intersection of the $\frac{V^2}{2\,g}$-curve, plotted as a function of A (for $\frac{Q^2}{2\,g} = 0.1$), with the curve of $\left(\frac{V^2}{2\,g}\right)_c$ for Throat No. 1. The dimension, $b_1\,c_1$, represents the depth of water, c_1 being the intersection of the vertical through a_1, with the A-curve plotted in terms of d for Throat No. 1; and the length, $a_1\,c_1$, being the total energy head in the throat.

The next step is then to find a vertical segment, $a'_1\,c'_1$, which will be equal in length to $a_1\,c_1$ and which will have its upper end on the $\frac{V^2}{2\,g}$-curve in terms of A for $\frac{Q^2}{2\,g} = 0.1$, and its lower end on the d-curve in terms of A for the channel. Then, $a'_1\,b'_1$ will be the velocity head, $b'_1\,c'_1$, the depth of water, and $a'_1\,c'_1$, the total energy head above the throat. In a similar manner, it is seen that the segment, $b_2\,c_2$, represents the depth of water in the throat and $b'_2\,c'_2$, the depth of water in the channel, if the same discharge flows through Throat No. 2 in the critical condition, $a'_2\,c'_2$ being equal to $a_2\,c_2$.

It is evident that the curve of $\frac{V^2}{2\,g} = f(A)$ for any constant, $\frac{Q^2}{2\,g}$, will be the same, whatever the channels and throats may be. The other curves in Fig. 20 were drawn by assuming channels and throats such as those in Fig. 21. The depth, d, is always referred to the plane through the channel bottom, at a given section. The detailed formulas by which these curves were computed are not reported.

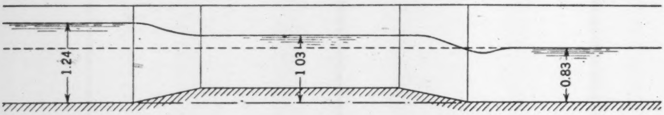

FIG. 23.—PROFILE, THROAT NO. 1; $\frac{Q_2}{2\,g} = 0.3$.

In order, rapidly, to sketch the profiles of the water surface in the flume, it will be useful to make diagrams such as those in Fig. 22, in which the values of $\frac{Q^2}{2\,g}$ are entered as ordinates and the values of d (computed as described previously), as abscissas. The curves of $\frac{Q^2}{2\,g}$, as a function of d, are drawn for the throats and the channel above the throat. Then, in Fig. 22, at $\frac{Q^2}{2\,g} = 0.1$, are recorded the ordinates, bc_1, bc_2, bc'_1, bc'_2, obtained from Fig. 20, which represent the depth, d, for Throats Nos. 1 and 2 and for the water in the channel above either Throat No. 1 or Throat No. 2. By varying $\frac{Q^2}{2\,g}$, it becomes possible to obtain a sufficient number of points to trace such curves.

It will also be useful to draw the curve of $\frac{Q^2}{2\,g}$ as a function of d for the uniform regimen that is present below the throat. In Fig. 22, this curve has been drawn on the basis of Manning's formula, assuming a slope, $S = 0.0005$ and $n = 0.012$. Fig. 23 represents a profile with Throat No. 1, relative to a discharge, Q, such that $\frac{Q^2}{2\,g} = 0.3$, the values for d of 1.24 above the throat, 1.03 at the throat, and 0.83 below the throat having been obtained from Fig. 22.

By the same method by which the curves of d were drawn in Fig. 22, it is easy to draw those for ϵ as a function of the $\frac{Q^2}{2\,g}$- curves which may be considered equal to those drawn by the authors in Figs. 8 and 10. It would then be easy to select from the throats studied the one best adapted to a particular case, more satisfactorily than under the conditions recorded by the authors in their paper.

HAROLD K. PALMER,[25] M. AM. SOC. C. E. AND FRED D. BOWLUS,[26] ASSOC. M. AM. SOC. C. E. (by letter).—From the many constructive discussions received, the writers are encouraged to hope that, more and more, water will be measured by Venturi flumes developing critical depths. Especially will this be true when more accurate verification can be obtained, in hydraulic laboratories, of some of the principles involved, and more simplified calculations of flow can be made, as suggested by some of the discussers.

Mr. Hopkins has developed excellent formulas for calculating co-ordinates on the quantity-energy head curves. Since these curves form the basis of all Venturi flume rating curves, the writers suggest that all notations referring to the frictional loss, varying with the shape of the throat, and to velocity head, varying with the velocity, be omitted from the terms of the formulas offered by Mr. Hopkins. This would mean substituting ε for Z in his formulas. In order that these may be readily available, the formulas for the more common throat sections are summarized as follows: For a flume of rectangular cross-section, Equation (26) becomes:

$$Q = 3.09\ b\ \varepsilon^{1.5} \qquad \text{(50)}$$

for a flume of V-shaped cross-section, Equation (28) becomes:

$$Q = 2.297\ p\ \varepsilon^{2.5} \qquad \text{(51)}$$

and, for a flume of trapezoidal cross-section, Equation (31) becomes:

$$Q = 3.06\ (b + 0.72\ p\ \varepsilon)\ \varepsilon^{1.5} \qquad \text{(52)}$$

Professor Arredi has suggested a most welcome graphical method of determining the proper size for a Venturi flume throat in any given installation and for drawing the rating curve, thus obviating the more laborious method advanced by the writers.

---

[25] Chf. Draftsman, Los Angeles County Sanitation Dists., Los Angeles, Calif.

[26] Res. Engr., Los Angeles County Sanitation Dist. No. 2, Whittier, Calif.

Mr. Stevens describes a slab, curved in longitudinal section (which he has already used in circular conduits), based on somewhat the same principle as that of the writers. This would probably add some refinement by reducing frictional losses which, however, might be smaller than the recording device could register. The writers believe that the insertion of a level section in the bottom slab will be positive assurance that critical depth is obtained with parallel flow, as proved by their early experiments. They do not agree with Mr. Stevens as to the preference of the simple flat slab over the trapezoidal form of throat. The Los Angeles County Sanitation Districts had a 6-in. slab with a 3-ft level section (6 ft including transitions), installed in a 54-in. sewer, but found it necessary to change to a trapezoidal flume for greater accuracy. One difficulty with a slab is that a thickness required to give good results during peak flows may cause deposits of silt or sludge at low flows. For very small flows in a sewer, a flume with side contractions and no bottom slab would be better.

The writers also disagree with Mr. Stevens' statement that whenever the depth of tail-water below the throat of a Venturi flume is more than 65% of that above the throat, correct calculations of the flow can be obtained only by recording depths at the two points. The writers have recently been able to investigate this point by installing a flume in an irrigation ditch of the Arroyo Ditch and Water Company (see Fig. 24), and believe that within the range of accuracy of a recorder the flow can be calculated from a single head-water depth above the flume when the tail-water depth is approximately 90% of the head-water depth. Dr. Engel has found this percentage to be as high as 92. A simple analysis of losses and depths of flow through a rectangular Venturi flume installed in a conduit with a grade so flat as to cause a low velocity, tends to substantiate the correctness of the latter figure (92%). In this case the depth of water in the throat at the point of critical velocity is practically two-thirds the head-water depth, or the velocity head equal to one-third the head-water depth (neglecting the small velocity head above the throat). As the water passes from the restricted throat section into the normal cross-section of the conduit below the flume, a condition obtains similar to that in a pipe enlargement, in which case it is the usual practice to consider that the loss is 25% of the difference in velocity heads. Neglecting the slight velocity head of the tail-water, only 25% of the velocity head in the throat would be lost, or one-twelfth the total energy head. This amounts to 8% and thus would leave the tail-water depth at about 92% of the head-water depth.

The writers have observed also that if the jump, or undulations, occur in the transition section below the throat, there is no effect on the water depth above the meter, but when the undulations occur in the throat and are backed up to a point near the section of critical depth, the head-water depth may be affected. It is best, therefore, to design the throat so that the jump will occur in the lower transition, or with the tail-water depth less than 90% of the head-water depth.

The writers are indebted to Mr. Stevens for the details of his float mechanism which should give accurate readings without being affected by floating débris.

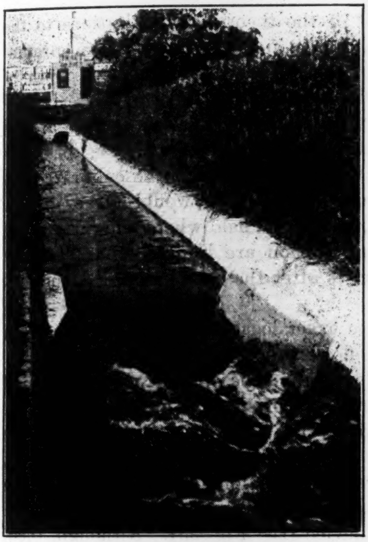

FIG. 24.—VENTURI FLUME IN WHICH JUMP OCCURS BELOW THROAT WITH NO APPARENT BACK-WATER EFFECT. VELOCITY ABOVE THROAT IS ABOUT 2.5 FEET PER SECOND, RESULTING IN SURFACE WAVES.

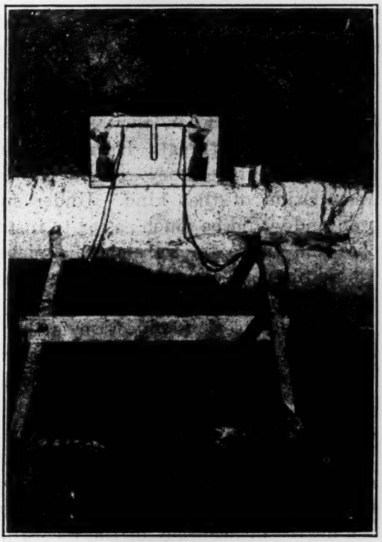

FIG. 25.—DIFFERENTIAL HEAD METER SET TO REGISTER LOSS OF HEAD AT ENTRANCE TO FLUME. IN THIS CASE LOSS WAS 0.01 FOOT FOR 10 CUBIC FEET PER SECOND.

Dr. Engel claims, in his English experiments, an accuracy for Venturi flumes of 99.5%, but unfortunately in the two cases for which he published the data, the water did not flow at critical depths in the throat and, therefore, the results are not applicable to the present case. The accuracy attained seems to vary inversely as some power of the velocity above the throat. Dr. Engel questions the accuracy of the Parshall meter, but in the United States it is generally accepted as a standard method of measuring water, and the device has been legalized by the Division of Water Rights of the California Department of Public Works. The writers have apparently been misunderstood in the test comparison with the Parshall meter. As the wooden Venturi flume was installed in an irregular channel the comparative results with the Parshall meter were only submitted to show the general adaptability of the flume throughout a considerable range in flow, in a sewer where it would have been impossible to have installed a weir. Dr. Engel states that the important point regarding losses due to the installation of a Venturi flume in a conduit has been entirely neglected by the writers. In the writers' method of computing a rating curve, the loss of energy up stream from the throat affects the rating curve, whereas the loss down stream has no effect as long as it does not cause a backing up of the water. In the formula for the Venturi flume as given by Dr. Engel, the loss of head up stream is taken care of in the constant, C_f, but it is probably a function of the length of the throat and flow, being negligible for smaller throats and also for small flows.

Mr. Rouse has ably discussed several of the theoretical limitations to the proposed method of using these flumes, which apply in cases where circumstances permit more than the ordinary accuracy of measuring the depth of water, or in very large installations. The writers had some of these limitations in mind when they suggested measuring the loss of energy at the entrance to the throat. He rightly questions its suitability as a control meter in hydraulic laboratory experiments as it would be necessary to calibrate each installation of that kind. Under such cases the weir would serve just as well and would be much easier to install, but in the field where allowable grade loss and funds for an elaborate metering station are limited, and especially where the need for measuring the flow arises after the completion of a conduit, the Venturi flume appears superior.

His most serious objection is that the exact location of the critical depth section is unknown, and varies with the flow; this is true, but it is the minimum energy rather than the critical depth that the writers use; and small variation from critical depth, or some curvature of surface, may occur without an appreciable effect on the energy-head depth. There is a difference in the height of the energy head at the control section in the throat and the point of measurement, depending on the hydraulic conditions in this section of the conduit; but it is small and can be measured easily and allowed for within the degree of accuracy of the recording device (see Fig. 25). Although, theoretically, it is a drawback, practically the error is less than the sensitivity of the recording devices now available.

The following case illustrates some of the difficulties met in field installations. In a 24-in. trapezoidal flume set in a 54-in. sewer having a grade of 0.15%, a flow averaging 21.5 cu ft per sec produced a record with a blurred line nearly 0.25 in. in width, due to small surface waves superimposed on longer waves with a period of a minute or more. The flow varied from 20.6 to 22.4 cu ft per sec and the mean could be obtained only by estimating the middle of the trace.

Mr. Rouse takes exception to the writers' attempt at measuring flow over a great range by the method proposed. This difficulty is one which must be met in sewage-flow measurements where the daily maximum may be three times the minimum, and during a storm a much greater range is to be expected. If the sewerage system is growing, the daily maximum ten years hence may easily be ten times the minimum of to-day. In storm drains the flow is even more erratic. This precludes the use of the hook-gauge for measuring depths and substitutes the stage recorder; therefore, in considering the degree of accuracy to be attained, it must be borne in mind that refinements too small to be shown on the record need not be considered.

Mr. Rouse feels that this investigation should have been performed in a laboratory, with which the writers fully agree, but no laboratory was available, and there was great need of finding some method of installing meters in constructed sewers where weirs had been found inadequate. After the investigation had developed a practical meter, it was discussed with other engineers in the Southwest who showed great interest in it and urged that discussions and results be published at once. The writers are confident that flumes carefully constructed in accordance with their recommendations will give accurate results.

However, it is hoped that laboratory work will be undertaken to investigate some of the following uncertain points: (*a*) Proper length of throat; (*b*) formula for energy loss in head-water; (*c*) maximum ratio of tail-water depth to head-water depth; (*d*) proper angle of transition to axis of conduit; and, (*e*) accuracy of measurement as a function of velocity of approach.

THE STRESS FUNCTION AND PHOTO-ELASTICITY APPLIED TO DAMS

By John H. A. Brahtz,[1] Esq.

With Discussion by Messrs. I. K. Silverman, Fred L. Plummer, Arshag G. Solakian, Lars R. Jorgensen, Elmer O. Bergman, D. P. Krynine, and John H. A. Brahtz.

Synopsis

The object of Part I of this paper is to familiarize engineers with the use of the Airy stress function for the solution of problems in plane stress and plane strain when ordinary engineering methods fail to give even approximate results.

The object of Part II is to familiarize the engineer with the photo-elastic phenomenon and its application to civil engineering structures and to compare results obtained in this way with the theoretical results obtained in Part I.

A brief popular outline of the theory, accompanied by a description of the apparatus developed at the California Institute of Technology, at Pasadena, Calif., is given. Methods of evaluating stresses are explained and applied to experiments on Morris Dam.

Introduction

Ordinarily, the theory of the Airy function found in textbooks[2] is based on the assumption that body forces (weight and inertia) can be neglected. This is entirely inadequate in civil engineering structures in which the stresses due to weight often are greater than those caused by boundary forces. Furthermore, in texts in which the body forces are included the definitions of stresses are generally such that the form of the function is not invariant to a change in co-ordinates. The stress definitions given herein, including both

---

Note.—Published in September, 1935, *Proceedings*.

[1] With the U. S. Bureau of Reclamation, Denver, Colo.

[2] See, for example, "Applied Elasticity", by J. Prescott.

boundary and body forces, are such that the stress function will be of the same form in rectangular and polar co-ordinates.[3]

The stress function is restricted to isotropic materials which follow Hooke's law in both compression and tension. It may also be applied, however, to concrete masonry structures if the resulting stresses are those of compression, or very slight tension, even if the elastic constants are not strictly constant for all stresses. It is generally conceded that a slight variation in the elastic modulus has little effect on the final stress distribution, except, of course, at singular points or at points of high stress concentration. With these assumptions the stress function may then be applied to a slice of a gravity dam. The question of uplift is not considered in this treatment, but it is assumed: (1) That there is sufficient resultant average compression at all points of the dam to overcome any internal pore pressures that may exist; and (2) that the pores are so small that the average stress distribution at a point may still be found as in isotropic material.

This paper, together with theoretical and experimental work done by others, shows that for purposes of analysis the triangular gravity dam on an elastic foundation may be divided conveniently into three regions: (1) The upper two-thirds of the dam proper; (2) the lower one-third, including the base region of the foundation; and (3) the foundation proper. Finally, special investigation must be made in the regions close to the heel and toe whether they are sharp corners or fillets, and near the crown. In the present application, stress functions have been derived for four cases and a twofold purpose is served: (*a*) To show the methods of deriving stress functions; and (*b*) to obtain specific results applicable to the gravity dam on an elastic foundation. In most cases the derivations have been omitted, due to the limitation of space. The original manuscript is on file in Engineering Societies' Library, in New York, N. Y., and at the California Institute of Technology, at Pasadena, Calif.

Application I.—The stress functions, stresses, and deflections valid in the upper part of triangular dams are derived for hydrostatic, and are given for body, forces with computed results plotted in the case of Morris Dam. In addition, the stress functions are given for a number of special loadings.

Application II.—The stress functions applicable in the foundation are given with stresses and deflections for concentrated and distributed loads, the computed results being plotted for a study of Grand Coulee Dam.

Application III.—The "corner-function" applicable at sharp re-entrant corners is derived. Two methods of procedure are given for the determination of stresses in the lower part of gravity dams. The results are plotted for a study of Grand Coulee Dam.

Application IV.—An approximate method is derived for the determination of stresses at re-entrant sharp and rounded corners. Examples are computed for Morris Dam.

It should be emphasized that even if the gravity dam is used for illustrative examples of application, the aim is not to advance new design criteria. The writer hopes, however, that the methods described will help to obtain a closer estimate of the stresses that actually occur. It is worthy of note that a state of stress computed by the Airy stress function is in equilibrium and compatible with Hooke's generalized law.

[3] "Notes on the Airy Stress Function", by John H. A. Brahtz, *Bulletin*, Am. Math. Soc., June, 1934.

ACKNOWLEDGMENT

Acknowledgment is freely given to Theodor von Kármán, Elwood Mead, S. B. Morris, J. L. Savage, and R. F. Walter, Members, Am. Soc. C. E., and to Professor H. Bateman, of the California Institute of Technology, Pasadena, Calif., for their valuable suggestions and co-operation in the preparation of this paper. The photo-elastic experiments on Morris Dam were made possible through the financial support of the Pasadena Water Department.

PART I.—THE THEORY OF THE AIRY STRESS FUNCTION

In this section the stress function is defined in rectangular and polar co-ordinates. Convenient forms of boundary conditions are treated.

A two-dimensional elastic system under plane stress or plane strain is in equilibrium if the stress components are defined as follows:

By rectangular co-ordinates:

$$\sigma_x = \frac{\partial^2 F}{\partial y^2} - g_x\, x - g_y\, y \ldots\ldots\ldots\ldots (1a)$$

$$\sigma_y = \frac{\partial^2 F}{\partial x^2} - g_x\, x - g_y\, y \ldots\ldots\ldots\ldots (1b)$$

and,

$$\tau_{x,\,y} = -\frac{\partial^2 F}{\partial x\, \partial y} \ldots\ldots\ldots\ldots (1c)$$

in which σ_x and σ_y = components of normal stress parallel to the X-axis and the Y-axis, respectively; $\tau_{x,\,y}$ = shear stress in the direction of the X-axis or the Y-axis; F = a stress function; and g = the total body force per unit volume, with components, g_x and g_y along the X and Y-axes.

In the polar co-ordinates:

$$\sigma_r = \frac{\partial^2 F}{r^2\, \partial \theta^2} + \frac{\partial F}{r\, \partial r} - gr \cos\,(\theta - \beta) \ldots\ldots\ldots\ldots (2a)$$

$$\sigma_\theta = \frac{\partial^2 F}{\partial r^2} - gr \cos\,(\theta - \beta) \ldots\ldots\ldots\ldots (2b)$$

and,

$$\tau_{r,\,\theta} = -\frac{\partial}{\partial r}\left(\frac{\partial F}{r\, \partial \theta}\right) \ldots\ldots\ldots\ldots (2c)$$

If, now, F is so restricted that it is a solution to the differential equation:

$$\nabla^4 F \equiv \frac{\partial^4 F}{\partial x^4} + 2\,\frac{\partial^4 F}{\partial x^2\, \partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \ldots\ldots\ldots\ldots (3a)$$

or,

$$\nabla^4 F \equiv \left(\frac{\partial^2}{\partial r^2} + \frac{\partial}{r\, \partial r} + \frac{\partial^2}{r^2\, \partial \theta^2}\right)^2 F = 0 \ldots\ldots\ldots\ldots (3b)$$

the stress defined in Equations (1) and (2) will also be compatible with the generalized Hooke's law. Problems in plane stress or plane strain have thus been reduced to the determination of the functions, F, that satisfy Equations (3) and such that the stresses determined by Equations (1) or Equations (2) agree with the given force distributions over the boundaries of the structure. The first part is very simple because it can be verified that both the real and imaginary parts of the expression:

$$F = A_1 f_1 (z) + A_2 x f_2 (z) + A_3 y f_3(z) + A_4 r^2 f_4 (z) \ldots\ldots\ldots (4)$$

satisfy Equations (3). A_1, A_2, A_3, and A_4 are arbitrary constants; f_1, f_2, f_3, and f_4 are arbitrary analytic functions of the complex variable, $z = x + i\,y$; $r^2 = x^2 + y^2$; and $i = \sqrt{-1}$.

The second part of the problem (to satisfy the boundary conditions) is usually difficult, and must be solved for each individual case. It is important to realize that as soon as the stress function is known the stresses are also known at all points by Equations (1) or Equations (2).

BOUNDARY CONDITIONS

Referring to Fig. 1 the boundary conditions to be satisfied by $F(x, y)$ may be formulated in terms of well-known engineering concepts, as follows: Let the area enclosed by the hatched boundary curve represent a plane elastic body of unit thickness, held in equilibrium by a system of forces, P_n (concentrated or continuously distributed), acting on the boundary, ABC, and body forces, g, per unit volume; g_x and g_y = components of g along the co-ordinate axes; and H and V = the forces along the X-axis and Y-axis per unit length of the boundary.

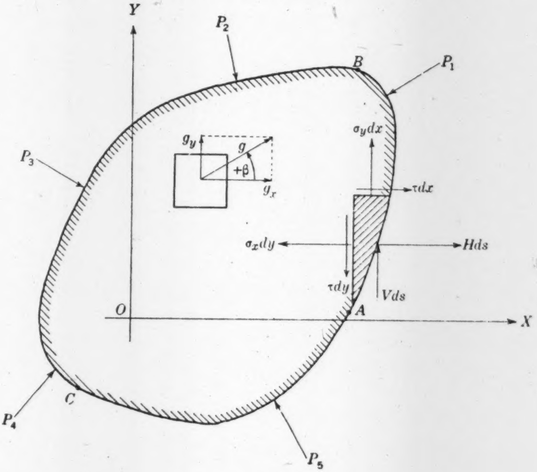

FIG. 1.

Consider an element, ds, at the boundary with co-ordinates (x, y). It is in equilibrium under the stresses and the boundary forces, $H\,ds$ and $V\,ds$, (Fig. 1). By projecting all forces on the co-ordinate axes and taking moments about a point, B, of the boundary with co-ordinates, $x_B\, y_B$, the conditions of equilibrium are:

$$\sigma_x\, dy - \tau\, dx = H\, ds \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

$$\sigma_y\, dx - \tau\, dy = -V\, ds \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

and,

$$(\sigma_x\, dy - \tau\, dx)\,(y_B - y) + (\sigma_y\, dx - \tau\, dy)\,(x_B - x) = dM \ldots (5c)$$

in which dM indicates the moment of $H\,ds$ and $V\,ds$ about Point B, positive in direction (counter-clockwise about Point O, Fig. 1). The body forces of the element are of higher order of magnitude and need not be considered.

By substituting the stresses as defined by Equations (1) and integrating the equations from Point A, Fig. 1, along the boundary in the positive direction to Point B, the following equations are obtained:

$$\left(\frac{\partial F}{\partial y}\right)_B - \left(\frac{\partial F}{\partial y}\right)_A = X + g_x \int_A^B x\, dy + g_y \int_A^B y\, dy \ldots\ldots (6a)$$

$$\left(\frac{\partial F}{\partial x}\right)_B - \left(\frac{\partial F}{\partial x}\right)_A = -\, Y + g_x \int_A^B x\, dx + g_y \int_A^B y\, dx \ldots (6b)$$

and,

$$F_B - F_A - (x_B - x_A)\left(\frac{\partial F}{\partial x}\right)_A - (y_B - y_A)\left(\frac{\partial F}{\partial y}\right)_A$$

$$= M + \int_A^B (x g_x + y g_y)\Big[(x_B - x)\, dx + (y_B - y)\, dy\Big] \ldots\ldots\ldots\ldots (6c)$$

in which X and Y are the projections along the X-axis and Y-axis; and M = the moment about B of all boundary forces between A and B. By a suitable choice of co-ordinate axes Equations (6) can be simplified somewhat. From the definition of the stresses in Equations (1), etc., it follows that a constant and terms that are linear in x and y, added to the stress function, contribute no stress. Therefore, by choosing the origin at Point A, Fig. 1, it is always possible to arrange matters so that $F_A = \left(\frac{\partial F}{\partial x}\right)_A = \left(\frac{\partial F}{\partial y}\right)_A = 0$. The boundary equations then become:

$$\left(\frac{\partial F}{\partial y}\right)_B = X_B + g_x \int_0^B x\, dy + \frac{1}{2}\, g_y\, y^2_B \ldots\ldots\ldots\ldots (7a)$$

$$\left(\frac{\partial F}{\partial x}\right)_B = -\, Y_B + \frac{1}{2}\, g_x\, x^2_B + g_y \int_0^B y\, dx \ldots\ldots\ldots (7b)$$

and,

$$F_B = M_B + g_x \int_0^B (y_B - y)\, x\, dy + g_y \int_0^B (x_B - x)\, y\, dx$$

$$+ \frac{1}{6} x^3_B\, g_x + \frac{1}{6} y^3_B\, g_y \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7c)$$

In the definitions of X_B, Y_B, and M_B, it must be remembered that the integrations are to be carried out from the origin (Point A, Fig. 1) in the positive (X-Y) direction. Hence, if Point B is located in the negative direction from the origin, the signs of X_B, Y_B, and M_B, as defined in connection with Equations (6), must be reversed, exactly as in taking moments, thrust, and shear at a section of a beam in bending. This formulation of the boundary conditions will be found especially useful when approximate solutions are desired; that is, in case the boundary conditions are to be satisfied only at a few points.

In exact solutions (that is, if the boundary conditions can be satisfied at all points of the boundary), only two of the three sets of formulas Equations (5), (6), and (7) need to be considered, the third will be satisfied automatically. If no body forces exist (that is, if $g_x = g_y = 0$) Equations (5), (6), (7) become especially simple and instructive. In this case the following simple interpretations of the stress function, F_P, and its partial derivatives $\frac{\partial F}{\partial x}$ and $\frac{\partial F}{\partial y}$, are evident by Equations (7).

The value of F_P (the stress function for the given boundary forces) at any point, B, of the boundary is equal to the moment of all forces acting on the boundary between the origin and Point B. The value of $\frac{\partial F_P}{\partial y}$ at Point B is equal to the projection on the X-axis of the same forces and $\frac{\partial F_P}{\partial x}$ equals the negative projection on the Y-axis.

It is often convenient to determine two functions, F_P and F_g, the first representing the boundary forces and the second the body forces; then, $F = F_P + F_g$. If no mass forces exist the boundary conditions can be given a simple form on the portions of the boundary where no forces are acting, namely:

$$F = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8a)$$

and, the derivative normal to the boundary,

$$\frac{\partial F}{\partial n} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

When the stress function, F, is known, the displacements, u, parallel to the X-axis, and v, parallel to the Y-axis, can be determined in the case of plane stress by the expressions:

$$E\, u = -\,(1 + \mu)\,\frac{\partial F}{\partial x} - \frac{1 - \mu}{2}\,(g_x\, x^2 - g_x\, y^2 + 2\, g_y\, x\, y) + f_1 + A\, y + B \,..(9a)$$

and,

$$E\,v = -(1+\mu)\,\frac{\partial F}{\partial y} - \frac{1-\mu}{2}\,(g_y\,y^2 - g_y\,x^2 + 2\,g_x\,x\,y) + f_2 - A\,x + C\,. \tag{9b}$$

in which, E is Young's modulus; μ is Poisson's ratio; f_1 = real part of $\int f(z)\,dz$; f_2 = imaginary part of $\int f(z)\,dz$; and, $f(z)$ is the analytic function of the complex variable:

$$z = x + i\,y = r\,e^{i\theta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{10}$$

such that $\nabla^2 F$ = the real part of $f(z)$. The constants A, B, and C in Equations (9) determine the reference axis for u and v and only effect a solid-body rotation and translation.

In polar co-ordinates the radial and tangential displacements, u_r and v_θ, are given by:

$$E\,u_r = -(1+\mu)\,\frac{\partial F}{\partial r} - \frac{1-\mu}{2}\,g\,r^2 \cos(\theta - \beta) + f'_1 + B\cos\theta + C\sin\theta\,. \tag{11}$$

and,

$$E\,v_\theta = -(1+\mu)\,\frac{\partial F}{r\,\partial\theta} - \frac{1-\mu}{2}\,g\,r^2 \sin(\theta - \beta) + f'_2 + A\,r$$
$$+\,C\cos\theta - B\sin\theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{12}$$

in which f'_1 = real part of $e^{-i\theta}\int f(z)\,dz$; f'_2 = imaginary part of $e^{-i\theta}\int f(z)\,dz$; and, $f(z)$ is defined as in connection with Equations (9). In Equations (11) and (12), the constants, A, B, and C, have the same meaning as in Equations (9). If no mass forces occur, $g = 0$. Displacements in the case of plane strain are found by Equations (9), (11), and (12), by replacing E with $\frac{E}{1-\mu^2}$ and μ with $\frac{\mu}{1-\mu}$.

Application I.—Stresses in the Upper Part of Triangular Gravity Dams

In order to indicate the general procedure for determining the stress function in the case of two-dimensional structures for a given loading the case of the infinite wedge with hydrostatic pressure on one side, and no body forces, will be developed in some detail. The solution was first offered by M. Levy.[4]

Assume the hydrostatic pressure on the up-stream face, $y = 0$, to be p at a unit distance from the top measured along the face; then, by Equations (1) with $y = 0$, the boundary conditions are (remembering that no mass forces occur so that $g_x = g_y = 0$):

$$\sigma_y \equiv \frac{\partial^2 F}{\partial x^2} = -\,p x \ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{13}$$

---

[4] *Comptes Rendus*, Vol. 127, 1898, pp. 10–15.

and,

$$\tau \equiv - \frac{\partial^2 F}{\partial x \, \partial y} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

When $y = x \tan \gamma = x K$; and, therefore, $\frac{dy}{dx} = K$: By Equations (5*a*) and (5*b*) (remembering that no boundary forces exist on the rear face):

$$\frac{\partial^2 F}{\partial y^2} K + \frac{\partial^2 F}{\partial x \, \partial y} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

and,

$$\frac{\partial^2 F}{\partial x^2} \frac{1}{K} + \frac{\partial^2 F}{\partial x \, \partial y} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15b)$$

It is evident that the polynomial,

$$F_p = A x^3 + B y^3 + C x^2 y + D x y^2 \ldots\ldots\ldots\ldots\ldots (16)$$

satisfies Equations (3), and, therefore, F_p is an Airy stress function. If the arbitrary constants A, B, C, and D, can be determined such that the boundary conditions are satisfied, Equation (16) is the solution.

By substitution of F_p into Equations (13) and (14) and with $y = 0$: $6 A x = - p x$. Consequently, $A = \frac{-p}{6}$; $-2 C x = 0$; and, $C = 0$. By substitution of F_p into Equations (15) and with $y = K x$; $6 B x K^2 + 4 D x K = 0$; $- \frac{p x}{K} + 2 D x K = 0$; $B = - \frac{p}{3 K^3}$; and $D = + \frac{p}{2 K^2}$.

With these values of A, B, C, and D, introduced into Equation (16) the stress function for the hydrostatic forces becomes:

$$F_p = - \frac{p}{6 K^3} (x^3 K^3 + 2 y^3 - 3 x y^2 K) \ldots\ldots\ldots\ldots (17)$$

By the definitions expressed as Equations (1), with $g_x = g_y = 0$, the stresses are:

$$\sigma_x = \frac{p}{K^3} (x K - 2y) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (18a)$$

$$\sigma_y = - p x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18b)$$

and,

$$\tau = - \frac{p}{K^2} y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18c)$$

The displacements corresponding to Equation (17) are derived in some detail in order to illustrate the use of the general equations (9); thus: $\frac{\partial F_p}{\partial x} = - \frac{p}{2 K^3} (K^3 x^2 - K y^2)$; $\frac{\partial F_p}{\partial y} = - \frac{p}{K^3} (y^2 - K x y)$; and,

$$\nabla^2 F \equiv \frac{\partial^2 F}{\partial x^2} + \frac{\partial^2 F}{\partial y^2} = \frac{p}{K^3} (x K - x K^3 - 2 y) \equiv a x + b y$$

in which $a = \frac{p}{K^3}(K - K^3)$; and, $b = -\frac{2p}{K^3}$. Referring to Equation (10), $\nabla^2 F$ = real part of $f(z) = f(x + i\,y)$. Hence, $f(z) = az - ibz = (a - ib)z$; and,

$$\int f(z)\,dz = \frac{1}{2}(a - ib)\,z^2 = \left[\frac{a}{2}(x^2 - y^2) + bxy\right] + i\left[axy - \frac{b}{2}(x^2 - y^2)\right] \quad\ldots\ldots\ldots\ldots(19)$$

Then, referring to Equations (9), $f_1 = \frac{a}{2}(x^2 - y^2 + bxy$ = real part of Equation (19); and, $f_2 = axy - \frac{b}{2}(x^2 - y^2)$ = imaginary part of Equation (19). Substituting these quantities into Equations (9):

$$u = \frac{p}{2\,E_1\,K^3}\left[(1 + \mu_1)(K^3 x^2 - Ky^2) + (K - K^3)(x^2 - y^2) - 4xy + 2\,Ay + B\right] \quad\ldots\ldots\ldots\ldots(20a)$$

and,

$$v = \frac{p}{E_1 K^3}\left[(1 + \mu_1)(y^2 - Kxy) + x^2 - y^2 + (K - K^3)\,xy - Ax + C\right] \quad\ldots(20b)$$

In Equations (20) E_1 and μ_1 are Young's modulus and Poisson's ratio, respectively, for the dam in case of plane stress ($\sigma_z = 0$). In case of plane strain, E_1 and μ_1 are found, as explained in connection with Equations (11) and (12).

Mass Forces.—Let the components of the mass forces (weight and earthquake forces) be g_x and g_y along the X-axis and Y-axis, and assume that no forces are acting on the faces of the dam. It may be verified that the function:

$$F_g = \frac{1}{6K^2}\left[g_x K^2 x^3 + (g_x K + g_y K^2 - 2\,g_y)y^3 + 3\,g_y K\,xy^2\right] \quad\ldots(21)$$

will satisfy the boundary conditions expressed by Equations (5) or Equations (7). By Equations (1) the stresses are:

$$\sigma_x = \frac{1}{K}\left[(g_y - g_x K)\,x + \left(g_x - \frac{2g_y}{K}\right)y\right] \quad\ldots\ldots\ldots(22a)$$

$$\sigma_y = -g_y\,y \quad\ldots\ldots\ldots\ldots(22b)$$

and,

$$\tau = -\frac{yg_y}{K} \quad\ldots\ldots\ldots\ldots(22c)$$

The displacements corresponding to Equation (21) are found by substituting,

$$\frac{\partial F_g}{\partial x} = \frac{1}{2K}\,(K g_x\, x^2 + g_y\, y^2) \qquad (23a)$$

$$\frac{\partial F_g}{\partial y} = \frac{1}{2K^2}\,[(g_x K + g_y K^2 - 2g_y)\, y^2 + 2K\, g_y\, x\, y] \qquad (23b)$$

$$f_1 = \frac{1}{2\,K}\,(K g_x + g_y)\,(x^2 - y^2) + \frac{1}{K^2}\,(K g_x + K^2 g_y - 2\,g_y)\,xy \qquad (23c)$$

and,

$$f_2 = \frac{1}{K}\,(K g_x + g_y)\,xy - \frac{1}{2K^2}\,(K g_x + K^2 g_y - 2 g_y)\,(x^2 - y^2) \qquad (23d)$$

into Equations (9).

It will be seen by Equations (18) and (22) that all stresses are linear along any straight line in the triangular dam of infinite height. This agrees with the assumptions of engineering practice. It will be shown subsequently that this is not true near the base in a dam of finite height.

The boundary stresses computed by Equations (17) and (21) for Morris Dam, in California, are plotted in Fig. 2.

FIG. 2.—PRINCIPAL STRESSES ALONG BOUNDARY.

Additional Solutions in Polar Co-Ordinates[5] *for the Triangular Dam of Infinite Height.*—Simple expressions are obtained when the bisector of the top angle, $\gamma = 2\alpha$, is chosen as the X-axis, and the Y-axis is positive down stream; as, for example:

(1) When the full hydrostatic pressure, pr, is exerted on the up-stream face, and with no forces on the down-stream face:

$$F_p = \frac{pr^3}{24}\left[(3\sin^2\alpha - \sin^2\theta)\,\frac{\sin\theta}{\sin^3\alpha} - (3\cos^2\alpha - \cos^2\theta)\,\frac{\cos\theta}{\cos^3\alpha}\right]$$

---

[5] For greater detail refer to Carothers' "Plain Strains in a Wedge, with Applications for Masonry Dams", *Proceedings*, Royal Soc., Edinburgh, Vol. 53 (1913), pp. 292–308.

(2) When a uniform pressure, p, is exerted on both faces:

$$F = -\frac{1}{2}\,pr^2 \quad \ldots\ldots (24)$$

(3) When a uniform pressure, p, is exerted on the up-stream face and uniform tension, p, is exerted on the down-stream face:

$$F = \frac{pr^2\,(\sin 2\theta - 2\theta \cos 2\alpha)}{2\,(\sin 2\alpha - 2\alpha \cos 2\alpha)} \quad \ldots\ldots (25)$$

(4) When a uniform pressure is exerted on the up-stream face, with no force on the down-stream face:

$$F = \frac{1}{4}\,pr^2\,\frac{\sin 2\theta - \sin 2\alpha - (2\theta - 2\alpha)\cos 2\alpha}{\sin 2\alpha - 2\alpha \cos 2\alpha} \quad \ldots\ldots (26)$$

(5) With a pressure, pr, on the up-stream face and tension, pr, on the down-stream face:

$$F = \frac{pr^3}{6}\,\frac{\cos\alpha \sin 3\theta - 3\cos 3\alpha \sin\theta}{\cos\alpha \sin 3\alpha - 3\cos 3\alpha \sin\alpha} \quad \ldots\ldots (27)$$

(6) With a pressure, pr, on both faces use Equation (27), substituting "sin" for "cos" and "cos" for "sin" throughout.

(7) With a moment, M, per unit of the Z-axis (positive in direction $+\theta$) acting at the vertex:

$$F = -\frac{M}{2}\,\frac{\sin 2\theta - 2\theta \cos 2\alpha}{\sin 2\alpha - 2\alpha \cos 2\alpha} \quad \ldots\ldots (28)$$

(8) With a force, P, per unit length of the Z-axis acting at the vertex and directed along the positive Y-axis:

$$F = P\,\frac{r\,\theta \cos\theta}{2\alpha - \sin 2\alpha} \quad \ldots\ldots (29)$$

(9) With a pressure, p, directed along the positive X-axis, use Equation (29), substituting "$-\sin\theta$" for "$\cos\theta$", and "$+\cos 2\alpha$" for "$-\sin 2\alpha$"; and

(10) With body forces, g, per unit volume, directed at an angle, β, with the X-axis:

$$F_g = \frac{gr^3}{12}\left[\frac{\cos\beta}{\cos^2\alpha}\,(3\cos^2\alpha \cos\theta - \cos^3\theta) + \frac{\sin\beta}{\sin^2\alpha}\,(3\sin^2\alpha \sin\theta - \sin^3\theta)\right] \quad \ldots\ldots (30)$$

The stresses are obtained by Equations (2) with $g = 0$ if no mass forces exist.

APPLICATION II.—STRESSES IN FOUNDATIONS.[6]

Let a tangential line load, Q, act per unit thickness of the infinite half plane (foundation). With the co-ordinate system in Fig. 3 it is easily verified that the function, $F = \frac{-Q}{\pi} r\,\theta \sin\theta = -\frac{Q}{\pi}\, y \tan^{-1}\frac{y}{x}$, is an Airy function because Equations (3) are satisfied. It satisfies the boundary conditions, $F = 0$, when $\theta = 0$, and $\theta = \pi$. Therefore, by Equations (8) no normal forces act on the X-axis. Furthermore, $\frac{\partial F}{\partial y} = 0$ when $\theta = 0$, and $-Q$ when

---

[6] For a more detailed solution, see "Applications Potentiels à l'Etude de Equilibre et du Mouvements des Solides Elastiques", by J. Bouissinesq, Paris, 1885.

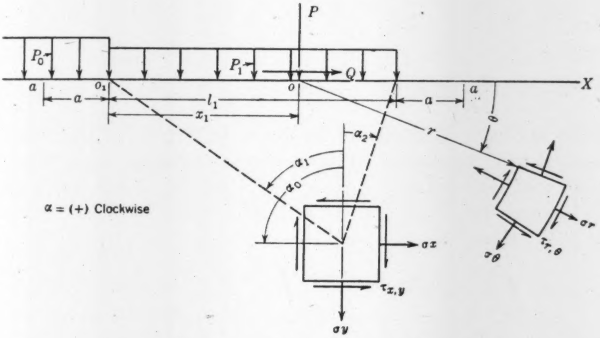

FIG. 3.

$\theta = \pi$. Therefore, by Equations (7) no tangential force distribution occurs when $r > 0$, or when $r < 0$, but a force, $+Q$, occurs at $r = 0$ because here $\frac{\partial F}{\partial y}$ makes a jump equal to $+Q$.

The stresses are found by Equations (2) with $g = 0$; thus:

$$\sigma_r = -\frac{2\,Q}{\pi}\,\frac{\cos\theta}{r} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31a)$$

and,

$$\sigma_\theta = \tau_{r\theta} = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31b)$$

The rectangular stress components in the foundation may be found by the formulas:

$$\sigma_x = \sigma_r \cos^2\theta = -\frac{2\,Q}{\pi}\,\frac{\cos^3\theta}{r} \quad\ldots\ldots\ldots\ldots\ldots\ldots (32a)$$

$$\sigma_y = \sigma_r \sin^2\theta = -\frac{2\,Q}{\pi}\,\frac{\cos\theta\sin^2\theta}{r} \quad\ldots\ldots\ldots\ldots\ldots (32b)$$

and,

$$\tau_{x,\,y} = \frac{\sigma_r}{2}\sin 2\,\theta = -\frac{2\,Q}{\pi}\,\frac{\cos^2\theta\,\sin\theta}{r} \quad\ldots\ldots\ldots\ldots (32c)$$

The influence function,

$$F = -\frac{1}{\pi}\, y \tan^{-1}\frac{y}{x - x_1} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

gives the stresses in the foundation due to a unit tangential force acting at a point, $(x_1, 0)$, and directed along the positive X-axis in a positive direction. For a uniform distribution, q_1, over a distance, l_1, it will be found by integration of Equation (33) that the stresses are:

$$\sigma_x = \frac{q_1}{\pi}\left[\, + (\log \cos^2 \alpha_1 - \cos^2 \alpha_1) - (\log \cos^2 \alpha_2 - \cos^2 \alpha_2)\right] \ldots (34a)$$

$$\sigma_y = \frac{q_1}{2\pi}\left[+ \cos 2\alpha_1 - \cos 2\alpha_2\right] \ldots\ldots\ldots\ldots (34b)$$

and,

$$\tau_{x,\,y} = \frac{q_1}{2\pi}\left[+ (2\alpha_1 - \sin 2\alpha_1) - (2\alpha_2 - \sin 2\alpha_2)\right] \ldots\ldots (34c)$$

in which the angles, α_1 and α_2, are as shown in Fig. 3. Equations (34) are easily extended to a number of uniform distributions, q_1, q_2, q_3, etc.

At Point a of the surface, $\sigma_y = \tau = 0$ (see Fig. 2(*b*)) and σ_x by Equations (34) becomes invalid; $\sigma_x = \sigma_r$ is then obtained by direct integration of Equations (31); thus:

$$\sigma_x = \mp \int_a^{a+l_1} \sigma_r \, dr = \mp \frac{2q_1}{\pi} \int_o^{a+l_1} \frac{dr}{r} = \mp \frac{2\,q_1}{\pi} \log \frac{a + l_1}{a} \ldots . (35)$$

in which minus is to be used if a is on the positive side of the distribution, q_1.

By Equations (9) (remembering that $g = 0$) the displacements due to Equation (33) are:

$$u = -\frac{1}{\pi\, E_2}\left\{(1 + \mu_2)\frac{(x - x_1)^2}{(x - x_1)^2 + y^2} + \log\left[(x - x_1)^2 + y^2\right] - Ay + C\right\} .. (36a)$$

and,

$$v = \frac{1}{\pi\, E_2}\left\{(1 + \mu_2)\left[\, y\frac{x - x_1}{(x - x_1)^2 + y^2} + \tan^{-1}\frac{y}{x - x_1}\right]\right.$$

$$\left. - 2\tan^{-1}\frac{y}{x - x_1} + Ax + B\right\} \ldots\ldots\ldots\ldots\ldots (36b)$$

Next, let a normal compression, P, act per unit thickness. The stress function for this load, $F = +\frac{P}{\pi}\, r\, \theta \cos\theta = +\frac{P}{\pi}\, x \tan^{-1}\left(\frac{y}{x}\right)$, will satisfy the boundary conditions. The stresses by Equations (2), with $g = 0$, are: $\sigma_r = -\frac{2\,P}{\pi}\frac{\sin\theta}{r}$; $\sigma_\theta = 0$; and $\tau = 0$.

The rectangular components of stress due to P are:

$\sigma_x = -\frac{2P}{\pi}\frac{\sin\theta\cos^2\theta}{r}$; $\sigma_y = -\frac{2P}{\pi}\frac{\sin^3\theta}{r}$; and, $\tau_{x,\,y} = -\frac{2P}{\pi}\frac{\sin^2\theta\cos\theta}{r}$

The influence function,

$$F = \frac{1}{\pi}(x - x_1)\tan^{-1}\left(\frac{y}{x - x_1}\right) \ldots\ldots\ldots\ldots\ldots (37)$$

will give the stresses in the foundation due to a unit normal pressure at the point, $(x_1, 0)$.

For a uniform distribution, p_1, over the distance, l_1 (Fig. 3), the stresses are:

$$\sigma_x = \frac{p_1}{2\pi}\left[+ (2\alpha_1 - \sin 2\alpha_1) - (2\alpha_2 - \sin 2\alpha_2)\right] \tag{38a}$$

$$\sigma_y = \frac{p_1}{2\pi}\left[+ (2\alpha_1 + \sin 2\alpha_1) - (2\alpha_2 + \sin 2\alpha_2)\right] \tag{38b}$$

and,

$$\tau_{x,\,y} = \frac{p_1}{2\pi}\left[+ \cos 2\alpha_1 - \cos 2\alpha_2\right] \tag{38c}$$

Equations (38) can be extended to several uniform distributions, p_1, p_2, p_3, etc. The displacements due to Equation (37) are:

$$u = \frac{1}{\pi E_2}\left\{(1 + \mu_2)\left[y\,\frac{x - x_1}{(x - x_1)^2 + y^2} - \tan^{-1}\frac{y}{x - x_1}\right] + 2\tan^{-1}\frac{y}{x - x_1} + Ay + B\right\}$$

and,

$$v = -\frac{1}{\pi E_2}\left\{(1 + \mu_2)\,\frac{(x - x_1)^2}{(x - x_1)^2 + y^2} + \log\left[(x - x_1)^2 + y^2\right] + Ax + C\right\}$$

An interesting case occurs when p_0 is the uniform reservoir pressure on the foundation above a dam. If the X-axis is chosen positive down stream, the stresses are:

$$\sigma_x = \frac{-p_0}{2\pi}\left[\pi + 2\alpha_1 - \sin 2\alpha_1\right] \tag{39a}$$

$$\sigma_y = \frac{-p_0}{2\pi}\left[\pi + 2\alpha_1 + \sin 2\alpha_1\right] \tag{39b}$$

and,

$$\tau_{x,y} = \frac{-p_0}{2\pi}\left[1 + \cos 2\alpha_1\right] \tag{39c}$$

The corresponding stress function is $F = + \dfrac{p_0\, r^2}{4}(\sin 2\theta - 2\theta)$, with the origin at the heel. The corresponding displacements are:

$$u = \frac{p_0}{\pi E_2}\left\{(1 + \mu_2)\, x \tan^{-1}\frac{y}{x} + 2x\tan^{-1}\frac{y}{x} - y\log(x^2 + y^2) + Ay + B\right\} \tag{40a}$$

and,

$$v = \frac{p_0}{\pi E_2}\left\{(1 + \mu_2)\, y \tan^{-1}\frac{y}{x} - 2y\tan^{-1}\frac{y}{x} + x\log(x^2 + y^2) - Ax + C\right\} \tag{40b}$$

Finally, the stresses in the foundation due to the weight, g, per unit volume are: $\sigma_x = \sigma_y = -gy$; and $\tau_{x,\,y} = 0$.

APPLICATION III.—STRESSES IN THE REGION OF THE BASE OF THE GRAVITY DAM

In the third application of the theory, polar co-ordinates will be used to determine "corner-functions" for a wedge or a corner with an angle, γ. The "corner-function" is defined such as to give no forces on the straight boundaries of the wedge or the corner. For the present purpose it is convenient to choose the co-ordinate system shown in Fig. 4. These functions appear in connection with the exact solutions by the writer[7] for stresses in two-dimensional corners. H. M. Westergaard, M. Am. Soc. C. E., in a communication to Professor von Kármán, has called attention to the existence of such functions, which he used for the investigation of stresses in the region of the toe and heel of dams, cracks in concrete, etc.

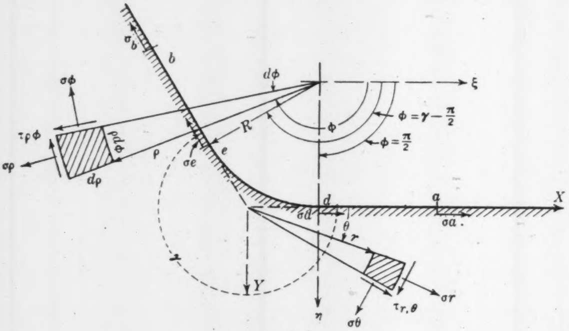

FIG. 4.

The definition of this function is expressed by Equations (8); hence, when $\theta = 0$ and $\theta = \gamma$:

$$F = 0 \quad \text{(41a)}$$

and,

$$\frac{\partial F}{\partial n} = \frac{\partial F}{r\, \partial \theta} = 0 \quad \text{(41b)}$$

Consider the real part of the following function which, by Equation (4), is known to be a solution of Equations (3):

$$F = [(B - i A)\, x + (C - i D)\, y]\, z^n \quad \text{(42)}$$

in which $x = r \cos \theta$; $y = r \sin \theta$; $z = r\, e^{i\theta} = r\, (\cos \theta + i \sin \theta)$; and, $z^n = r\, e^{in\theta} = r^n\, (\cos n\, \theta + i \sin n\, \theta)$. By substitution of these expressions into Equation (42) and taking the real part only:

$$F = r^{n+1}\, [B \cos n\, \theta \cos \theta + A \sin n\, \theta \cos \theta + C \cos n\, \theta \sin \theta + D \sin n\, \theta \sin \theta] \quad \text{(43)}$$

---

[7] Presented to the California Institute of Technology in 1932, in partial fulfillment of the requirement for the degree of Doctor of Philosophy; also contained in *Technical Memorandum No. 420*, U. S. Bureau of Reclamation, Denver, Colo.; excerpt published in *Applied Mechanics*, April–June, 1933, Vol. 1, No. 2; and in *Physics*, Vol. 4, No. 2, February, 1933.

It is to be noted that, by starting with a complex function of the type of Equation (4), Airy functions are easily produced and the task of verifying Equations (3) is avoided.

The constants, A, B, C, D, and n, must be determined by the boundary conditions expressed in Equations (41) and it will be found that the "corner-function" (Equation (43)) becomes:

$$F = A' r^{n+1} \left[n \cos n\,\theta \sin \theta + m \sin n\,\theta \sin \theta - \sin n\,\theta \cos \theta \right] \ldots\ldots (44)$$

in which,

$$n \sin \gamma = \pm \sin n\,\gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

and,

$$m = \cot \gamma - n \cot n\,\gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

The stresses produced by Equation (44) are found by Equations (3) with $g = 0$. The displacements corresponding to Equation (44) are:

$$\begin{aligned} u = A' \frac{r^n}{E_1} \Big\{ & (1 + \mu_1) \left[n \cos \theta \sin (n - 1)\,\theta + \sin n\,\theta - n^2 \sin \theta \cos (n - 1)\,\theta \right. \\ & \left. - m\,n \sin \theta \sin (n - 1)\,\theta \right] - 2 \sin n\,\theta - 2\,n \sin n\,\theta \\ & + 2\,m \cos n\,\theta \Big\} + C\,r \sin \theta + D \end{aligned}$$

and,

$$\begin{aligned} v = A' \frac{r^n}{E_1} \Big\{ & (1 + \mu_1) \left[n \cos \theta \cos (n - 1)\,\theta - n \cos n\,\theta - m \sin n\,\theta \right. \\ & \left. + n^2 \sin \theta \sin (n - 1)\,\theta - m\,n \sin \theta \cos (n - 1)\,\theta \right] \\ & + 2 \cos n\,\theta + 2\,n \cos n\,\theta + 2\,m \sin n\,\theta \Big\} - C\,r \cos \theta + E \end{aligned}$$

in which C, D, and E are arbitrary constants used to fix the reference system for u and v. The values of n that satisfy Equation (45) will be referred to as "corner-values." It will be found that when $\pi < \gamma < 2\,\pi$, there are two significant real roots, n_0 and n_1, the others are complex; when $\gamma = \pi$, all roots are real: 1, 2, 3, etc.; when $\gamma = 2\,\pi$, all roots are real: $\frac{1}{2}, 1, \frac{3}{2}, 2$, etc.; and, when $0 < \gamma < \pi$, all roots are complex. The real roots, n_0 and n_1, for various values of γ are given in Fig. 5, based on the formulas:

$$\sin n_0\,\gamma = -\,n_0 \sin \gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots (47a)$$

and,

$$\sin n_1\,\gamma = +\,n_1 \sin \gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots (47b)$$

The complex roots may be found as follows: Let $n = a + i\,b$, which, substituted in Equation (45) gives:

$$\pm\,(a + i\,b) \sin \gamma = \sin a\,\gamma \cosh b\,\gamma + i \cos a\,\gamma \sinh b\,\gamma$$

Equating real and imaginary parts, the following simultaneous equations are obtained:

$$\sin a\,\gamma \cosh \gamma\, b = \pm\, a \sin \gamma \quad \text{.................} (48a)$$

and,

$$\cos a\,\gamma \sinh b\,\gamma = \pm\, b \sin \gamma \quad \text{.................} (48b)$$

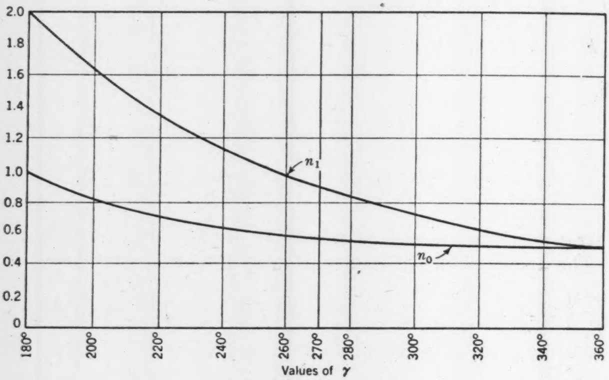

FIG. 5.

When γ is known, approximate values for a and b are found by:

$$a_k = \pm \frac{\pi\,(2\,k - 1) - \epsilon_k}{2\,\gamma} \quad \text{..................} (49a)$$

and,

$$b_k = \pm \frac{1}{\gamma} \log \left\{ \frac{\pi\,(2\,k - 1) - \epsilon_k}{\gamma} \sin \gamma \right\} \quad \text{.........} (49b)$$

in which,

$$\epsilon_k = \frac{4 \log \left(\dfrac{\pi\,(2\,k - 1) \sin \gamma}{\gamma} \right)}{\pi\,(2\,k - 1)} \quad \text{..............} (49c)$$

and, $k = 2, 3, 4, 5$, etc.

The values, a_k and b_k, obtained by Equations (49a) and (49b) will not satisfy Equations (48) exactly; therefore, they must be further adjusted.[8]

When n_k is known the corresponding value of m_k is found by Equation (46). Let $m = d + i\,e$ which, substituted into Equation (46), separating real and imaginary parts and making use of Equations (48), gives $e = b \tan a\,\gamma$; and $d = \cot \gamma - a \cot a\,\gamma$.

The various quantities in Equations (44) have now been expressed in terms of γ so that, when the angle, γ, is known, the "corner-function" is fully determined except for the arbitrary constant, A'. Each complex value of n will furnish a real and imaginary part of Equation (44). Both parts will satisfy the required boundary conditions; therefore, two functions are obtained for each value of n, each with an arbitrary constant, A and B, respectively. Furthermore, the sum of the functions obtained for all values of n will satisfy the boundary conditions. This function may be written:

---

[8] Adjustment demonstrated in record manuscript, filed for reference in Engineering Societies Library, New York, N. Y.

$$F_\gamma = \text{real part of} \sum_{0,\,1,\,2,\,3,\,\text{etc.}}^{k=} (A_k - i\,B_k)\,F_k \text{.... ......} \tag{50}$$

in which F_k is given by Equation (44).

The function, F_γ, contains a double infinity of arbitrary constants, A_k and B_k, and is constituted so that it corresponds to the case in which there are no forces acting on the straight boundaries of the corner, γ, irrespective of the values of A_k and B_k. At points inside the corner the stresses will not be zero, but the stress distribution will be such that the resultant of the stresses acting on any line terminating at points of the boundaries will be zero. In other words the function, F_γ, will only affect the distribution of the stresses. It is important that the full significance of F_γ is realized. It is extremely useful for the investigation of stresses at sharp corners and for the correction of stresses in structures if the boundary lines differ from those assumed in the original computations.

Application of F_γ for the Determination of Stresses Near the Base of a Straight Triangular Gravity Dam on an Infinite Elastic Foundation

Two cases will serve to demonstrate the foregoing theory. In Case 1, the elastic properties of the dam and foundation are assumed to be the same throughout; and, in Case 2, they are different in the dam and foundation, but constant throughout in each of the two.

Case 1.—Consider an infinite elastic homogeneous plate of unit thickness. On this plate imagine the boundary lines of the cross-section of the dam and its foundation. These lines will divide the plane into two separate regions one of which is a slice of the dam and its foundation. The problem is to determine a function, F, that will deliver stresses between the two regions equal to the loads on the dam and its foundation. This function then will deliver the correct stresses throughout. Incidentally, it is interesting to note that F will give the stresses in both regions of the infinite plate.

Select the height of the dam (see Fig. 2), measured along the up-stream face, as the unit of length. Assume a full hydrostatic load on the up-stream face and constant pressure, p, on the up-stream foundation. Let the uniform mass forces (weight and inertia) be g per unit volume acting at an angle, β, with the X-axis. It is assumed that the forces, if any, acting on the rear face and the down-stream foundation are known.

Then the boundary conditions which must be satisfied by the stress function, F, are: (1) When $\theta = 0$; $y = 0$; (up-stream face): $\sigma_\theta = -\,p\,(1 - r)$; and, $\tau = 0$; (2) when $\theta = \gamma$; $y = x \tan \gamma = x\,K$; (up-stream foundation): $\sigma_\theta = -\,p$; and $\tau = 0$; and, (3) the rear face and down-stream foundation will be considered later. Let,

$$F = -\,F_p + F_0 + F_g + F_\gamma \text{................} \tag{51}$$

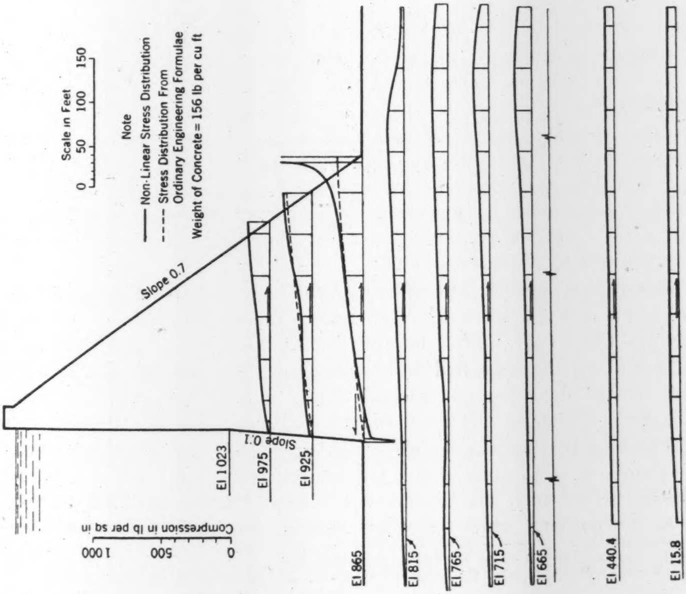
(b) PRINCIPAL STRESSES



(a) SHEARING STRESSES

FIG. 7.

in which F_p, F_g, F_0, and F_γ are given in Equations (17), (21), (24), and (50); γ is the re-entrant angle at the heel ($\gamma > \pi$); and, $K = \tan \gamma$.

By adding the stresses when $y = 0$ and $y = K x$, respectively, due to the various functions in Equation (51), it will be found that Conditions (1) and (2) are satisfied exactly. (It is to be noted that F_γ was determined so as to give no contribution on these lines.)

There remains the matter of satisfying the conditions along the line, *T B D A,* in Fig. 2(*b*). For this purpose the form of the boundary conditions derived in Equations (7) is utilized.

In Equation (51), F is determinate with the exception of the arbitrary constants, A_k and B_k, in the function, F_γ. This double infinity of constants is used to satisfy Equations (7*a*) and (7*b*), at all points of the line, *T B D A*. The right-hand sides of Equations (7*a*) and (7*b*) are completely known and can be computed at all points when the forces on the dam are known. A double infinity of simultaneous equations is obtained with a double infinity of unknowns, A_k and B_k. This problem is solved, mathematically, by expanding the right-hand sides of Equations (7*a*) and (7*b*) in terms of the "corner-functions," F_γ. In the practical solution of the problem it is only necessary to satisfy Equations (7) for a finite number of points. In this case it is better to include all three of Equations (7). It will be found that if they are satisfied at three points, *B, D, a*nd *A* (Fig. 2(*b*)), Equations (7) will be closely satisfied at intermediate points. This can be checked by plotting F, $\frac{\partial F}{\partial x}$, and $\frac{\partial F}{\partial y}$, along the line, *T B D A*, and comparing the results with the values computed by the right-hand sides of Equations (7).

Three equations of conditions are thus obtained at each point, *B*, *D*, and *A*, a total of nine equations. This means that nine constants, A_k and B_k, must be included in F_γ.

When only a finite number of points, *B, D, A*, etc., are used, it is necessary to compute the stress functions for both the heel and the toe; that is, for the two different angles, γ. As soon as the constants, A_k and B_k are determined, F_γ is known by Equation (50). Thus, the total stress function valid in the region of the corner is known by Equation (51) and the stresses can be determined by Equations (2).

The stresses computed in one of the preliminary studies of Grand Coulee Dam[9] are given in Figs. 6 and 7. The stresses in the foundation were found by Equations (34), (35), (38), and (39), after the normal stress and shear distributions along the base had been computed. The stresses in the upper two-thirds of the dam are not shown. They may be computed by Equations (18) and (22), or by the usual engineering methods.

It will be seen that all stresses are compressive and tend to become infinite at the heel and toe. Of course, this is not possible because the material will become plastic before such magnitudes are reached and redistributions will occur near the corners, which must be considered as singular points where the elastic assumptions do not hold. The redistribution cannot be computed by the elastic theory, but it is evident that, after the plastic flow takes place, the stresses will be decreased near the corner and slightly increased a short distance from the corner. It will be noticed that the theoretical stresses are extremely high over only a minute distance so that the actual forces involved are very small. The effect of a redistribution, therefore, can only be slight.

---

[9] The details are contained in *Technical Memorandum No. 403* by Chief Designing Engineer J. L. Savage, M. Am. Soc. C. E., U. S. Bureau of Reclamation, Denver, Colo.

In order to be able to predict the elastic stresses at the heel and toe it would be necessary to fillet the corner with a large enough curvature to keep the theoretical stresses within the elastic limit at all times. This was done in other studies of this dam.

Case 2.—Referring to Fig. 2, consider the dam as a triangle with elastic modulus, F_1, and Poisson's ratio, μ_1, resting on an elastic foundation which is considered as an infinite half plane with modulus, E_2, and Poisson's ratio, μ_2. A slice, one unit wide, across the dam and into the foundation is considered. It will be assumed that no separation or slippage will occur between the base and the foundation. This implies that, when all effects are considered, the resulting normal stresses are compression, and that the shear stresses are within the permissible relation to the normal stresses.

All forces acting on the dam and on the foundations are known, except the reactions between the two. The problem is to determine these reactions such that the elastically deformed base and foundation make a perfect fit when equilibrium exists. This is expressed by demanding that the relative displacements of the dam and the foundation must be zero along the base.

With the co-ordinate system as in Fig. 4, let the stress function for the dam be $F = F_p + F_g + F_\gamma$, corresponding to full hydrostatic pressure on the up-stream face, and the mass forces, g, per unit volume. Functions F_p and F_g are given by Equations (17) and (21); and F_γ is the "corner-function" derived in Equation (50) with γ equal to the top angle of the dam ($\gamma < \pi$). In this case F_γ may be considered as a correction to the basic function, $F_p + F_g$, for the infinite wedge. It has already been indicated that F_γ does not alter the force system which acts on the faces of the dam. Its value is known except for the arbitrary constants, A_k and B_k, which must be determined by making the deformed base of the dam congruent with the deformed foundation line. By this method it is possible to determine: (1) The effect of a variation of the ratio, $\frac{E_1}{E_2}$, on the stresses, in which E_1 and E_2 are Young's modulus for the dam and foundation, respectively; (2) the effect of uniform shrinkage of the dam relative to the foundation; and (3) it includes Case 1 when $E_1 = E_2$ and $\mu_1 = \mu_2$.

APPLICATION IV.—APPROXIMATE BOUNDARY STRESSES AT SHARP AND ROUNDED CORNERS OR FILLETS

Formulas are developed herein for the boundary stresses at sharp and rounded corners of elastic structures, using only the real "corner-values," n_0 and n_1, given in Fig. 5. The method is applicable to any structure with any loading. Numerical examples are computed in the case of a triangular dam.

Theory Pertaining to Sharp Corners.—Assume that the body forces and the forces acting on the boundaries, $\theta = 0$ and $\theta = \gamma$, of the corner in Fig. 4 is represented by a function, F_2, and that the stresses, σ_a and σ_b, at the points, $r = a$ and $r = b$, of the boundaries are known, or have been computed by ordinary engineering methods. It is required to determine a function, F, to represent the state of stress at the corner such that, when $\theta = 0$:

$$F = F_2 \qquad \text{(52a)}$$

and,

$$\frac{\partial F}{\partial \theta} = \frac{\partial F_2}{\partial \theta} \qquad \text{(52b)}$$

Then by Equations (2),

$$\left[\frac{\partial^2 F}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F}{\partial r} - r\,g\cos(\theta - \beta)\right]_{\binom{\theta = 0}{r = a}} = \sigma_a \qquad \text{(53)}$$

On the boundary, $\theta = \gamma$, Equations (52) and (53) apply likewise except, of course, that here $\theta = \gamma$, $r = b$, and σ_a is replaced by σ_b. Let,

$$F = F_2 + F_\gamma \qquad \text{(54)}$$

Function F_γ is the "corner-function" for γ given by Equation (50), with $k = 0$ and 1; that is, only the real values, n_0 and n_1, found by Fig. 5 are involved. Hence, $F_\gamma = F_0 + F_1$, in which F_0 and F_1 are given by Equation (44) for $n = n_0$ and $n = n_1$.

It will be seen that F defined by Equation (54) satisfies Equation (52). It only remains to determine the constants, A_0 and A_1, such that Equation (53) will be satisfied.

By substituting F into this formula and re-arranging:

$$\left[\frac{\partial^2 F_\gamma}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F_\gamma}{\partial r}\right]_{\binom{\theta = 0}{r = a}} = \sigma_a - \left[\frac{\partial^2 F_2}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F_2}{\partial r} - r\,g\cos(\theta - \beta)\right]_{\binom{\theta = 0}{r = a}} \qquad \text{(55)}$$

and, the analogous equation for $\theta = \gamma$, $r = b$, in which every term is known except A_0 and A_1. The brackets on the right side of Equation (55) are the stresses σ_r, computed from the function F_2 by Equations (2). The derivation of F_2 will be given subsequently herein. Denote these terms by $Q_{0,a}$ and $Q_{\gamma,b}$. In general, let

$$Q_{r,\theta} = \frac{\partial^2 F_2}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F_2}{\partial r} - r\,g\cos(\theta - \beta) \qquad \text{(56)}$$

and let subscripts denote the co-ordinates of the point at which the quantities are to be computed.

By partial differentiations of F_γ given by Equation (44):

$$\left[\frac{\partial^2 F_\gamma}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F_\gamma}{\partial r}\right]_{\theta=0} = 2\,A_0\,n_0\,m_0\,r^{n_0-1} + 2\,A_1\,n_1\,m_1\,r^{n_1-1} \ldots\ldots (57a)$$

and,

$$\left[\frac{\partial^2 F_\gamma}{r^2 \partial \theta^2} + \frac{1}{r}\frac{\partial F_\gamma}{\partial r}\right]_{\theta=\gamma} = 2A_0\,n_0\,m_0\,r^{n_0-1} - 2\,A_1\,n_1\,m_1\,r^{n_1-1} \ldots\ldots (57b)$$

Substituting back into Equation (55), the following equations are obtained:

$$2\,A_0\,n_0\,m_0\,a^{n_0-1} + 2\,A_1\,n_1\,m_1\,a^{n_1-1} = \sigma_a - Q_{o,a} \ldots\ldots\ldots (58a)$$

and,

$$2\,A_0\,n_0\,m_0\,b^{n_0-1} - 2\,A_1\,n_1\,m_1\,b^{n_1-1} = \sigma_b - Q_{o,b} \ldots\ldots\ldots (58b)$$

In most cases it is possible to choose $a = b$, and, if so, further simplification is possible: Placing $a = b$ in Equations (58) and solving:

$$A_0 = \frac{\sigma_a - Q_{o,a} + \sigma_b - Q_{\gamma,b}}{4\,n_0\,m_0\,a^{n_0-1}} \ldots\ldots\ldots\ldots\ldots\ldots (59a)$$

and,

$$A_1 = \frac{\sigma_a - Q_{o,a} - \sigma_b + Q_{\gamma,b}}{4\,n_1\,m_1\,a^{n_1-1}} \ldots\ldots\ldots\ldots\ldots\ldots (59b)$$

The stress function, $F = F_2 + F_\gamma = F_0 + F_1 + F_2$, is now completely known and the stresses can be found by the definitions in Equations (2); thus:

$$(\sigma_r)_{\theta=0} = \frac{\sigma_a - Q_{o,a} + \sigma_b - Q_{\gamma,b}}{2}\left(\frac{r}{a}\right)^{n_0-1}$$

$$+ \frac{\sigma_a - Q_{o,a} - \sigma_b + Q_{\gamma,b}}{2}\left(\frac{r}{a}\right)^{n_1-1} + Q_{o,r} \ldots\ldots\ldots\ldots (60a)$$

and,

$$(\sigma_r)_{\theta=\gamma} = \frac{\sigma_a - Q_{o,a} + \sigma_b - Q_{\gamma,b}}{2}\left(\frac{r}{a}\right)^{n_0-1}$$

$$- \frac{\sigma_a - Q_{o,a} - \sigma_b + Q_{\gamma,b}}{2}\left(\frac{r}{a}\right)^{n_1-1} + Q_{\gamma,r} \ldots\ldots\ldots\ldots (60b)$$

The function, F_2, will now be given for a dam. Let $F_2 = F_p + F_g$, in which F_p is the part of F_2 due to the external forces acting on the boundaries, $\theta = 0$ and $\theta = \gamma$ (Fig. 4); and, F_g is the part of F_2 entirely due to the body forces, g, per unit volume.

Case 1.—In this case there are no external forces acting on the boundaries, $\theta = 0$ and $\theta = \gamma$, on the stretch, a to b. Hence, $F_p = 0$, and by Equation (56), $Q_{r,\theta} = 0$.

Case 2.—There is a constant pressure, p, on the boundary $\theta = 0$, and a pressure $(1 - r)\ p$ on $\theta = \gamma$. By a co-ordinate transformation in Equation (17) and superposing $-\frac{1}{2}\,p\,r^2$, it will be found that,

$$F_p = \frac{pr^3 \sin^2\theta}{12 \sin^3\gamma}\,[3\cos\theta \sin 2\gamma + 6\sin\theta\sin^2\gamma - 4\sin\theta] - \tfrac{1}{2}\,pr^2 \ldots (61)$$

will satisfy the conditions of this case. Then by Equation (56):

$$Q_{0,\,r} = \frac{pr\cos\gamma}{\sin^2\gamma} - p \ldots\ldots\ldots\ldots\ldots\ldots (62a)$$

and,

$$Q_{\gamma,r} = -\frac{pr\cos^2\gamma}{\sin^2\gamma} - p \ldots\ldots\ldots\ldots\ldots (62b)$$

Case 3.—Only mass forces are considered, and the function, F_g, must be such that σ_θ and $\tau_{r,\theta}$ are zero along the straight boundaries, $\theta = 0$, and $\theta = \gamma$. Substituting polar co-ordinates into Equation (21) and placing $g_x = g\cos\beta$ and $g_y = g\sin\beta$:

$$F_g = \frac{g\,r^3}{6}\left[\frac{\cos\beta}{\tan\gamma}\sin^3\theta + \frac{3\sin\beta}{\tan\gamma}\cos\theta\sin^2\theta - \frac{2\sin\beta}{\tan^2\gamma}\sin^3\theta\right.$$
$$\left. + \sin\beta\sin^3\theta + \cos\beta\cos^3\theta\right] \ldots\ldots\ldots\ldots\ldots\ldots (63)$$

By Equation (56):

$$Q_{0,r} = -\frac{rg\sin(\gamma - \beta)}{\sin\gamma} \ldots\ldots\ldots\ldots\ldots\ldots (64a)$$

and,

$$Q_{\gamma,\,r} = -\frac{rg\sin\beta}{\sin\gamma} \ldots\ldots\ldots\ldots\ldots\ldots (64b)$$

It will be seen in Fig. 5 that n_0 is always less than unity for angles between 180 and 360 degrees. This means that the stresses found by Equations (60) will approach infinity as the radius vector, r, approaches zero. In other words, a mathematically sharp re-entrant corner cannot occur in a structure without having the stresses exceed the elastic limit, contrary to the assumptions of the mathematical theory of elasticity. The material becomes plastic and the stresses in the immediate neighborhood must be redistributed.

Theory Pertaining to Fillets.—In order to predict the elastic stresses it is necessary to abandon the sharp corner and assume a finite curvature. In this case the preceding formulas no longer are valid in the immediate neighborhood of the corner. Photo-elastic experimentation has shown, as might be expected, that a slight curvature only will effect the stresses in the immediate neighborhood (that is, at distances of the order of magnitude of the radius of curvature). The stresses, σ_r, at the tangent points, d and e, Fig. 4, may still be computed (on the side of safety) as if the corner was sharp.

With the foregoing assumption an approximate method is developed herein for the determination of the stresses on the boundary of the fillet. The origin is chosen in the center of curvature and the axes, ξ and η, are parallel to Axes X and Y. The notations, ρ, ϕ, are used for the polar co-ordinates in the new system.

Assume that the stresses, σ_d and σ_e, have been computed by the methods shown (such as, by Equations (60)), and assume that a constant pressure is exerted on the curved boundary, $\rho = R$. If there is no pressure, $p = 0$. Now, consider the stress function:

$$F = (B_1 \cos \phi + B_2 \sin \phi) \left(\frac{1}{\rho} + \frac{2 \rho \log \rho}{R^2} \right) - \frac{1}{2} \rho^2 p$$

$$+ \frac{1}{2} g R^2 \rho \phi \sin (\phi - \beta) \quad \text{..................(65)}$$

With Equations (2) applied to Equation (65) it is easily verified that when $\rho = R$, $\sigma_\rho = - p$; and $\tau_{\rho,\phi} = 0$ for any value of ϕ.

The arbitrary constants, B_1 and B_2, are now to be determined such that when $\rho = R$, and $\phi = \frac{\pi}{2}$:

$$\sigma_\phi = \sigma_d \quad \text{........................(66a)}$$

and when $\rho = R$, and $\phi = \gamma - \frac{\pi}{2}$:

$$\sigma_\phi = \sigma_e \quad \text{........................(66b)}$$

By applying Equations (2) to Equation (65):

$$\sigma_\phi = (B_1 \cos \phi + B_2 \sin \phi) \left(\frac{2}{\rho^3} + \frac{2}{\rho R^2} \right) - p - \rho g \cos (\phi - \beta) \quad \text{..(67)}$$

Hence, by the conditions expressed in Equations (66):

$$B_1 = [\sigma_e + p + (\sigma_d + p) \cos \gamma + g R \cos \beta \sin \gamma] \; \frac{R^3}{4 \sin \gamma} \quad \text{...(68a)}$$

and,

$$B_2 = [\sigma_d + p + g R \sin \beta] \; \frac{R^3}{4} \quad \text{...............(68b)}$$

Substituting back into Equation (67) with $\rho = R$:

$$(\sigma_\phi)_{\rho=R} = [\sigma_e + p + (\sigma_d + p) \cos \gamma] \frac{\cos \phi}{\sin \gamma} + (\sigma_d + p) \sin \phi - p \quad \text{..(69)}$$

The method of procedure is best shown by a few typical examples.

EXAMPLES COMPUTED BY APPROXIMATE THEORY

The underlying assumptions are based, to a large extent, on results of photo-elastic experiments conducted in connection with the Morris Dam (see Part II). It is natural, therefore, to base the example on computations for this dam, because verification is possible. A cross-section of the Morris Dam is shown in Fig. 2. Theory and experiments have shown that the stresses in the upper two-thirds of the dam can be computed accurately by Equations (17) and (21). The height of the dam is taken as the unit of length. All stresses must be multiplied later by the actual height, H.

Up-Stream Corner, Hydrostatic Loading.—Consider first the up-stream corner with full hydrostatic pressure, $p(1 - r)$, on the up-stream face and constant pressure, p, on the foundation above the dam. The body forces will be considered subsequently; that is, $g = 0$.

For this loading the value of $F_2 = F_p$ is given in Equation (61). Points a and b (Figs. 2 and 4) are chosen as $r = a = b = 0.3$; the stress, σ_a, can be computed with reasonable accuracy by superposing Equations (35) and (39a); q_1 in Equation (35) is the total horizontal water pressure on the dam uniformly distributed over the base l_1; and p_0 in Equation (39a) is the pressure, p, on the up-stream foundation.

In the present application, a is an up-stream point; $q_1 = \dfrac{p}{2\,l_1}$; and, $l_1 = 0.86$. The total stress, then, is $\sigma_a = + \dfrac{p}{0.86\,\pi} \log \dfrac{1.16}{0.3} - p = -\,0.500\,p$.

Point b is sufficiently far from the base so that σ_b may be computed as σ_x by Equation (18a). In the present application, $K = \tan 41° 52' = 0.8963$; $x = 0.7$; $y = 0$; and $\sigma_b = +\,0.871\,p$.

The up-stream corner angle, γ, $= 267° 08'$. By Fig. 5, $n_0 = 0.55$; and $n_1 = 0.93$; and, by Equation (46), $m_0 = 0.895$; and $m_1 = -\,0.318$. The quantities, $Q_{0,a}$ and $Q_{\gamma,b}$, are now found by placing $a = b = 0.3$ in Equations (62); thus: $Q_{0,r} = -\,(1 + 0.05\,r)\,p$; $Q_{\gamma,r} = -\,(1 + 0.0025\,r)\,p$; $Q_{0,a} = -\,1.015\,p$; and $Q_{\gamma,b} = -\,1.001\,p$. By substitution in Equations (60);

$$(\sigma_r)_{\theta=0} = \left[0.6945\left(\frac{1}{r}\right)^{0.45} - 0.6785\left(\frac{1}{r}\right)^{0.07} - 0.05\,r - 1\right]p \quad \ldots(70a)$$

and,

$$(\sigma_r)_{\theta=\gamma} = \left[0.6945\left(\frac{1}{r}\right)^{0.45} + 0.6785\left(\frac{1}{r}\right)^{0.07} - 0.0025\,r - 1\right]p \quad \ldots(70b)$$

In Equations (70), it is to be noted that: r is measured in units of height of dam and p is the actual hydrostatic pressure at the base. By Equations (70), σ_r becomes infinite as $r \rightarrow 0$. To eliminate this condition assume a finite radius of curvature, $R = 0.025$, at the corner with tangent points at $d = e - R \cot 0.5\,\gamma = 0.0238$ (see Figs. 2 and 4).

Now, compute σ_d by Equation (70a) and σ_e by Equation (70b) for $r = e = d = 0.0238$; thus, $\sigma_d = +\,1.943\,p$; and $\sigma_e = +\,3.523\,p$. Substitute in Equation (69) with $g = 0$:

$$(\sigma_\phi)_{\rho=R} = [-\,4.3813 \cos\phi + 2.943 \sin\phi - 1]\,p \quad \ldots\ldots\ldots(71)$$

The maximum occurs when $\phi = 146° 07'$; and σ_ϕ (max.) $= +\,4.278\,p$. The stresses computed by Equations (70) and (71) are plotted in Fig. 2(a).

Up-Stream Corner, Mass Forces.—Now, consider mass forces only; that is, let $p = 0$. Only vertical forces are assumed to exist; hence, $\beta = 90°$; $g_x = 0$; and $g = g_y$ = weight per unit volume. The stress, σ_a, computed by

Equation (39*a*) is zero; σ_b is computed as σ_x by Equation (22*a*) (for $x = 0.7$; $y = 0$, and $K = 0.8963$); and, therefore, $\sigma_a = 0$, and $\sigma_b = -0.660\, g$.

Now, compute the quantities, Q, etc., by Equations (64), with $\beta = 90°$; $\gamma = 267° \, 08'$; and $a = b = 0.3$; thus: $Q_{0,r} = +0.0501\, r\, g$; $Q_{\gamma,r} = +1.001\, r\, g$; $Q_{0,a} = +0.015\, g$; and $Q_{\gamma,b} = +0.3003\, g$.

By substitution in Equations (60) with $p = 0$, and n_0 and n_1 as before:

$$(\sigma_r)_{\theta=0} = \left[-0.2837 \left(\frac{1}{r}\right)^{0.45} + 0.4345 \left(\frac{1}{r}\right)^{0.07} + 0.0501\, r \right] g \quad \ldots(72a)$$

and,

$$(\sigma_r)_{\theta=\gamma} = \left[-0.2837 \left(\frac{1}{r}\right)^{0.45} - 0.4345 \left(\frac{1}{r}\right)^{0.07} + 1.001\, r \right] g \quad \ldots(72b)$$

in which r is measured in units of H. Again, the stresses become infinite for the sharp corner when $r \to 0$. The radius of curvature, $R = 0.025$, is assumed as before, and $d = e = 0.0238$. By Equations (72) with $r = d = e = 0.0238$; $\sigma_d = -0.9596\, g$; and $\sigma_e = -2.0657\, g$. Substitute in Equation (69) with $p = 0$, thus:

$$(\sigma_r)_{\rho=R} = [+2.0202 \cos\phi - 0.9695 \sin\phi]\, g \ldots\ldots\ldots\ldots(73)$$

The maximum occurs when $\phi = 154° \, 36'$; and maximum $\sigma_\phi = -2.237\, g$. The stresses computed by Equations (72) and (73) are plotted in Fig. 2(*b*). For the section under consideration let $p = 108.5$ lb per sq in., and $g = 2.5\, p = 271$ lb per sq in., corresponding to 156-lb concrete.

In computing the stresses for the down-stream corner the procedure is exactly the same as for the up-stream corner. The origin is chosen at the toe with the X-axis along the down-stream foundation and the Y-axis positive into the foundation. If no pressures act on the down-stream face and foundation, $F_p = 0$; and F_g is again given by Equation (63), with γ equal to the re-entrant corner angle of the toe, and $\beta = 90°$, if the foundation is horizontal and if inertia forces do not exist. Point b (Fig. 2 (*b*)) is chosen on the down-stream face and Point a on the down-stream foundation, such that $r_a = r_b = -\dfrac{0.3}{\sin\gamma}$. The radial stress, $\sigma_b = \sigma_x + \sigma_y$, is computed by Equations (18) in the case of hydrostatic loading and by Equations (22) in the case of mass forces. The stress, σ_a, is computed by Equation (85) and becomes negative. The results are plotted in Fig. 2 for the Morris Dam, assuming a fillet radius of $0.025\, H$ as at the up-stream corner.

The Morris Dam is not designed with fillets, but it was necessary to manufacture the models used for the photo-elastic experiments (scale, 1:600) with a $\frac{1}{8}$-in. radius (0.025 × height) at the corners to prevent failure when hydrostatic load was applied in the absence of body forces. For this reason the same radius was used in the computations for stresses in the fillets.

The approximate method of analysis is recommended only for preliminary work, in order to fix suitable dimensions in the base region of the section. In the final analysis one of the methods explained in Application III should be used.

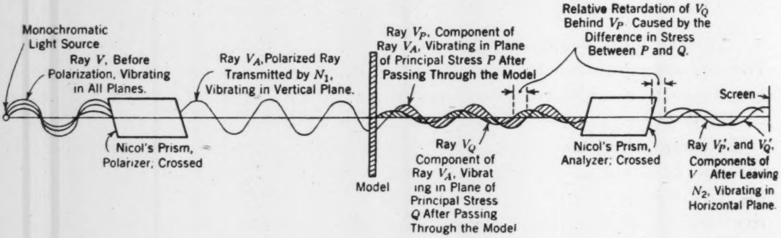
Based on the present computations and those for other radii of fillets it would seem that, for stable gravity dams, radii of 0.04 H to 0.08 H would be suitable at the heel and 0.10 H to 0.20 H at the toe, depending on the height of the dam and the quality of the masonry. The up-stream fillet is determined for the case of an empty reservoir, the down-stream one for the case of a full reservoir.

PART II.—PHOTO-ELASTIC EXPERIMENTS IN CONNECTION WITH THE MORRIS DAM, IN CALIFORNIA

Brief Outline of the Photo-Elastic Phenomenon

Although the principles involved in photo-elastic stress analysis may be found in treatises on photo-elasticity[10] a short description is given herewith, for the sake of completeness.

About 125 years ago the English physicist, Sir David Brewster, discovered that isotropic media become doubly refracting when placed under stress. They then behave optically as crystalline media. The planes of principal stress correspond to the crystal planes. If a plane-polarized monochromatic ray (see Fig. 8), is sent normally through a plate stressed in its own plane, the ray will be resolved into two component rays each vibrating in a plane of principal stress. The two ray components will usually have different velocities in the two planes; therefore, while passing through the plate the wave front of one ray will get ahead of the wave front of the other ray a small distance, δ, which is called the relative optical displacement of the two ray components. If, after leaving the plate, the two components are combined so as to vibrate again in the same plane, interference will take place due to the relative displacement, δ. Complete interference will occur when $\delta = 0$, 1, ... n, wave lengths. This furnishes a means of measuring the displacements. It has been shown theoretically by Clerk Maxwell[11], and verified experimentally that the difference in magnitudes of the two principal stresses, σ_P and σ_Q, at the line of passage is in direct proportion to the relative displacement. The latter can be measured in terms of wave lengths of the light by counting the order, n, of interference, hence:



Monochromatic Light Source
Ray V, Before Polarization, Vibrating in All Planes.
Nicol's Prism, Polarizer; Crossed
Ray V_A, Polarized Ray Transmitted by N_1, Vibrating in Vertical Plane.
Model
Ray V_P, Component of Ray V_A, Vibrating in Plane of Principal Stress P After Passing Through the Model
Ray V_Q Component of Ray V_A, Vibrating in Plane of Principal Stress Q After Passing Through the Model
Relative Retardation of V_Q Behind V_P Caused by the Difference in Stress Between P and Q.
Nicol's Prism, Analyzer; Crossed
Screen
Ray V_P', and V_Q', Components of V After Leaving N_2, Vibrating in Horizontal Plane.

[10] "Photo-Elasticity", by Coker and Filon.

[11] "On the Equilibrium of Elastic Solids", by Clerk Maxwell, *Transactions*, Royal Soc. Edinburgh, Vol. XX, Pt. I; also, "Photo-Elasticity", by Coker and Filon, p. 198.

in which C is a constant which depends on the type of material, the thickness of the plate, and the wave length of the light. It will be shown later how C is determined. (It is to be noted in passing that the number of fringes is directly proportional to the thickness of the plate.)

The principal stress difference, $\sigma_P - \sigma_Q$, is equal to twice the maximum shear at the line of passage; hence, this quantity is known when the fringe order, n, is observed. Furthermore, $\sigma_P - \sigma_Q$ will change continuously from point to point in the plate; therefore, the optical displacements, δ, will do likewise, and equal integral values of n will occur along continuous interference bands called "isochromatics" which then may be defined as lines of equal maximum shear.

The plane polariscope is shown schematically in Fig. 8, with explanatory notes. The two Nicol's prisms, the polarizer and the analyzer, are "crossed"; that is, their polarizing planes are set at right angles so that no light will reach the screen, when the plate is not in the field or when it is unstressed.

As already explained alternate dark and light bands, "isochromatics", will appear on the screen when the stressed plate is placed in the path of the light. Along the edges of the model one of the stresses, σ_P or σ_Q, is known, and the fringe order, n, can be observed so that the other stress (σ_Q or σ_P) may be computed by Equation (74) when C is known.

CALIBRATION

The simplest way to determine the value of C is to subject a beam of rectangular cross-section to uniform bending. The beam must be cut from the model material. The fringe pattern obtained in a bakelite test beam is shown in Fig. 9. The dark band at mid-height is the isochromatic of zero order ($n = 0$), or the neutral axis. The constant bending moment and the dimensions of the beam section can be measured so that the horizontal stress at the extreme fibers can be computed. In the present experiment, $\sigma_P = 1\,055$ lb per sq in. No load occurs at mid-span; that is, $\sigma_Q = 0$. The fringe order, n, is counted at the top or bottom (in this case, 6), the neutral axis being of zero order. Hence, by Equation (74),

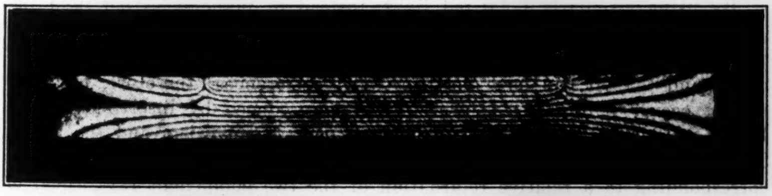

FIG. 9.—ISOCHROMATICS IN CALIBRATION BEAM.

$$C = \frac{\sigma_P - \sigma_Q}{n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

or, $\frac{1\,055}{6} = 176$ lb per sq in. The even spacing of the parallel fringes shows that the engineering assumption of linear stress distribution holds exactly for a beam of uniform thickness stressed with constant bending moment. The thickness of the beam was 0.346 in. and white light with a blue Wratten filter (about 4 100 Angstrom) was used. This filter and models, 0.346 in. thick, were used in both the experiments to be described. If the thickness, t, of the model were different from that of the test beam, T, merely multiply C in Equation (75) by $\frac{T}{t}$.

It may happen that Ray V_A (Fig. 8) is vibrating in the plane of the principal stress, σ_P, at the line of passage. In this case Ray V_A (= Ray V_P) will pass unmolested through the plate and the orthogonal component, V_Q, will be zero. Therefore, nothing will happen on the screen and darkness will prevail in the image of the point of passage, the Nicol's prisms being "crossed". When the polarizing plane of the polarizer is set at a known angle the rays automatically will seek the points in the model at which one of the principal stresses is parallel to the polarizing plane. The stress directions in a model will generally vary continuously (except at singular points) so that the dark points just described will also form a continuous band in the image known as an "isoclinic" or locus of points having their principal stresses parallel to the known plane of polarization. If the polarizer and analyzer are now rotated together through a certain angle, another isoclinic will appear, etc. In this manner the direction of the principal stresses can be found throughout the model.

Although the location of the isoclinic changes with each prism setting, the system of isochromatics will remain stationary and, therefore, are easily distinguished.

By using circularly polarized light, instead of plane polarized light the isoclinics can be eliminated. In this experiment the light vector, V_A, is made to rotate with a high, uniform, angular velocity while passing through the model and thus it can have no directional preferences; therefore, isoclinics cannot occur. Circularly polarized light is produced by inserting what is known as a "quarter wave plate" between each Nicol prism and the model. These crystalline plates are usually obtained by splitting mica to a thickness corresponding to a relative retardation of the two component rays, equal to one-fourth the wave length used in the experiment. The theory of this phenomenon may be found in treatises on passage of light through crystalline media.[13]

By using materials of low optical sensitivity (that is, a very large C in Equation (74)) such as plate glass, the isoclinic lines which are only a function of the stress direction can be made to appear sharply long before the model is stressed sufficiently for the isochromatics to show except as a slight illumination of the glass. The latter effect makes the isoclinic stand out clearly as a black line on a light background (see Fig. 13). Glass without initial stresses must be used, and is distinguished by holding the unstressed glass plate in the field of the polariscope before cutting it into the desired model.

---

[13] "Photo-Elasticity", by Coker and Filon, p. 73.

The bakelite plates used for the isochromatics generally had to be annealed before planing, polishing, and modeling, by heating them in a well controlled oven to about 80° C for a couple of hours and then cooling them gradually to room temperature over a period of about 10 hr. A newer type of bakelite usually does not need to be annealed.

EVALUATION OF STRESSES

The lines of principal stress can be drawn when the system of isoclinic lines is known as explained subsequently under the heading, "Hydrostatic Loading; Isoclinics" (see, also, Fig. 10). The magnitude of stress along the lines of principal stress can then be integrated by use of the isochromatic lines, the known boundary forces, and Equation (74). Methods for this work are given in treatises on photo-elasticity.[13]

FIG. 11.—GRAPHICAL INTEGRATION OF PRINCIPAL STRESSES.

In many types of problems, even when body forces are to be dealt with, the following method is convenient for determining the magnitudes, σ_P and σ_Q, along given lines of principal stress. The method is essentially structural and was developed by considering that the structure is composed of two systems of orthogonal arches bounded by the lines of principal stress. These arch strips are interlaced in such a way that only normal forces (no shear) exist on any element or block bounded by the four principal stress lines; that is, two from each system. The integration problem is then reduced to the determination of the force polygon, being given the funicular curve and certain reactions.

---

[13] "Photo-Elasticity," by Coker and Filon, pp. 143–146.

Consider the element, A_1, B_1, A_2, B_2, bounded by the principal lines of stress shown in Fig. 11(*a*). The only forces acting on the element are $P_{1,1}$, $P_{1,2}$, $Q_{1,1}$, and $Q_{2,1}$, normal to Surfaces A_1, B_1, etc., and perhaps the mass force, M_1. If $P_{1,1}$, $Q_{1,1}$, and M_1 are assumed to be known in magnitude and direction, then $P_{1,2}$ and $Q_{2,1}$ can be found by constructing the force polygon.

Proceed to the element, A_2 B_2 A_3 B_3, etc., until all the forces, $P_{1,n}$ and $Q_{2,n}$, are found. It is necessary to start the construction at the boundary, A_1, A_2, A_3, etc., where the forces, $Q_{1,n}$ and P_1, are known or can be found by the isochromatics and boundary forces. When all the forces, $Q_{2,n}$, are found, consider B_1, B_2, B_3, etc., as a new boundary, apply the now known forces, $Q_{2,n}$, reversed, and the known forces, $P_{2,1}$, and find the forces, $Q_{3,n}$ and $P_{2,n}$, by construction, etc. The average stresses over the elementary sides are found by dividing the forces by the corresponding sides. Finally, the principal stresses at B_2, say, will be:

$$\sigma_Q = \frac{1}{2}\left[\frac{Q_{2,1}}{B_1\,B_2} + \frac{Q_{2,2}}{B_2\,B_3}\right] \qquad \text{(76a)}$$

and,

$$\sigma_P = \frac{1}{2}\left[\frac{P_{1,2}}{A_2\,B_2} + \frac{P_{2,2}}{B_2\,C_2}\right] \qquad \text{(76b)}$$

It will be seen that Equations (74) furnish a check on $\sigma_P - \sigma_Q$ at all points, which should be made after the completion of the stresses along each line of principal stress.

The construction is easily arranged in a force diagram so that duplications of lines are avoided. Note that if the lines curve rapidly small elements must be used.

The integration of stresses along principal lines of stress is tedious and often not very accurate in complicated stress patterns. Consequently, efforts have been made to obtain other methods.

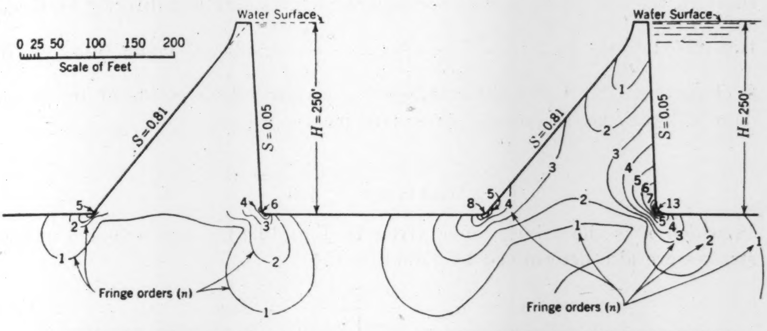
A two-dimensional state of stress is determined completely when the principal stresses, σ_P and σ_Q, and their directions are known at all points; $\sigma_P - \sigma_Q$ is known throughout by the isochromatics and by Equation (74). The directions are known by the isoclinics; hence, if $\sigma_P + \sigma_Q$ can be found, the state of stress is determinate; $\sigma_Q + \sigma_P$ can be obtained by measuring the lateral dilations of the model with an extensometer,[13] or by the membrane analogy.[14]

BODY FORCES

Body forces — weight and inertia — are difficult to apply correctly in photo-elastic experimentation. It is possible to examine isolated regions in the model by substituting the surrounding mass forces by equivalent external loads as long as these forces are placed far enough away from the region in question to permit proper distribution. This method was used in the experiment shown in Fig. 2(*b*) and Fig. 12(*a*).

---

[14] See p. 927.



(*a*) DUE TO WEIGHT OF DAM CORRECT IN FOUNDATION ONLY

(*b*) FOR HYDROSTATIC PRESSURE ON UPSTREAM FACE AND FOUNDATION

FIG. 12.—ISOCHROMATICS.

The weight of the model itself is too slight to have any effect unless it is magnified many times. The easiest method would be to rotate the model and observe it whenever it passes through the optical field. This method has not yet been attempted, and it will require a steady rotor mechanism, free of vibration, to obtain a good photographic exposure of the photo-elastic lines. The polariscope used by the writer would be admirably suited for such an experiment. The model could be attached to one end of a rigid rotor and the photographic plate to the other end, each passing through the optical field simultaneously with the same relative angular velocity. A new method has been developed by the writer in connection with experimentation on the Grand Coulee Dam, by which only the corrections to the straight-line stress distribution are involved. An interesting equivalent boundary loading has recently been pointed out by M. A. Biot.[15]

Stresses have been determined experimentally for the section shown in Fig. 2, under all critical loading conditions, including earthquake accelerations and uniform shrinkage relative to the foundation.

Hydrostatic Load on the Up-Stream Face and Foundation: Isochromatics.—A bakelite model, with blue filter and quarter-wave plates, was used to produce isochromatics. The model scale was 1: 600; the photographic scale, 1: 900; and the loading factor, 4.6, which means that the hydrostatic pressure at any point in the model was 4.6 times as great as at the corresponding point of the actual dam. The up-stream face was loaded linearly by three levers, each applying the correct force through knife-edges to a steel shoe. The uniform distribution on the up-stream foundation was applied by a single lever acting on a heavy steel shoe. Soaped rubber paddings were used between the shoes and the edge of the model, in order to avoid shear forces and local concentrations.

---

[15] *Transactions*, A. S. M. E., Vol. 2, No. 2, June, 1935.

The isochromatics are plotted in Fig. 12(*b*) and, from these, the maximum shear in the model, in pounds per square inch, is obtained directly by Equation (74); thus: $\tau_{\text{max.}} = \dfrac{\sigma_P - \sigma_Q}{2} = \dfrac{n\,C}{2} = 88\,n$, C being equal to 176 by Equation (75). The shear stresses at corresponding points of the actual dam will then be, in pounds per square inch,

$$\tau_{\text{max.}} = \frac{88\,n}{\text{Load factor}} = \frac{88\,n}{4.6} = 19\,n \ldots\ldots\ldots\ldots\ldots (77)$$

in which n is the fringe order given in Fig. 12(*b*). The actual boundary stresses are also determined by Equation (74):

$$\sigma_P - \sigma_Q = \frac{176\,n}{\text{Load factor}} = 38\,n \ldots\ldots\ldots\ldots\ldots (78)$$

On the rear face and foundation, $\sigma_P = 0$; hence:

$$\sigma_Q = -38\,n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

On the up-stream face and foundation of the dam, the hydrostatic pressure is, in pounds per square inch, $\sigma_Q = \dfrac{-62.5}{144}\,h' = -0.434\,h'$, in which h' is the depth, in feet, to the point in the prototype, $= \dfrac{h \times 900}{12} = 75\,h$, and h is the depth, in inches, to the corresponding point in the photograph. Hence, by Equation (78),

$$\sigma_P = 38\,n - 32.55\,h \ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

in which n is the fringe order at the point in question.

The experimental results obtained by substituting the fringe order, n, along the boundaries of Fig. 12(*b*) into Equations (79) and (80) are plotted in Fig. 2(*a*) with the theoretical values obtained in Part I of this paper.

It will be noticed that in the upper two-thirds of the dam the stresses obtained by Equations (18) agree with experimentation. In the base region the boundary stresses are in close agreement with the approximate methods discussed under the heading, "Application IV", in Part I. It can be shown that the isochromatics for the infinite wedge are concentric ellipses with their centers at the vertex, agreeing with the upper isochromatics in Fig. 12(*b*). A slight disagreement between the computed and experimental values may be expected due to the finite crown width, which is neglected in Equation (17).

Hydrostatic Loading: Isoclinics.—A plate-glass model and white light without the quarter-wave plates were used to produce isoclinics. The photographic scale again was 1: 900. It is to be noted that the isoclinics are independent of the loading factor as defined previously, except that these lines become sharper with increased factor. In order to cover the entire region it is only necessary to obtain the isoclinics for various prism settings, α, through a range of 90°, as shown in Fig. 10(*b*). A separate photograph is necessary of course for each prism setting, a sample of which is shown in Fig. 13 corresponding to the prism setting, α_3, in Fig. 10(*b*). The isoclinics are plotted in Fig. 10(*a*), and the lines of principal stress are obtained in the following manner: Through a_1 of Fig. 10(*a*) draw $a_1 a_2$ perpendicular to α_1 of Fig. 10(*b*); then draw $a_2 a_3$ perpendicular to α_2, etc. The points, $a_2 a_3$, etc., are taken approximately midway between the corresponding isoclinics, 1, 2, etc.

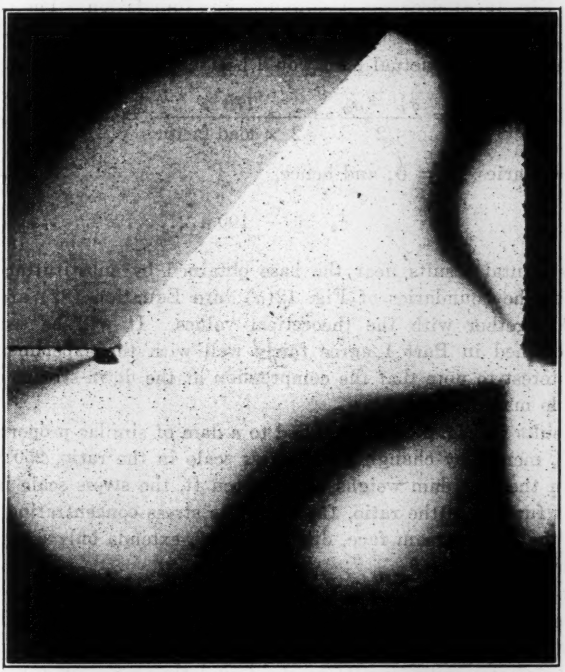


FIG. 13.—ISOCLINIC LINES FOR PRISM SETTING, α_3, IN FIG. 10(*b*).

It can be shown that the isoclinics for the wedge are straight lines radiating from the vertex, agreeing approximately with the upper two-thirds of Fig. 10(*a*). The isoclinics perhaps show more clearly than any other argument the effect of the foundation on the stresses in the base region. The corners in the models were rounded; with sharp corners, all isoclinics would be represented at each corner.

Weight Forces (Correct in Base Region Only).—In this experiment the stresses were obtained near the base due to the weight. Owing to the loading difficulties only the stresses near the base and in the foundation were determined. The forces representing the weight of the dam above the base were applied through a single lever distributing the weight to four points in such a manner that the resultant was correct at the base. The isochromatics are plotted in Fig. 12(*a*) near the base and in the foundation. The photographic scale was 1:900, and the loading factor was 1.75, based on 156-lb concrete.

The stresses in the actual dam would be (see Fig. 12(*a*)):

$$\tau_{\text{max.}} = \frac{\sigma_P - \sigma_Q}{2} = \frac{176\,n}{2 \times \text{load factor}} = 50\,n \ldots\ldots\ldots\ldots (81)$$

On the boundaries, $\sigma_P = 0$; and hence,

$$\sigma_Q = -\ 100\,n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

The experimental results near the base obtained by substituting the fringe order, n, at the boundaries of Fig. 12(*a*) into Equation (82) are plotted in Fig. 2(*b*) together with the theoretical values. It will be seen that the stresses obtained in Part I agree fairly well with the experimental results. It is of interest to note that the compression at the down-stream corner is of considerable magnitude.

The results in Fig. 2 can be applied to a dam of similar proportions, but of height, H', merely by changing the stress scale in the ratio, 250 : H'. If the concrete in the new dam weighs w lb per cu ft, the stress scale in Fig. 2(*b*) is changed further in the ratio, 156 : w. The stress concentration in the base region at the down-stream face, due to weight, extends only a short distance into the dam.

The foundation was clamped between rubber gaskets to the steel frame along three edges. This arrangement allowed elastic deformation to take place so as to produce, as closely as possible, the effect of an infinite half-plane. The photo-elastic results in the foundation, of course, are only valid in the region near the base.

In the interpretation of experimental results from model to prototype it is important to note that in two-dimensional problems: (1) The stress distribution is independent of the elastic properties; and (2) the stresses in the prototype are directly proportional to the stresses at corresponding points in the model.

The discrepancy between the experimental and theoretical curves of Fig. 2(*a*) may be due partly to incorrectness in the pressure, Q, at the fillet of the model and partly to a slight shop error in the radius of the fillet. Other experiments with larger fillet radii showed much better agreement between experimental and theoretical values of fillet stresses. Very small radii were used in these experiments in order to produce as closely as possible the effect of sharp corners.

Based on the comparison between theory and photo-elastic experimentation the writer concludes that results obtained by the foregoing application of the mathematical theory for isotropic media which behave in accordance with Hooke's law are reasonably correct. It remains only to justify the application to materials, such as concrete masonry, which do not strictly follow Hooke's law. Of course, this can only be done by observations in the field and in testing laboratories. A great many such data are already available, but it is beyond the scope of this paper to treat on this subject. A well placed system of electrical strain-gauges was installed in a section of Morris Dam which, in time, will throw further light on this point, on the question of shrinkage effects, and on lateral stresses in long gravity dams.

DISCUSSION

I. K. SILVERMAN,[16] JUN. AM. SOC. C. E. (by letter).—The first solution for the stresses in a gravity dam based on the equations of the theory of elasticity was given by Lévy.[17] However, this solution holds only for an infinite wedge and does not take into account the elastic action of the base. Lévy's solution coincides with the ordinary engineering methods for the determination of the stresses in triangular dams and, at the same time, gives the law for the distribution of the shearing stresses. Until recent times very little experimenal work has appeared in English or American engineering literature on this important question. The experiments[18] of Ottley, Brightmore, Wilson, and Gore made in 1907, on this type of structure, were outstanding. On the other hand, there have been many theoretical investigations and among the outstanding ones are those of Wolf,[19] Vogt,[20] and Kalman.[21] The latter investigators have shown definitely that the influence of the foundation cannot be neglected and that the stresses in the lower third of the dam are greatly affected by its elastic behavior. The author has pointed to this fact and has furnished a valuable tool in the form of the function given by Equation (50), for the determination of the qualitative effect of the restraining action of the base. This function is important since it furnishes an infinite number of free constants which may be used to satisfy any number of elastic or stress conditions. Thus, it is to be seen that the stresses may be determined to any degree of mathematical accuracy. It is to be noted that Equation (43) is a solution of Equation (3*b*) and, therefore, describes a state of stress which is in equilibrium and compatible with Hooke's law.

This very important function may be determined by the usual methods for the solution of partial differential equations when the form of the solution is indicated by the nature of the problem. Consider the case of a rectangular plate[22] with its sides parallel to the OX and OY-axes in Fig. 1. The stresses on the sides, $y = \pm c$, are described as follows:

For $y = + c$:

$$\sigma_y = - B \sin \frac{m \pi x}{l} \quad \text{.....................} (83a)$$

and for $y = - c$,

$$\sigma_y = - A \sin \frac{m \pi x}{l} \quad \text{.....................} (83b)$$

---

[22] "Theory of Elasticity", by S. Timoshenko, Eng. Societies Monographs, McGraw-Hill. 1934, p. 44.

In both cases, $\tau_{xy} = 0$. From the nature of these given stresses and of the shape of the body, it is logical to assume that the Airy function is of the form:

$$F = \sin \frac{m \pi x}{l} Y \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

in which Y is a function of y only. Inserting Equation (84) into Equation (3*a*) an ordinary differential equation for Y is obtained, as follows:

$$\alpha^4 Y - 2 \alpha^2 \frac{d^2 Y}{dx^2} + \frac{d^4 Y}{dx^4} = 0 \ldots\ldots\ldots\ldots\ldots (85)$$

in which $\alpha = \frac{m \pi}{l}$. The solution of Equation (85) contains four constants of integration which may be determined from the boundary conditions expressed by Equations (83) and (84). The solution of Equation (85) is:

$$Y = C_1 \sinh \alpha y + C_2 \cosh \alpha y + C_3 y \cosh \alpha y + C_4 y \sinh \alpha y \ldots (86)$$

The Airy function is:

$$F = \sin \alpha \times [C_1 \sinh \alpha y + C_2 \cosh \alpha y + C_3 y \cosh \alpha y + C_4 y \sinh \alpha y] . (87)$$

Similarly, when the structure dealt with is bounded by two concentric circles or parts of concentric circles and the loads on the boundaries are expressed as functions of the angle, θ, the form of the Airy function is $F = R \sin n \theta$, or,

$$R \cos n \theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots (88)$$

in which R is a function of the variable, r, only. Inserting Equation (88) into Equation (3*b*) an ordinary differential equation is obtained for R. The solution of this equation yields the following Airy function.[23]

$$\begin{aligned} F = {} & a_0 \log r + b_0 r^2 + c_0 r^2 \log r + d_0 r^2 \theta + \frac{a_1}{2} r \theta \sin \theta + a'_0 \theta \\ & + (b_1 r^3 + a'_1 r^{-1} + b'_1 r \log r) \cos \theta - \frac{c_1}{2} r \theta \cos \theta \\ & + (d_1 r^3 + c'_1 r^{-1} + d'_1 r \log r) \sin \theta \\ & + \sum_{n=2}^{\infty} (a_n r^n + b_n r^{n+2} + a'_n r^{-n} + b'_n r^{-n+2}) \cos n \theta \\ & + \sum_{n=2}^{\infty} (c_n r^n + d_n r^{n+2} + c'_n r^{-n} + d'_n r^{-n+2}) \sin n \theta \ldots\ldots (89) \end{aligned}$$

in which the constants of integration are to be determined from the boundary conditions.

---

[23] "Theory of Elasticity", by S. Timoshenko, Eng. Societies Monographs, p. 114.

The most suitable function for the stresses at a sharp corner, of the type shown in Fig. 4, is of the form:

$$F = r^{n+1} f \ldots\ldots\ldots\ldots (90)$$

in which f is a function of the variable, θ, only. Insertion of Equation (90) into Equation (3*b*) gives the following ordinary differential equation for f:

$$\frac{d^4 f}{d\,\theta^4} + 2\,(n^2 + 1)\,\frac{d^2 f}{d\,\theta^2} + (n^2 - 1)^2 f = 0 \ldots\ldots\ldots\ldots (91)$$

The solution of Equation (91) is:

$$f = c_1 \cos\,(n - 1)\theta + c_2 \sin\,(n - 1)\theta + c_3 \sin\,(n + 1)\theta + c_4 \cos\,(n + 1)\theta . (92)$$

The constants of integration and the values of n that remain to be determined are obtained from the boundary conditions on the faces, $\theta = 0$ and $\theta = \gamma$. Expanding the terms of Equation (92), the resulting formula is identical with Equation (43) in which A, B, C, and D are constants of integration replacing c_1, c_2, c_3, and c_4 of Equation (92).

For the boundary conditions — $\theta = 0$; $\sigma_\theta = 0$; $\tau_{r\theta} = 0$; and $\theta = \gamma$; $\sigma_\theta = 0$; $\tau_{r\theta} = 0$ — a set of homogeneous linear equations is obtained, namely;

$$B = 0 \ldots\ldots\ldots\ldots (93)$$

$$A\,n + C = 0 \ldots\ldots\ldots\ldots (94)$$

$$D \sin n\,\gamma + A \sin n\,\gamma \cos \gamma + C \cos n\,\gamma \sin \gamma = 0 \ldots\ldots (95)$$

and,

$$D\,(n \cos n\,\gamma \sin \gamma + \sin n\,\gamma \cos \gamma) + A\,(n \cos n\,\gamma \cos \gamma - \sin n\,\gamma - \sin \gamma) + C\,(\cos n\,\gamma \cos \gamma - n \sin n\,\gamma \sin \gamma) = 0 \ldots\ldots (96)$$

The simultaneous solution of Equations (93) to (96) gives only relations between the constants, namely, $B = 0$; $\frac{C}{A} = -\,n$; and, $\frac{D}{A} = -\,(\cot \gamma - n \cot n\,\gamma)$. Assuming that $A = -\,1$, then $C = n$; and $D = (\cot \gamma - n \cot n\,\gamma) = m$, which values are identical with those of the author. Furthermore, in order that the constants may differ from zero, the following relation must hold true:

$$n^2 \sin^2 \gamma = \sin^2 n\,\gamma \ldots\ldots\ldots\ldots (97)$$

By means of Equation (97) any number of functions of Equation (43), each with a free constant, may be obtained to satisfy conditions on boundaries other than $\theta = 0$ and $\theta = \gamma$, as shown by Equation (50).

The function expressed by Equation (43) has appeared from time to time as special cases in engineering literature, but no general form has been given. H. M. Westergaard, M. Am. Soc. C. E.,[24] has applied this type of function when $\gamma = 360$ degrees. The function took the following form,

$$F = \sum_{n=1,2,3\ldots}^{n} K_n \frac{r^{n+1.5}}{2\,(n+0.5)\,(n+1.5)} \Big[(n-0.5)\sin(n+1.5)\,\theta - (n+1.5)\sin(n-0.5)\theta \Big] \ldots\ldots\ldots\ldots\ldots\ldots (98)$$

in which the coefficients, K_n, are free constants.

Fred L. Plummer,[25] Assoc. M. Am. Soc. C. E. (by letter).—It is unfortunate that so few practicing engineers are able to make use of many of the more fundamental and more generalized stress functions. In illustrating so effectively one application of the Airy stress function the author has performed a difficult but exceptionally valuable service to the profession. The writer wishes to discuss Part II of the paper which describes the use of photo-elastic studies in determining the distribution of principal and shearing stresses in dams. This method of analysis has many proper applications in the field of structural engineering and should be more generally understood and used by designing engineers. In many cases, quite crude apparatus will give qualitative results of great value.

The author calls attention to the difficulties encountered in attempting to simulate body forces (due to weight and inertia) in the model. The writer has met this problem in two ways. In one study a model was rotated together with a slotted wheel giving a stroboscopic effect. This method is similar to that suggested in the paper and gave satisfactory results. The apparatus is somewhat elaborate, however, and requires careful adjustment.

A much more direct solution may be effected by the use of models made of gelatin. This material may be secured in either "ground" or "sheet" form, at little cost. It should be soaked in cold water for at least 1 hr and then heated to a temperature of not more than 150° F. The concentration of the solution can be varied from 2% or 3% to about 50% (by weight), giving a wide range to the strength and stiffness of the mass which solidifies upon cooling. The stress-strain-optical properties are such as to make the material quite suitable for photo-elastic studies when body forces are of importance. These properties vary, however, as the material ages, and it is necessary, therefore, to make calibration tests at the time of the model tests. The writer has found concentrations of from 10 to 20% most suitable for models of gravity dams. Such models may have thicknesses as great as 6 in., as compared with a fraction of an inch which is common for models made of bakelite. This fact, together with the greater stress-optical sensitivity of the material, makes easy the determination of the stresses caused by the weight of the material itself. The use of much larger models is also made practical.

[24] "Stresses at a Crack, Size of the Crack, and the Bending of Reinforced Concrete" by H. M. Westergaard, *Journal*, Concrete Inst. November–December, 1933, p. 93.

[25] Assoc. Prof., Structural Eng., Case School of Applied Science, Cleveland, Ohio.

The writer has made several studies using this type of model. A brief description of one such study conducted in co-operation with the Zanesville, Ohio, Office of the U. S. Corps of Engineers may be of general interest. Major J. D. Arthur, Corps of Engineers, U. S. Army, District Engineer, T. T. Kappen, Assoc. M. Am. Soc. C. E., Chief of the Engineering Division, A. L. Alin, M. Am. Soc. C. E., Chief of the Dams and Reservoirs Division, and R. R. Philippe, Director of the Soils Laboratory, were responsible for the planning and conduct of the tests.

The structure under consideration was a gravity type of concrete dam. A typical cross-section of the spillway section is shown in Fig. 14. Two series of photo-elastic model studies were made. Bakelite models were used in the first series, the procedure being very similar to that outlined by the author, except that vertical loads were applied so as to simulate, successively, the proper intensity of weight forces at three different elevations (Elevation 850, Elevation 870, and Elevation 890). Gelatin models constructed to a scale of 1:60 were used for the remaining studies. The weight of the prototype was represented accurately by the weight of the model while the forces due to water pressure were reproduced by the use of a liquid having a weight, in pounds per cubic foot, bearing the same relation to 62.4 as that of the unit weight of the gelatin as tested had to the assumed unit weight of the concrete. Liquid pressures were applied directly to the model through a thin rubber diaphragm. It is believed that the external forces as well as the body forces were thus represented accurately. It was possible to study the changes in the combined stresses as the water level might rise in the prototype from empty reservoir to maximum flood level estimated in this case as Elevation 931, which corresponds to 15 ft of water over the top of the spillway. By varying the relative strength and stiffness of the mass of gelatin representing the foundation material, it is possible to study the effect of foundation materials of varying strength characteristics upon the stresses near the base of the dam.

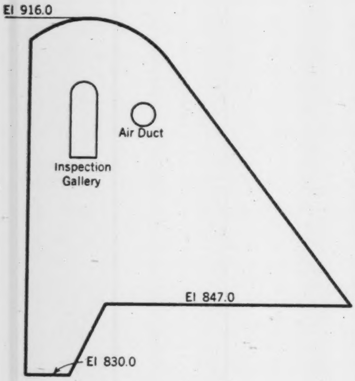

FIG. 14.

In this case it was especially desired to determine the stresses in the material around the openings for the air duct and inspection gallery, and in the cut-off anchor wall which was provided because of horizontal layers of soapstone that occurred in the foundation material. The results of the tests were highly satisfactory, the final design of steel reinforcement at these points being based on the test results.

ARSHAG G. SOLAKIAN,[26] ESQ. (by letter).—A description of the theoretical and experimental analysis of stresses in dams due to body forces and hydrostatic pressure is contained in this paper. Undoubtedly, it serves "to familiarize engineers with the use of the Airy stress function for the solution of problems in plane stress and plane strain * * *".

Much has been published in the United States concerning the optical principles involved in the art of stress analysis by means of polarized light and transparent materials, especially as applied to the determination of stresses in structural and machine elements. In this respect, the paper does not add considerably to the technique of photo-elastic measurements. Furthermore, the only experimental results offered are the boundary stress distribution curves and a photograph of an isoclinic band (which only serves to give the direction of the principal stresses along its path (Fig. 13)). The most useful patterns of stress fringes, which give a concrete idea as to the distribution of stresses in the model under specific types of loading, are omitted from the paper.

The method of conducting the experimental investigation (that is, of substituting body forces in the model by equivalent external loads) is not sufficiently accurate to justify its general adoption. It is for this reason that Mr. Brahtz finds that in certain cases (see following Equation (8)), in the upper two-thirds of the dam the stresses obtained agree with experimentation, and, in other cases, in the base region the boundary stresses are in close agreement with the approximate methods used in Part I. This indicates that for no special case of loading do the stresses in the entire field agree with those obtained by theory. An important objection to the superposition method of finding the resultant stresses (due to (1) the weight of the dam; (2) the vertical pressure of water over the top of the foundation; and (3) the lateral pressure of water against the face of the dam in contact), is that the principal stress orientations for the three different types of loading are different. Consequently, the investigator must go through a tedious analytical and graphical solution, which leads to results of questionable precision.

As Mr. Brahtz suggests, "the easiest method would be to rotate the model and observe it whenever it passes through the optical field". This is an exact method and has already been attempted with success in a similar problem, by making use of the centrifuge-polariscope apparatus developed at Columbia University[27], in New York City. A box containing the model of a retaining wall[28], with sand acting as back-fill, is allowed to rotate at constant speed to produce increased gravitational effects. A steady image of the stress fringes in the model is projected on the screen by means of a stroboscopic polarized light arrangement. The screen is stationary as in an ordinary polariscope of transmission type. The model and the sand are oriented in the box (see Fig. 15) in such a manner as to produce in the structure the resultant effect

[28] *Loc. cit.*, Fig. 3, p. 288.

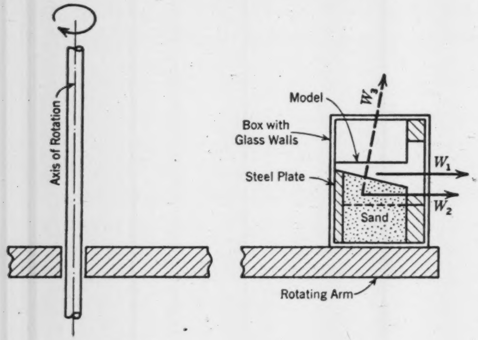

FIG. 15.—ARRANGEMENT OF MODEL AND SAND IN THE CENTRIFUGAL MACHINE.

(as to magnitude and direction of principal stresses) of the weight of the dam, W_1, the vertical pressure of the sand, W^2, and the lateral thrust of sand, W_3. A fringe pattern[27] of the stresses obtained by this method, with a bakelite model, and sand back-fill rotating at a speed of 1 500 rpm in a centrifugal field having a gravitational strength of 485, has been published elsewhere[29]. Because of the limited speed and length of the rotating arm of the centrifugal machine and the size of the model made of bakelite having a moderate optical sensitivity to applied stress, the number of fringes produced in the pattern are not sufficient for an exact determination of the stresses. A new photo-elastic material[30], having an optical sensitivity about three times greater than that of bakelite, would have permitted sufficient data to be secured from a pattern obtained under similar conditions, for an exact solution of the problem.

LARS R. JORGENSEN,[31] M. AM. SOC. C. E. (by letter).—In adding to the knowledge of gravity dam design the author has done an immense amount of work. Except, perhaps, for the multiple-arch, and the Ambursen types, the design of dams is not yet an exact science, and there is actual need for more work in this field.

The actual safety of a gravity dam is made up principally of the following items: The weight acting downward on the foundation opposing any tendency to slide; the capacity of the material to withstand vertical tension at and near the up-stream face; and the shearing strength of the material, generally concrete. Since no gravity dam is known to have failed by crushing of the material, dangerous compressive stresses apparently do not develop in that type; this also checks with theory.

Since the vertical tensile strength of the bond between horizontal joints is a very uncertain quantity, just as is the shearing strength of such joints, although perhaps to a lesser extent, these items are ordinarily neglected, as they should be, when computing the safety factor of a gravity dam. For such a structure, the weight times the coefficient of friction must be greater than the water load, in order to give a factor of safety greater than one, when the structure is acting strictly as a gravity dam.

[30] "A New Photoelastic Material", by A. G. Solakian, *Mechanical Engineering*, December, 1935.

[31] Cons. Hydro-Elec. Engr., Berkeley, Calif.

The writer has recently had an opportunity to make studies on a proposed gravity dam, 173 ft high, of triangular cross-section (top width, 20 ft) having a suggested base width of 75% of the height. In this case, the water load divided by the weight of the section was 0.55. Since the coefficient of friction may be between 0.6 and 0.75, this section acting as a gravity dam may have a factor of safety between 1.09 and 1.36, provided there is no uplift and no back-water. Such low factors of safety would not be considered in any other kind of a structure. On most well-built dams the factor of safety may be higher than the foregoing values indicate, but if it is, that fact will be due to the tensile and shearing strength of the concrete and not to gravity action.

Tests on models[32] have shown that stresses in dams are not linearly distributed as is generally assumed, but that tension does exist in the up-stream face of a loaded dam at and toward its junction with the foundation. These particular models had a base width of 77% of the height. The existence of tensile stresses in the up-stream face of a loaded gravity dam was also shown theoretically by Mr. B. F. Jakobsen[33], at least approximately, and by Ivan E. Houk, M. Am. Soc. C. E.[34]

A practical demonstration of the more than probable existence of tensile stresses in the up-stream face of a loaded so-called gravity dam is contained in the record of the failures of 68 gravity dams, with or without curvature, during the last 136 yr, or at the average rate of 1 every 2 yr. The best method for preventing such failures in the future is to accept the existence of these tensile stresses and provide gravity dams with a wider section than is customary at present.

The author shows a section of the Morris Dam on the San Gabriel River, in California. This dam would scarcely have any tension in the up-stream face at and near the foundation, since its base is about 86% of its height. With its Levy cross-section, this dam is perhaps the most conservative gravity dam in California, and, undoubtedly, is safe under any condition, since the factor of safety of such a section always will remain greater than one, without having to depend upon any help from the tensile strength or shearing strength of the concrete.

How far one can go below a Levy section is a matter of judgment, but any reduction below such a section will be at the expense of the safety factor. Many engineers seem to have an unlimited faith in any dam called a gravity dam; undoubtedly, that confidence is well placed when the base width is 86% of the height, but for base widths of 66.6% of the height—which a considerable number of dams have—that confidence is badly placed. The actual factor of safety of such a section will depend upon the capacity of the concrete to take tension in the up-stream face. Gravity action alone will not produce a factor of safety worth mentioning.

[33] "Stresses in Gravity Dams by Principle of Least Work", *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 489.

[34] *Western Construction News*, April 10, 1932, p. 190.

Whether arch action increases the stability of a gravity dam arched in plan, and to what extent, at least in winter, is a debatable question and one not easy to answer. The question is even disputed internationally. The French regulations for building dams discourage the practice of curving gravity dams in plan, whereas the Italian regulations encourage it. The Italian regulations even go so far as not to require contraction joints, whenever a gravity dam is curved in plan.

The latest dam failure was on the Orba River, in Italy, where a gravity dam about 40 ft high went out on August 13, 1935, causing a great loss of life and property below it. A cloudburst brought down more water than the spillways could take care of and forced the surplus to flow over the crest. The section of the dam was quite ample for the normal water load, but not for the increased water load, which was estimated at 50% above the normal. This shows that the normal factor of safety could not have been more than 1.50 from all sources, since this factor of safety was completely cancelled by a 50% increase in the water load.

When a dam fails, there is generally much more involved than just the cost of the structure. It is especially important to satisfy the worst condition of stress distribution that can exist in the structure, rather than the best. Several of the recent gravity dam failures point to the fact that tension does exist in the up-stream face at, and near, the bottom of a loaded dam of less than the Levy section. The assumption of linear stress distribution, or of the author's stress distribution, is not on the safe side, although no fault can be found with the mathematics in the paper. If it was safe, several of the recent gravity dam failures would not have happened.

The earlier French regulations for building gravity dams contained the provision that, at all points of the up-stream face, such dam sections must have a pressure at least equal to the water pressure. This requirement produces the so-called Levy section having a base width of about 85% of the height. The new rules allow smaller sections, but for full reservoir there must still be compression in the concrete at the up-stream face.

Especially when it is subject to high-water pressure, concrete deteriorates with age, this deterioration being most marked in the up-stream section, where it is water-soaked. In many dams, deposits of lime have been shoveled out of the inspection galleries. This material can have come from no other place than the section of dam lying up stream of the gallery. The deterioration is most pernicious in its effect on the tensile strength, which is most needed relatively in this portion. If the section is so slim that the factor of safety depends in any great degree on the tensile strength of the concrete, then the dam is likely to be in distress at a fairly early age. The best means to avoid tensile stresses in the up-stream face is to provide an ample section. If such a section is much less than a Levy section, especially on the side-hill part of the dam, the factor of safety will only be an uncertain amount greater than one, acting as a gravity dam. Sixty-eight failures of gravity dams bear ample witness to this fact.

Elmer O. Bergman,[85] M. Am. Soc. C. E. (by letter).—The treatment of the stresses due to the weight of the structure, as proposed in this paper, is a particularly valuable contribution to the subject. The author is to be commended, furthermore, for his able presentation of the Airy stress function and its application to the analysis of civil engineering structures.

In the past the Airy stress function has been applied mainly to the solution of problems of interest to the mechanical engineer in which the stresses due to weight can be neglected in comparison with those set up by the applied loads. Another important point of difference between the problem treated by the author and those dealt with in the literature of elasticity lies in the disparity of cost between a dam and the ordinary structural and machine elements. Because the solution of all but the simplest problems of elasticity is involved and laborious, an effort is made to obtain a design formula that is relatively easy to apply and is on the side of safety. This necessarily results in the use of more material which, in a large dam, might result in a considerable increase in cost. The author has developed an approximate solution in Application IV, but he recommends that its use be limited to preliminary work.

Any variable which is a function of two independent space variables can be represented by a surface. The surface represented by the Airy stress function is called the Airy surface. The curvatures and twists of such a surface using a small scale for F are given by Equations (1) and hence afford a geometrical representation of the stresses. It should be noted that, in this interpretation, the curvature of the surface along any section is related to the normal stress acting across that section. Thus, the curvature at a point in the direction parallel to x represents the stress, σ_y, at that point.

The condition that Equations (6) reduce to Equations (7) is that the x, y plane be tangent to the Airy surface at the origin. When no body forces are acting, the value of the Airy stress function, F, at any point (by Equation 7(c)), represents the moment of the forces between the origin and the point about the point. Thus, if the origin is taken as in Fig. 1, the moment at B is the moment about B of the internal and external forces acting along any line connecting the origin with B.

The Airy surface, therefore, is a two-dimensional analogue of the familiar bending moment diagram. The slope of the tangent line to the surface at any point represents the sum from the origin to the point of the forces perpendicular to the tangent line. Thus, the Airy surface furnishes a helpful means of visualizing the moments, shears, and stresses in the slab.

The writer has been connected with the testing and analysis of several models of dams constructed of a compound of commercial building plaster and diatomaceous earth, a material very similar in action to concrete, but having a much lower modulus of elasticity. The models consisted of thin slices from the central part of the dam where they can be considered as being in a state of plane strain. As tested, the models were in a state of plane stress. Under these conditions there is direct correspondence between the stresses in the model and prototype, but not between the displacements and the strains. (For the relations between displacements, see the author's discussion relating to Equations (9) to (12).) The strains due to dead load and live load were measured on four intersecting gauge lines at points in the dam and its foundation with optical strain-gauges.

---

[85] Assoc. Prof. of Civ. Eng., Univ. of Colorado, Boulder, Colo.

Vertical, horizontal, shearing, and principal stresses were computed from these strains and the elastic constants of the material. The results of these tests can not be compared directly with those of the author because they were not on the same section, but they show the same trend of action as indicated in Figs. 6 and 7, except that, due to plastic flow in the material of the model under high stress, the high concentration of stress at the heel and toe of the dam did not appear.

D. P. Krynine,[36] M. Am. Soc. C. E. (by letter).—The use of the Airy stress function in dam engineering is discussed in this highly interesting and important paper. The writer's attention has been especially attracted by the determination of stresses in foundations (Application II).

Limits of Application of the Stress Function to Dam Foundations.—As stated in the "Introduction" the use of the stress function is restricted to elastic isotropic materials. Granite or basalt rock may be considered as elastic and, to a certain extent, isotropic; and, consequently, elastic theories may be applied in the case of such foundations. The situation is more complicated if the foundation material is sandstone, for example, since it is questionable whether in all cases such a material satisfies the conditions of both elasticity and isotropy. On the other hand, a clay foundation would justify the application of the stress function, whereas, in the case of glacial drift, such an application would be misleading since the actual stress distribution is far different from the patterns given by the theory of elasticity.

The use of the stress function is always limited to the two-dimensional problem. In other words, satisfactory results may be expected from the application of the stress function to sections at some distance from the ends of the dam, but not otherwise. Near the ends, the problem is three-dimensional, and the stress function is not applicable.

Within these limitations Mr. Brahtz has demonstrated, in a comprehensive and intelligent manner, that stresses in a dam foundation can be determined by means of the stress function. It still remains to be proved that they should be thus determined and the writer is rather pessimistic in this respect.

Stress Distribution Under a Foundation.—It can be demonstrated that the value of the stress, σ, caused by a concentrated force, P, acting at the boundary of a semi-infinite earth mass (Fig. 16), is:

$$\sigma = \frac{\nu\, P}{2\, \pi\, \rho^2} \sin^{\nu-2} \theta \ldots\ldots\ldots\ldots\ldots\ldots (99)$$

Equation (99) has been proposed by John H. Griffith[37], M. Am. Soc. C. E., and Dr. O. K. Fröhlich.[37] It can be developed without making use of elastic theories. Hence, it is valid for any isotropic or statistically isotropic body. The coefficient, ν, is the so-called "concentration factor", and is equal to 3,

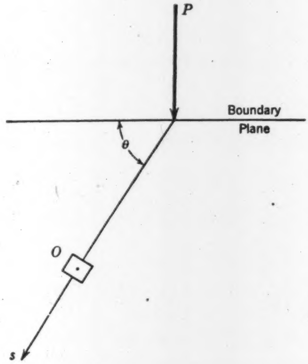

FIG. 16.

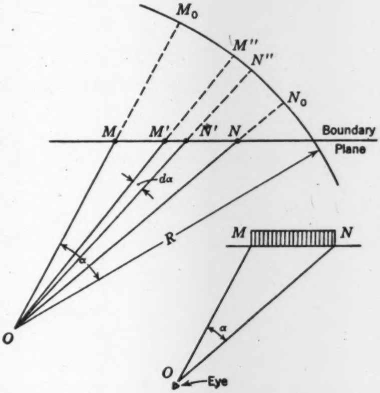

FIG. 17.

for the case of an isotropic elastic body in which the value of the reciprocal of Poisson's ratio, m, is equal to 2. For this case Equation (99) becomes:

$$\sigma = \frac{3\,P}{2\,\pi\,\rho^2}\sin\theta \quad \text{......................}(100)$$

Equation (100) may be obtained from those developed by Boussinesq[6], assuming that $m = 2$. A two-dimensional analogue to Equation (100) is Michell's expression for radial distribution[38]:

$$\sigma = \frac{2\,P}{\pi\,\rho}\sin\theta \quad \text{......................}(101)$$

The plane stress distribution does not depend on the value of Poisson's ratio, μ, and Equation (101) holds in the case of any value of that ratio.

Concentrated Forces at the Boundary of a Mass.—The problem in connection with Fig. 3 of the paper, in the case of a two-dimensional elastic body, may be treated in the form of a general case (that is, for any three-dimensional body, isotropic or statistically isotropic), by applying Equation (99). In the case of a horizontal force, Q, the solution may be written directly[39]:

$$\sigma_x = -\frac{\nu\,Q}{2\,\pi\,\rho^2}\cos^{\nu}\theta \quad \text{.................}(102a)$$

$$\sigma_y = -\frac{\nu\,Q}{2\,\pi\,\rho^2}\cos^{\nu-2}\theta\,\sin^2\theta \quad \text{...........}(102b)$$

---

[38] "Theory of Elasticity", by S. Timoshenko, p. 82, 1934.

[39] "Druckverteilung im Baugrunde", by O. K. Fröhlich, p. 27, 1934.

and,

$$\tau_{x,y} = -\frac{\nu Q}{2\pi\rho^2}\cos^{\nu-1}\theta\sin\theta \qquad (102c)$$

A two-dimensional analogue to Equations (102) for the particular case in which $\nu = 3$ leads directly to Equations (32) of the paper.

In the same manner the stresses caused by a vertical force, P, acting at the boundary are:

$$\sigma_x = -\frac{\nu P}{2\pi\rho^2}\sin^{\nu-2}\theta\cos^2\theta \qquad (103a)$$

$$\sigma_y = -\frac{\nu P}{2\pi\rho^2}\sin^{\nu}\theta \qquad (103b)$$

and,

$$\tau_{x,y} = -\frac{\nu P}{2\pi\rho^2}\sin^{\nu-1}\theta\cos\theta \qquad (103c)$$

For the case of a two-dimensional elastic mass the three-dimensional formulas (Equations (103)) may be easily reduced to those given by Mr. Brahtz immediately preceding Equation (37).

Uniform Load Distribution at the Boundary of a Two-Dimensional Mass; "Angle of Visibility".—The problem of a uniformly distributed load acting at the horizontal boundary of a mass may be also solved by applying the general formula, Equation (99). For the purposes of this discussion, a two-dimensional elastic mass only will be dealt with and Equation (101) will be applied. In Equations (38) and (39) Mr. Brahtz gives the values of the stresses, σ_x, σ_y, and $\tau_{x,y}$, as functions of two angles, α_1 and α_2. It is more convenient to use a single angle, $\alpha = \alpha_1 + \alpha_2$ (see Fig. 17). The angle, α, may be termed the "angle of visibility" since this is the angle at which a hypothetical observer placed at the given point, O, of the mass, would see the foundation if the mass were transparent. The writer understands that the conception of the "angle of visibility" was first introduced by Professor N. M. Gersevanov.[40] Tracing a circle of an arbitrary radius, R, with Point O as a center, and considering an elementary angle of visibility, $d\alpha$, corresponding to a loaded element, $M'N'$, at the boundary, the elementary stress, $d\sigma$, at Point O, would be, using Equation (101):

$$d\sigma = -2p\left[\frac{\rho\,d\alpha}{\cos\theta}\right]\frac{1}{\pi\rho}\cos\theta = -\frac{2p}{\pi}\,d\alpha \qquad (104)$$

Were the mass cylindrical (that is, circular in cross-section) with a radius, R, and were the arc, M_0N_0, loaded normally with the unit load, p, the corresponding elementary stress, $d\sigma$, at Point O, would be:

$$d\sigma = -2p\,[R\,d\alpha]\frac{1}{\pi R} = -\frac{2p}{\pi}\,d\alpha \qquad (105)$$

---

[40] "Principles of Dynamics of an Earth Mass", by N. M. Gersevanov, p. 153 (printed in Russian, in 1933).

since in this case the force, p $[R\,d\alpha]$, acts normally to the circular boundary of the mass, and the angle, θ, equals zero. Integrating Equations (104) and (105) through the entire angle, α, it may be stated that the sum of the principal stress, σ, at Point O, is proportional to the "angle of visibility", α:

$$\sigma = -\frac{2\,p}{\pi}\,\alpha \quad \text{.....................} (106)$$

It is also obvious that the sum of principal stresses at a point does not depend on the shape of the loaded surface provided the "angle of visibility", α, of the loaded surface remains the same, and the surface in question is loaded uniformly and normally.

It may be seen from Fig. 17 that using the "angle of visibility" an asymmetrical loading problem (loaded surface, $M\,N$) is reduced to a symmetrical problem (loaded surface, $M_0\,N_0$). This fact permits one to state directly that the direction of the major principal stress coincides with the bisector of the "angle of visibility." It is well known that the proof of this simple statement, as given in textbooks on elasticity, is rather complicated.

Projecting all the elementary stresses, $d\sigma$, on the normal to a plane, and integrating, the pressure normal to that plane is obtained. Thus:

$$d\sigma_x = -\frac{2\,p}{\pi}\,d\alpha\,\cos^2\theta = -\frac{p}{\frac{1}{2}\,\pi\,R^2}\,[R\,d\alpha\cos\theta]\,[R\cos\theta] \quad \text{...} (107a)$$

and,

$$d\sigma_y = -\frac{2\,p}{\pi}\,d\alpha\,\sin^2\theta = -\frac{p}{\frac{1}{2}\,\pi\,R^2}\,[R\,d\alpha\sin\theta]\,[R\sin\theta] \quad \text{...} (107b)$$

It may be seen from Fig. 18(a) that $[R\,d\alpha\,\sin\theta]$ and $[R\,d\alpha\,\cos\theta]$ are projections of the arc element, $R\,d\alpha$, on horizontal and vertical planes, respectively. In the same manner $[R\cos\theta]$ *and* $[R\sin\theta]$ are projections of the

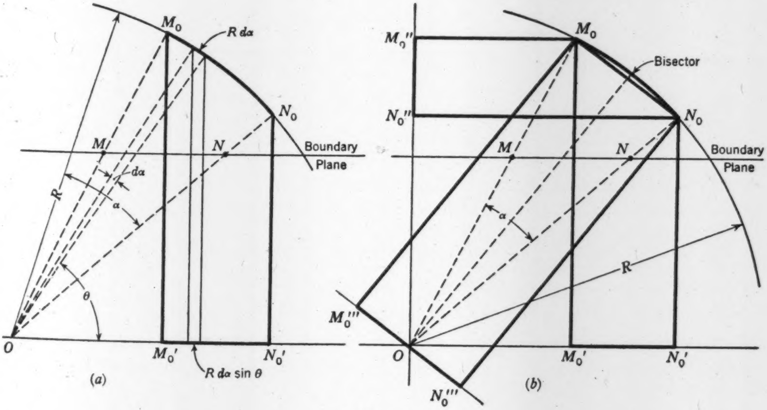

FIG. 18.

radius, R (also on horizontal and vertical planes, respectively). Designating the half area of a circle of a radius, R, by A, and integrating (Fig. 18(b)):

$$\sigma_x = -p \frac{\text{Area } M_o\, M''_o\, N''_o\, N_o}{A} \qquad \text{(108}a\text{)}$$

and,

$$\sigma_y = -p \frac{\text{Area } M_o\, M'_o\, N'_o\, N_o}{A} \qquad \text{(108}b\text{)}$$

Projecting now the arc, $M_o\,N_o$, on the normal to the bisector of the "angle of visibility", the values of the principal stresses, σ_1 and σ_2, may be obtained. The minor principal stress, σ_2, is proportional to the area between the chord, $M_o\,N_o$, and the arc, $M_o\,N_o$. The major principal stress is proportional to the sum of that area and the rectangle, $M_o\,M'''_o\,N'''_o\,N_o$. Shearing stresses may be easily obtained in the same way. Thus, the determination of stresses is reduced to a simple measurement of areas by planimeter. This method may be extended to the case of non-uniformly distributed vertical loads, which represents a problem that is almost impossible to attack by the use of the stress function method. Fig. 19(a) illustrates the determination of the stress, σ_y, in such a case. Each ordinate of the area, $M_o\,M'_o\,N'_o\,N_o$, is to be multiplied by the ratio, $\frac{p_1}{p}$, of the actual unit load, p_1, at a given point of the foundation, to a certain standard unit load, p.

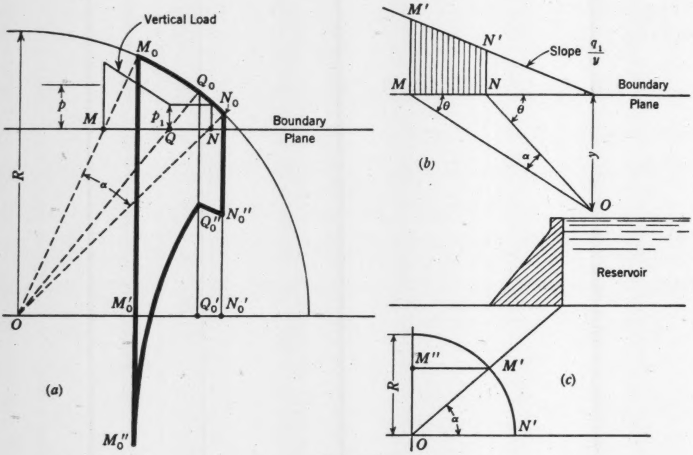

FIG. 19.

A horizontal force, Q, and a vertical, $P = Q \cot \theta$, produce equal stresses at a given point which follows from a simple inspection of the formulas expressing the stresses, σ_x, σ_y, and $\tau_{x,\,y}$. The problem of uniform distribution of a horizontal force, q_1, per unit of length of the distance, l_1, may be thus reduced to that of a non-uniform distribution of the vertical unit force,

$q_1 \cot \theta$, over the same distance, l_1. A straight line is drawn with its origin, O', at the boundary of the mass (Fig. 19(*b*)). The slope of this line is $\frac{q_1}{y}$, in which y is the depth of the given point, O. The "angle of visibility", α, would determine an area, $M\,M'\,N'\,N$, showing the law of distribution of the equivalent vertical load over the distance, $M\,N = l_1$. The problem is afterward solved according to Fig. 19(*a*) thus avoiding Equations (34). The problem of a non-uniform distribution of a horizontal force, q_1, may be also solved in a similar manner.

Reservoir Pressure.—This pressure determined by Mr. Brahtz analytically, may be readily found by graphics. Fig. 19(*c*) shows the graphic determination of the stress, σ_x, in the case of a long reservoir when one of the sides of the "angle of visibility" is practically horizontal. The stress in question is proportional to the area, $O\,N'\,M'\,M''$. The value of the radius, R, is arbitrary.

Value of the Poisson Ratio of a Dam Foundation and Displacement Formulas.—The author introduces the symbol, μ_2, as the Poisson ratio of the material comprising the dam foundation. One of the basic principles of soil mechanics is the incompressibility of soil particles. In other words, a soil particle is assumed to be capable of a change in its shape, but not its volume, in which case the value of Poisson's ratio would be 0.5. On the other hand, earth masses under action of their own weight produce lateral pressure, and the ratio of the lateral pressure to the vertical, or the "coefficient of pressure at rest", K, may equal 0.25 to 0.20, for example. If the elastic formula, $\kappa = \frac{\mu_2}{1 - \mu_2}$, is used for determining this coefficient of pressure at rest, the value of μ_2 would be one-fifth or one-sixth. Thus, a substance would have two different values of Poisson's ratio, which is obviously impossible. In the writer's opinion the conception of a "Poisson ratio" as applied to foundations, conveys a correct idea only in the case of elastic, dense rocks, such as some granites or basalts, and should not be used in other cases except, possibly, in the case of stiff clay foundations.

As to the displacement formulas, such as Equation (36) or Equation (40), in addition to containing an indefinite value of the Poisson ratio, μ_2, they are objectionable from the following points of view:

First.—They have been developed under the assumption that the earth mass is weightless and obeys Hooke's law unconditionally. An earth mass, however, has been under the action of its own weight perhaps for millions of years; elastic deformations have long since occurred, and the construction of a dam involves not merely the application of a relatively light load for which Hooke's law holds, but a further considerable increase in stress which, at some depth, probably exceeds the elastic limit. At such high ranges of loading, deformations increase more rapidly than the corresponding loads, even in perfectly elastic bodies, and in the given case there is a danger of under-estimating the value of the displacement if Equation (36) or Equation (40) is used. Such an under-estimation may be termed a "positive error."

Second.—A displacement connotes a movement, or translation, of matter. In order to move even a molecule a certain minimum of energy is required. Hence, it is logical to assume that, at a certain distance from the load, no displacement occurs which is contrary to the conditions of Equations (36) and (40). This fact may cause a "negative error."

Third.—It is known from every-day practice that elastic displacements in earth masses are accompanied by irreversible movements to such an extent that the elastic rebound after unloading a mass, sometimes reaches only 10% or 15% of the original displacement. No means has yet been devised for separating elastic, from inelastic, deformations; and only laboratory experiments furnish some bases for judgment as to the extent of the possible displacement. Positive and negative errors may compensate, and, in some cases, the observed settlement is found to agree closely with the value computed by elastic formulas; but by no means should this phenomenon be accepted as proof that such formulas would furnish satisfactory results in so far as displacements under any conceivable circumstances are concerned.

Shearing Stresses; Isochromatics.—Danger from shear is mostly a surface problem, and shear stresses are to be determined in the upper layers of the mass, close to its boundary surface. There is no danger of shear in deeper strata, where either compression or consolidation occurs. What matters in this connection is the maximum shearing stress, τ_{max}, as determined from the computed values of principal stresses or from isochromatics (see Fig. 12). The values of the shearing stress, $\tau_{x,y}$, acting in the horizontal plane (see heading "Application II.—Stresses in Foundations") are but of little interest for the designer of a foundation.

Attention should be called to Fig. 12(*a*) in which the shape of isochromatics reveals the overloading of the foundation of a dam near its edges. This diagram checks with photo-elastic experiments by other investigators when a punch is pressed against a two-dimensional elastic mass. It should be borne in mind, however, that loading experiments with rigid earth masses (such as sand) reveal overloading at the center of the base of the structure. This induces one to believe that isochromatics, as shown in Fig. 12(*a*), have a restricted meaning only and should be used when there is absolutely no doubt as to both elasticity and isotropy of the foundations, which evidently is not the general case. The same is true of Fig. 12(*b*).

Conclusion.—Applied mechanics, including the theory of elasticity, has been developed for the most part to find the answer to practical questions. It has happened that the attention of the Engineering Profession is principally directed toward machines and framed structures; hence the unusual development of mechanics in the study of such subjects as beams, columns, shafts, plates, disks, etc. The study of "masses" or bodies possessing three great dimensions has been relatively neglected. The masses, in turn, may be subdivided into "unlimited" or semi-infinite and "limited" masses. In the study of stress distribution in semi-infinite masses there have been the works of such investigators as Boussinesq, Michell, Carothers, and, in the past few years, of a number of research workers in soil mechanics. In the study of "limited" masses, such as concrete or masonry, notable progress has occurred lately, mostly due to research incidental to the design of dams, including photo-elasticity. In the latter category, the paper by Mr. Brahtz is a valuable contribution to the study of "limited" masses, and there is every reason to believe that his work along this line and his methods will be used to advantage not only by the builders of dams but also by workers in the allied fields of engineering science, such as soil mechanics.

JOHN H. A. BRAHTZ,[41] ESQ. (by letter).—In closing this paper, the writer wishes to express his appreciation for the many interesting discussions that have appeared. All have been of a high caliber, and illustrate the fact that engineers are getting away from antiquated rules of thumb. With a fuller realization of the importance of two-dimensional stress problems, they are attacking such problems with open minds, more and more leaning toward the theory of elasticity and its co-partner, photo-elasticity. This inquisitive and open-minded attitude is decidedly encouraging. Only thus can the profession advance.

In reviewing the discussions, those pertaining to theory will be considered first.

Mr. Silverman refers to, and very clearly demonstrates, the usual method for obtaining solutions to the differential equation (Equations (3)) as a product of two functions, each of which is a function only of one of the independent variables (x, y) or (r, θ), respectively. As stated in discussing Equation (44) of the paper, this method was purposely not employed, in order to demonstrate the use of the general expression, Equation (4). In separating Equation (4) into its real and imaginary parts, both of which will be solutions to Equations (3), either Cartesian or polar co-ordinates may be used simply by placing the complex variable, z, equal to $x + i\,y$, or $r(\cos\theta + i\sin\theta)$, respectively. In fact, the stress components and displacements are often obtained most easily by carrying out the differentiations of the stress function in complex form before taking real or imaginary parts. In this connection, the following expressions are useful. Let $f = U + i\,V$ be a holomorphic complex function and consider the real part only; then:

$$\frac{\partial U}{\partial x} = \text{real part of}\left(\frac{df}{dz}\right) = \mathsf{R}\left(\frac{df}{dz}\right) \quad \ldots\ldots\ldots\ldots(109a)$$

$$\frac{\partial U}{\partial y} = \text{imaginary part of} -\left(\frac{df}{dz}\right) = -\,\mathbf{I}\left(\frac{df}{dz}\right) \quad \ldots\ldots(109b)$$

$$\frac{\partial U}{\partial r} = +\,\mathsf{R}\left(e^{i\theta}\,\frac{df}{dz}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots(109c)$$

and,

$$\frac{\partial U}{r\,\partial\theta} = -\,\mathbf{I}\left(e^{i\theta}\,\frac{df}{dz}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots(109d)$$

---

[41] With the U. S. Bureau of Reclamation, Denver, Colo.

Altogether, the theory of functions of a complex variable has proved extremely useful and expedient in two-dimensional stress analysis.

It is to be noted that the first function of Equation (4) is holomorphic, the last three are not, and must be treated as products of holomorphic functions and x, y, or r^2, respectively, in carrying out the differentiations.

It is again emphasized that many methods are available for finding solutions to Equations (3). The trick is to find the proper combination of solutions which satisfies the given boundary conditions. Unfortunately, no general method is available for this purpose. On the other hand, if such a solution has been found in some manner, it is fortunate to know that it is unique.

In other words, to find the solution for a given two-dimensional elastic problem it is necessary to try this or that combination of known biharmonics (those which satisfy Equations (3)). If the solution is finally obtained—often after days or weeks of hard labor—the writer generally must resort to a phrase, such as "consider the following function", and then merely prove that it does satisfy all the conditions of the problem without being able to explain just how he obtained the function. This often leaves the reader with the impression that the writer possesses some mysterious technique, which is not at all the case.

The value of the Airy stress function to the practical engineer begins with an intimate knowledge of the few known simple exact mathematical solutions and the ability to combine them in such a manner as to give a good approximate solution of the problem at hand. As a rule, an exact mathematical solution to a practical problem is so unwieldy as to be of little or no practical use. Indeed, the assumptions that must be made as to the physical properties and behavior of the materials involved in practical constructions are generally such as to preclude an exact solution of any practical problem. It should be understood that at best only a close estimate of the stresses in the actual structure can be expected even from the most careful mathematical analysis or photo-elastic experimentation.

The solutions and formulas presented by the writer hold strictly only under the assumptions stated in the "Introduction." In practice these assumptions are never completely fulfilled. In fact, in some instances, it is impossible ever to determine the real properties. This is especially true in the case of foundations.

Professor Krynine treats this subject in his excellent discussion and points out the various materials for which elastic statistical isotropy may be assumed and others in which it may not. This should serve as a valuable guide for the designer of foundations.

The writer has dealt only with elastic media, in plain stress or plain strain. Professor Krynine has made a valuable contribution in extending the theory of foundations to three-dimensional plastic media. The apparent ambiguity in the value of Poisson's ratio, μ_2, for the foundation treated by Professor Krynine ceases to exist when it is again remembered that the formulas only hold for elastic media in plain stress or strain. In that case, no assumption is made as to the incompressibility of soil particles.

In computing stresses in a semi-infinite (three-dimensional) solid due to its own weight, to a uniformly distributed surface loading, or to a combination of both loadings, it would be proper to specify the horizontal strains equal to zero. This gives rise to the formulas[42]:

$$\sigma_x = \sigma_z = K\,\sigma_y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (110)$$

in which σ_y is the vertical stress equal to the total load above the point, and $K = \dfrac{\mu_2}{1 - \mu_2}$.

The displacement formulas presented by the writer are useful for the analysis of a long straight gravity dam on an elastic or quasi-elastic foundation, even if the elastic modulus of the dam itself differs from that of the foundation. The method of procedure of this problem was outlined under Case 2 in the paper. Numerical results have been developed as shown graphically in Fig. 20. The curves were obtained in connection with a study of Grand Coulee Dam (440 ft high), with an up-stream slope of 0.15, a down-stream slope of 0.8, and with concrete weighing 156 lb per cu ft. The curves indicate qualitatively the tendencies of distribution at the base as the foundation stiffens relative to the dam. The analysis did not take into consideration the stress concentrations near the heel and the toe. It is of interest to notice the general agreement between the curves for rigid foundation ($n = \infty$), and those obtained by Mr. B. F. Jakobsen[43].

FIG. 20.—STRESS DISTRIBUTION, GRAND COULEE DAM.

---

[42] *Bulletin 117*, Iowa Eng. Experiment Station, pp. 39–43.

[43] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 489.

Professor Bergman points out in a lucid manner the physical interpretation of the curvatures in the Airy surface. These properties are used in the "slab analogy", an experimental method by which stresses in a two-dimensional problem can be obtained by measuring curvatures and twists in a warped elastic slab. This is possible since the differential equation (Equations (3)), of the Airy elastic stress function, $\nabla^4 F = 0$, has the same form as the differential equation for the normal displacements, z. of a warped elastic slab, $\nabla^4 z = 0$, when the curvatures are held to a low magnitude. This means that the curvatures must be measured by means of microscopes or correspondingly sensitive measuring devices. In the analogy, the curvature of the slab at any point is proportional to the normal stress in a perpendicular direction in the prototype, and the twist at any point is proportional to the corresponding shear. Naturally, the slab must be warped by twists and curvatures at the boundaries that are themselves proportional to the boundary forces acting as the prototype.

Professor Bergman has been closely connected with model experiments conducted on dams by the U. S. Bureau of Reclamation, at the University of Colorado, under the direction of Ivan E. Houk, M. Am. Soc. C. E. It is indeed gratifying to contemplate the testimony of Professor Bergman that good general agreement exists between the theoretical results presented by the writer and this type of experimentation. That the stress concentrations at sharp corners were, to a large extent, relieved by plastic flow was to be expected. In deriving the approximate formulas for fillets the writer did so in order to be able to design a fillet with a safe elastic stress distribution without recourse to plastic time-flow of which very little is known under alternating load conditions.

In the "Introduction" to the paper the writer stated specifically that the intention was not to set up design criteria, and that the question of uplift was disregarded, except to assume that sufficient compression must exist to counteract the effect of uplift or liquid pore pressure. It is correct, therefore, to apply the theoretical results only to dam sections in which this is true, or at least where the resulting tension is not sufficient to cause rupture. In connection with this question, Mr. Jorgensen cites several dam failures and shows that, in all cases, the total effective slope (up-stream plus down-stream slope) was far less than the slopes called for by the Lévy criterion. No doubt, the question of internal liquid pressures in concrete is of great importance. Theoretical studies are now being made by the writer for the purpose of determining the effect of pore pressure on the stresses in hydraulic structures. No real headway can be made in application to practical structures until the question of "contact area" between particles has been settled experimentally for various concrete mixtures. Experiments to that end have been inaugurated at the laboratories of the Bureau of Reclamation. Some work has already been done in this field by various experimenters[44], but there seems to be a wide difference in opinion; in fact, the value given for effective contact area varies from 2 to 40 per cent. Until the question is settled beyond a doubt it would seem necessary, then, to assume the contact area to be practically zero, which means that full uplift must be assumed to exist. Assume, for example, that triangular uplift pressure exists at the base, equal to the full reservoir head at the heel and zero at the toe (which is reasonable for a nearly impervious dam on a pervious foundation), and apply this to the study of Grand Coulee Dam as shown in Fig. 6. It will be found that the vertical normal stresses (Fig. 6(*a*)) near the up-stream face and the horizontal normal stresses in the same region of the foundation, Fig. 6(*b*)) both become tension. The final section of Grand Coulee Dam has been designed with an up-stream slope of 0.15 and a down-stream slope of 0.8.

---

[44] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1052.

It will be noticed in Fig. 6(*a*) that the vertical normal compression stress near the heel is considerably less than that computed by the straight-line formula (Lévy). This would more than bear out Mr. Jorgensen's contention, and would indicate that, due to the restraint of the foundation, a section even heavier than the Lévy cross-section is needed in cases of rather rigid foundations if the experiments confirm the evidence that full uplift must be applied to the dam. This contention is still more true if earthquake accelerations are to be considered and the situation is further aggravated by shrinkage stresses.

Fig. 20(*a*) would indicate that the ratio, n, between the elastic moduli in the foundation and the dam has an important influence on the stress situation at the heel. Further studies along this line should be made so that this seemingly important effect can be taken into consideration in the design of the minimum section on a given foundation. The approximations made in the analysis underlying Fig. 20 were such as to indicate that the curves for $n = 0.5$ deviate slightly too much from the Lévy line.

A theoretical study of the situation around the heel, in which an open crack was assumed to exist under full uplift, demanded an effective total slope of 0.87 (with 150-lb concrete) for stability.

Mr. Jorgensen also touches upon the subject of curved gravity dams. The problem is three-dimensional, so that the individual case must be dealt with separately. The writer has no opinion to offer on the subject. Studies made by Mr. Jakobsen seem to justify the impression that the only point in favor of a curvature without arch action is public psychology.

Parts I and II of the paper were originally presented in two separate manuscripts. It was finally deemed advisable to combine them, and with the limitation set on a single paper, it became necessary to reduce both. Consequently, only sufficient description was retained of the photo-elastic material to show general methods and give the necessary checks on the theoretical results obtained in Part I. Furthermore, the photo-elastic work was conducted as early as 1931–1932 and much improved technique has been introduced since then. Reference to Fig. 21 will show that large spherical reflectors were used instead of the much more expensive lenses, and that the polarizing unit is offset from the analyzing unit, thus providing a convenient large space for the model and operator[45].

---

[45] *Review of Scientific Instruments*, February, 1934, pp. 80–83.

The important features of the two discussions dealing with Part II are the methods for the determination of stresses due to body forces. It is of interest to note that Professor Plummer and Mr. Solakian have developed the centrifugal method independently. Professor Plummer finds that the method gives good results, but that it requires elaborate apparatus and very careful adjustments, and he prefers the direct-loading method described in his very excellent discussion and developed in co-operation with the U. S. Corps of Engineers, at Zanesville, Ohio. Professor Plummer gives new and valuable information in the preparation of gelatin models. If the optical creep in this very optically sensitive substance will not prevent a reliable calibration, the writer believes it will be of inestimable value in photo-elastic experimentation, especially on foundations and related problems.

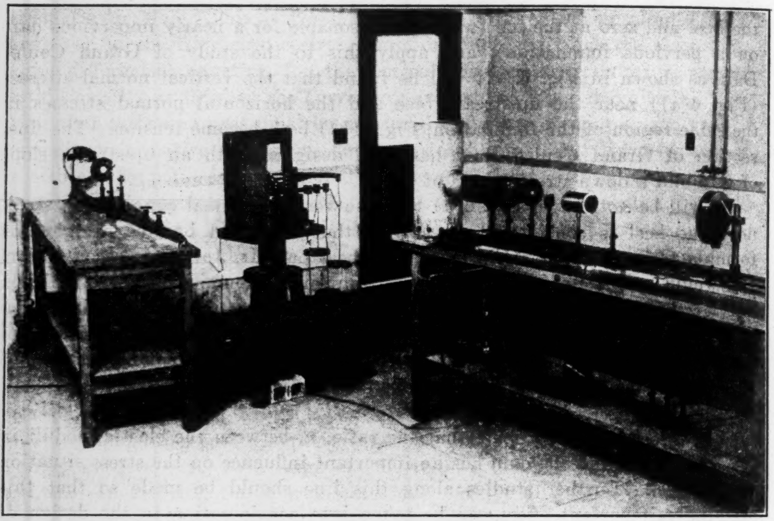

FIG. 21.—VIEW OF PHOTO-ELASTIC LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY.

The writer has adopted the ingenious method, suggested by Dr. Biot, of loading the boundaries with normal force distributions equal to $K y'$, in which K is equal to the weight of the material in the prototype, and y' is the distance from the point of the boundary measured in the direction of the body force to a convenient line perpendicular to that force. This loading will deliver the correct isochromatics and isoclinics due to body forces.

Let the principal stresses obtained from the foregoing loading be σ'_1 and σ'_2; then, the actual stresses at a point due to body force will be.

$$\sigma_1 = \sigma'_1 - K y \qquad (111a)$$

and,

$$\sigma_2 = \sigma'_2 - K y \qquad (111b)$$

in which y is the ordinate to the point measured in the same system as y'. The correctness of this method can be proved directly by use of the Airy stress function. It has been used extensively and very successfully in the photo-elastic laboratory of the U. S. Bureau of Reclamation.

Mr. Solakian objects to the method of superposition of water loads and body forces. As a matter of fact, in the case of dams and many other civil engineering structures, both sets of stresses are usually required separately, either for design purposes or if strains are to be measured in the prototype due to water load (live load) only.

In conclusion, the writer wishes to announce the construction of a new photo-elastic interferometer for the Bureau of Reclamation by which the individual principal stresses at a point can be found directly. It will mark a new advance in technique which promises considerable time-saving. The apparatus was designed by John Soehrens, Jun. Am. Soc. C. E., in the photo-elastic laboratory, and was built under his supervision.

Paper No. 1950

FLOOD AND EROSION CONTROL PROBLEMS AND THEIR SOLUTION

By E. Courtlandt Eaton,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Arthur G. Pickett, R. W. Davenport, C. S. Jarvis, Harry F. Blaney, W. P. Rowe, J. B. Lippincott, E. I. Kotok and C. J. Kraebel, Donald M. Baker, and E. Courtlandt Eaton.

Synopsis

The flood and erosion control problems treated in this paper occur in highly developed areas where there is a relatively low seasonal run-off; these areas, however, are subject to brief, although violent, torrential storms, that result in floods of exceptionally high intensity. When fires denude the sparse vegetation from steep mountain slopes the flood intensities increase and added débris hazards occur, due to erosion.

Basic precipitation and run-off records are given in this paper, as are engineering methods of constructing hydrographs of expected floods, and the regulation needed for control. Similarly, measurements of erosion quantities are presented with suggested solutions of control and a method of avoiding unnecessary capital expenditures in advance of requirements. The incidental conservation of flood waters for domestic use and for irrigation is discussed.

Introduction

Los Angeles County in California, with a population of about 2 250 000 (of whom more than 85% are residents of cities), covers an area of 4 115 sq miles. Its population increase has been nearly 180% since the last major flood (1914), and assessed property values rose, in the same period (1914 to 1931), from \$850 000 000 to more than \$4 000 000 000. The County's petroleum, agricultural, motion picture, and manufacturing industries have an

---

Note.—Published in September, 1935, *Proceedings*.

[1] Cons. Engr., Los Angeles, Calif.

aggregate annual value of more than $1 000 000 000. It is estimated that only 8% of the present population have experienced, or have a realization of, the 1914 flood.

Property valued at more than $300 000 000 and containing 380 000 persons, is subject to possible inundation due to floods.[3] Hazards may be classified under two main heads: The main valleys and coastal plains are subject to inundation by either the overflow of present channels or by the departure of the rivers from existing to new locations; and, in the foot-hill areas, the perils are from sudden flash floods, and débris flows, particularly following water-shed denudation by fires. Valley inundation may be anticipated, by at least hours, from distant mountain rainfall records. Foot-hill débris flows may result if burned catchment areas, after becoming saturated with water, are subjected to high-intensity storms. Such flow occurs without warning and may follow storms of high intensity or cloudbursts, almost immediately.

The factors that combine to menace life and property in this region are: (*a*) Exceptionally precipitous gradients; (*b*) short mountain streams; (*c*) the unstable character of deep weathered mountain cover held from erosion by sparse vegetation; and (*d*) the characteristic violent torrential storms. Protection from floods may operate to conserve the average annual 120 000 acre-ft of flood water that is now wasted.

The paper describes physical conditions and methods of solving problems, especially those dealing with the relatively new engineering field of erosion control. Necessarily, full details cannot be included, but the foot-note references serve as a bibliography of public reports.

PHYSICAL CONDITIONS

Of the 4 115 sq miles that constitute Los Angeles County, 70%, or 2 758 sq miles, is included in the south slopes which drain to the Pacific Ocean (see Fig. 1). The area comprises 1 589 sq miles of mountain water-shed (809 sq miles of which is in Federal forests); 285 sq miles of small water-sheds; and 884 sq miles of valley plains sloping toward the ocean. About 210 000 acres of valley land is under irrigation, and 235 000 acres is devoted to industrial and domestic purposes.

The high mountain areas form a northern boundary of approximately 45 miles, crest length, from which the two major collecting rivers—the San Gabriel and Los Angeles—originate and, after traversing the valleys, they converge and discharge into the ocean at points only six miles apart. Mountain peaks rise to Elevation 10 080 (United States Geological Survey datum). The main rivers are forced to converge by the foot-hills that project on to the plains—the Santa Monica hills from the west and the Puente and San José hills from the east.

The San Gabriel River has a tributary drainage of about 800 sq miles and the Los Angeles River one of about 900 sq miles. The largest catchment of the San Gabriel River is 213 sq miles of the San Gabriel water-shed; that of the Los Angeles River is the Big and Little Tujunga water-sheds with 137 sq miles. The remaining drainages of both rivers are made

FIG. 1.—MAP OF LOS ANGELES COUNTY: DRAINAGES TO PACIFIC OCEAN.

up of numerous small streams originating in more than 100 mountain and foot-hill water-sheds ranging in size from 0.5 sq mile to 30 sq miles.

A third drainage system is Ballona Creek fed from 134 sq miles, its principal supply being the run-off from the streets of Los Angeles, Hollywood, and Beverly Hills, transported to Ballona Creek through storm drains. Its ocean outlet is near Venice, Calif. A fourth drainage is Nigger Slough, similarly deriving its main supply from impervious areas. Its discharge point is near San Pedro, Calif.

Along the coast from Venice westward to the Los Angeles County line about twenty individual streams flow directly into the Pacific Ocean. The largest are Malibu Creek, with a drainage area of 67 sq miles; Topanga Creek (20 sq miles), and Mandeville, Rustic, and Sullivan Canyons (12 sq miles), the latter group passing through Santa Monica, Calif.

Mountain and foot-hill drainages have well-defined canyon channels on precipitous grades of 20 to 30%, sharply flattening from 8 to 10% where they debouch on to unstable delta areas. In many instances cones show little evidence of active channels, and, during the dry cycle (1914 to 1931), home sites were sold readily in foot-hill territories by real estate agents who were themselves possibly ignorant of hazards. Normally, mountain and foot-hill watersheds are covered with a chaparral type of vegetation, efficiently functioning as retarders of flood flows and controlling erosion.

HISTORIC FLOODS

The most recent major floods occurred in 1914 and 1916. In 1914 there were two storm periods: One on January 25, with a maximum intensity of 2.6 in. in 24 hr; and the other on February 18, with an intensity of 4.26 in. Exclusive of harbor damages the estimated loss from these two floods was $10 000 000. Conservatively estimated representative flood peaks were[3] as shown in Table 1. Many lives were lost, thousands of people were made homeless, thirty-five bridges were destroyed, and, for six days, there was little communication with the outside world.

TABLE 1.—REPRESENTATIVE PEAK FLOWS

Stream	Drainage area, in square miles	Peak run-off, in cubic feet per second per square mile
San Gabriel River	229	117
Big Tujunga	118	115
Arroyo Seco	39	366
Sawpit	7	550

Engineers concede that this was by no means a record flood. During previous floods within a 70-yr period, main rivers have materially changed their courses, the Los Angeles River changing from westerly to southwesterly, and the San Gabriel River cutting its new channel from 3 to 6 miles south-easterly. A new river, the Rio Hondo, cut its way and connected the San Gabriel and the Los Angeles River.

---

[3] Rept. of Board of Engrs. on Flood Control to the Los Angeles County Board of Supervisors, January 25, 1917, by H. Hawgood, Charles T. Leeds, J. B. Lippincott, and F. H. Olmsted, Members, Am. Soc. C. E.

Early settlers testify to the occurrence of severe floods in 1815, and again in 1825, and, successively, five major flood periods are recorded in 1861–62, 1884, 1886, 1889, and 1914.[3]

During the unparalleled dry period, 1916 to 1931, rapid development altered conditions radically, crowding former channel and ponding areas. The increased development of paving and impervious areas alone, totaling more than 55 sq miles, has increased the rates and quantities of run-off, and decreased the natural absorption and consequent replenishment of subterranean storages.

A curve prepared in 1931 (see Fig. 2) shows past trends of seasonal rainfall. After this curve was plotted a prediction was made of an uptrend into a wet cycle with increasing wet periods, comparable to the period, 1881–90, in which interval one or more major floods would occur.[3]

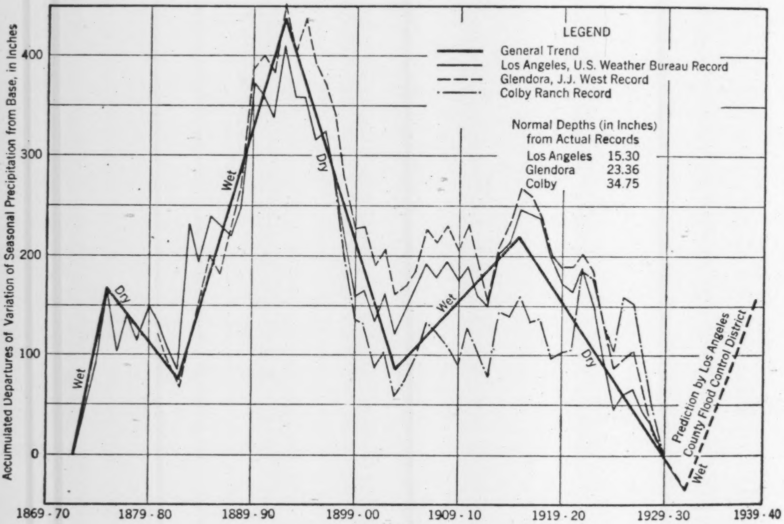

FIG. 2.—GENERAL TREND, SEASONAL RAINFALL.

RAINFALL—RUN-OFF

A co-ordinated system of 237 rainfall and 197 run-off stations was installed by the Los Angeles County Flood Control District commencing in 1927. The more important stations were equipped with recorders. The year, 1931–32, not a year of general flood, had valley rainfall totaling 114% of the normal, that in the mountains totaling 113% of its normal. The seasonal run-off from the San Gabriel River exceeded the combined run-off of the three previous years. Summarized records from three drainages follow: (*a*) San

Gabriel-West Fork—area, 49 sq miles; (*b*) Little Tujunga Creek—area, 21 sq miles; and, (*c*) Ballona Creek—area, 112 sq miles.

The San Gabriel and Tujunga water-sheds are mountain catchments with cover in good condition. The San Gabriel water-shed was burned in 1924, but its brush growth is now (1935) restored. The Tujunga water-shed has not been burned since 1919. Ballona Creek is of a different character, draining flat valley territory, including street drainage from Los Angeles, Hollywood, and Beverly Hills.

The season (1931–32) contained two storm periods, one in December, 1931, and the other in February, 1932. Table 2 gives the distribution of precipitation, maximum 24-hr intensities, and the resulting run-off. The distribution of the San Gabriel run-off was affected by snow. There was 6 to 8 in. of snow above Elevation 4 000 during December, 1931; and 4 to 8 in., during January, 1932; the snow disappeared by February 26, 1932.

TABLE 2.—DISTRIBUTION OF PRECIPITATION, 1931–32

Both mountain catchments (particularly the Little Tujunga, the flow of which was not affected by snowfall), show the relatively large proportion of annual precipitation required to produce sufficient saturation to permit run-off. Mountain and foot-hill catchments are deeply covered with weathered material, ranging from the porous disintegrated granites to the less porous soils with higher clay content; consequently, separate values for any water-shed under consideration must be determined. The flood flows will depend upon: (1) Slopes, character of soils and cover (organic growth, litter, etc); (2) the quantity and rate of rainfall required to produce saturation; (3) the 24-hr and 1-hr intensities; and (4) how closely the high-intensity storms follow upon the saturation period.

On the Little Tujunga water-shed from February 6 to 10, 1932, the rains totaled 5.13 in. with 24-hr intensities, on three consecutive days, of 2.10, 1.10, and 1.15 in. The run-off in the succeeding five days totaled 1.05 in., or a ratio of run-off to rainfall, of −20 per cent.

On both mountain catchments a total of 10 in. of rainfall was required before appreciable run-off occurred. Contrasted with this is the relatively quick response of run-off to rainfall on Ballona Creek. A total rain of 0.17 in. was followed (November 15, 1931) by a 24-hr rain of 0.96 in., of which 17% appeared in a few hours as run-off. Table 3 shows the rainfall-run-off relation for maximum month, day, and hour, for the three catchments.

TABLE 3.—COMPARISON BETWEEN RAINFALL AND RUN-OFF, 1931–32

FLOOD HYDROGRAPH DETERMINATION

Studies of the Big Tujunga water-shed are given herein, showing a method of computing possible flood flows, the results, and the regulation required. This catchment, as yet only partly controlled, is the largest individual tributary of the Los Angeles River drainage. Its control is a necessity because of the flood hazard to the thousands living adjacent to the Tujunga Wash and to those living along the Lower Los Angeles River. That most of these people have not, personally, observed conditions causing or accompanying a major flood makes the hazard none the less real.

The Big Tujunga drainage area above the U. S. Geological Survey gauging station ($3\frac{1}{2}$ miles up stream from the mouth of the canyon) is 106 sq miles; to the mouth of the canyon it is 113.5 sq miles; and to a dam site farthest down stream (6 miles below the canyon mouth), 124.5 sq miles. Its average width is 7 miles. The range of elevation is from 1 250 ft at the canyon mouth to the highest peak, Pacifico Mountain, 7 078 ft (U. S. Geological Survey).

Rainfall records are available at thirteen stations in, or applicable to, the drainage. The longest dates back to 1872; the shortest to 1902. The U. S. Geological Survey has gauged the stream only since October 28, 1916, but, fortunately, long-time records are available on the contiguous San Gabriel water-shed. In computing the probable flood peak the procedure was as described in the following paragraphs.[4]

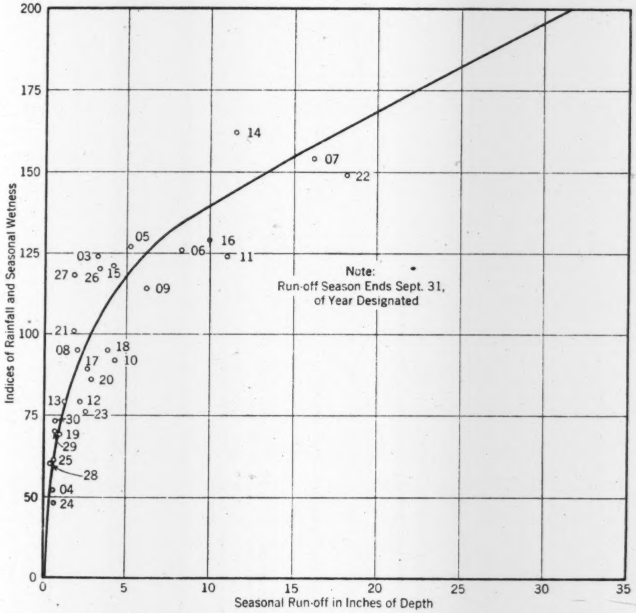

FIG. 3.—BIG TUJUNGA WATER-SHED—INDICATED SEASONAL RUN-OFF, IN INCHES OF DEPTH.

A correlation was prepared from the longer rainfall-run-off records on the San Gabriel water-shed. The results, together with actual Tujunga records, were plotted against the master indices of mean seasonal rainfall and are shown in Fig. 3 in which the seasonal run-off is expressed as depth, in inches, on the water-shed.

---

[4] Rept. on Big Tujunga Creek Flood Control and Conservation Possibilities, by Franklin Thomas, M. Am. Soc. C. E., September 22, 1931.

Table 5 is a summarization of the results. In its preparation, the curve, Fig. 3, was used to provide the values in Column (5) only when actual, or the correlated, records were not available. As summarized, Table 5 gave the following:

Seasonal Run-Off, in Inches of Depth:	
Fifty-eight year average	5.8
Maximum (1883–84)	47.7
Minimum (1876–77)	0.2
Seasonal Rainfall, in Inches of Depth (Composite for Tujunga Water-Shed):	
Fifty-eight year average	27.3
Maximum	65.8
Minimum	6.8
Ratio of Run-Off to Rainfall, in Percentage:	
Fifty-eight year average	21
Maximum	72
Minimum	2

Rainfall indices for years of largest flows are shown on Fig. 4. In arriving at the expectancy of a major flood it was decided to use the flood of 1883–84 as a criterion for protection, because all indications pointed to that year as the one of major flood in the 58-yr period.

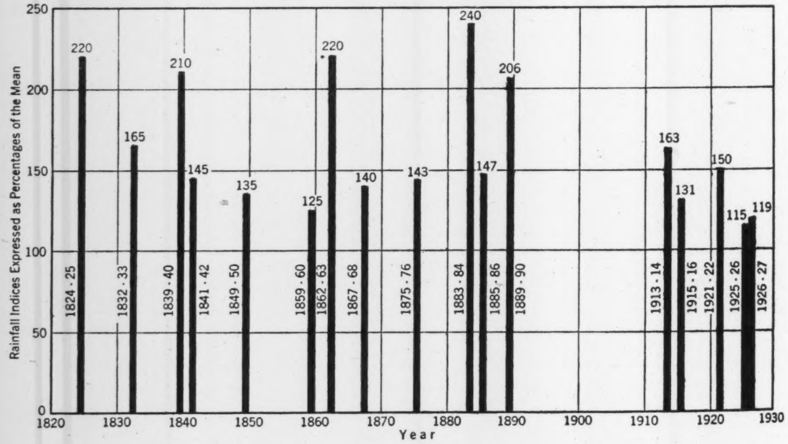

FIG. 4.—RAINFALL INDICES FOR YEARS OF LARGE FLOODS.

The mountain soil cover is disintegrated to great depth; practically no rain falls between May and October, both inclusive; and hydrographic experience has shown that on this area a total of about 10 in. of rainfall causes saturation. If this is closely followed by high-intensity storms, floods are inevitable, the magnitude rising rapidly with increasing intensities.

Although it would be possible, under conditions of concentrated rainfall of high intensity, for a flood to occur in a season of index of less than 100, ordinarily the distribution is such that years having indices less than 120 would seldom produce large floods; those with indices as high as 130 to 170 would almost invariably produce large floods; and indices above 200 represent so much rainfall that major floods would be inevitable.

In computing probable flood flow quantities it is necessary, therefore, to examine not only daily precipitation records but hourly intensities. Results of studies of probable maximum 24-hr precipitation of a frequency of once in 50 yr are shown as shaded zones in Fig. 5. Like studies of maximum sustained intensities, in inches per hour, are designated by lines and quantities also in Fig. 5.

A value for the possible 24-hr rainfall averaging 10.4 in. over the catchment, was adopted as well as hourly intensities ranging from 1.8 to 2.7 in. in various parts of the same water-shed. Isolated instances exist in small zones of 24-hr precipitation in excess of 12 in., but it was not expected that this quantity would be general over the entire water-shed.

Fig. 5.—Big Tujunga Water-Shed: Zones

Further experience showed that a critical 4-day storm may be expected, and that the run-off during that storm will not exceed 50% of the total seasonal run-off. Percentage ratios of maximum 4-day flows to seasonal run-off for the same years, are:

Year	Percentage ratio	Year	Percentage ratio
1906........	23	1921........	5
1914........	12	1926........	35
1916........	25	1927........	51

The flows from 1906 to 1916, inclusive, are derived by correlation with San Gabriel records, and the remainder are from actual records.

In a determination of desirable flood-regulating capacity it is necessary to know the effect of the lesser peak flows that will immediately precede the major flood peak. Daily discharges were plotted for critical periods during seven successive days on a number of water-sheds where rainfall-run-off records were available, which indicated that a 4-day hydrograph would involve as extensive a period as would materially affect flood storage; from such records the relation of successive peak flows was derived. The estimated distribution of run-off during a 4-day period on the Big Tujunga water-shed is given in

OF PRECIPITATION AND LINES OF INTENSITIES.

TABLE 6.—ESTIMATED DISTRIBUTION OF TOTAL RUN-OFF DURING FOUR-DAY PERIOD

Flood day	Run-off, in acre-feet	Rainfall, in inches	Run-off, in inches	Ratio: Run-off to rainfall
Maximum day	30 026	10.4	4.5	0.43
One day preceding	23 236	8.7	3.5	0.40
Two days preceding	13 316	6.7	2.0	0.30
Three days preceding	5 884	4.5	0.9	0.20
Total	72 462	30.3	10.9	0.36

Table 6. The successive peaks are shown on Fig. 6. The quantities refer to estimated flows at a point six miles down stream from the mouth of the canyon at Dam Site No. 5.

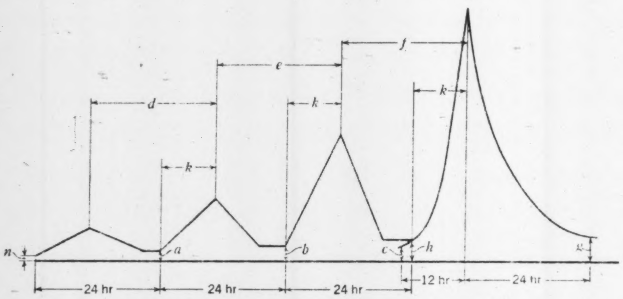

FIG. 6.—CONSTRUCTION OF FOUR-DAY HYDROGRAPH.

The 30 000 acre-ft in one day is equivalent to 241 acre-ft per sq mile of water-shed; the corresponding peak is 48 300 cu ft per sec, or 388 cu ft per sec per sq mile; and the ratio of 4-day to seasonal run-off is $\frac{72\ 462}{316\ 700}$, or 23 per cent. All the values appear reasonable and quite readily obtainable during a year of excess precipitation.

Five reservoir sites are available in the canyon and below its mouth. Operation studies were made of all combinations resulting in a decision that regulating storage totaling 27 360 acre-ft would reduce the flood peak of 48 300 cu ft per sec to 14 500 cu ft per sec, at a capital cost of about $152 per acre-ft, equivalent to $125 per cu ft per sec, of regulation affected. This regulating storage can be created by dams at three locations, developing capacities of 6 240, 7 170, and 13 950 acre-ft, respectively.

EROSION AND EROSION CONTROL

Erosion, in this instance, is defined as the washing of loose material from weathered mountain and foot-hill areas, and its deposition upon the lower valley floors. It results from the same, still active, natural forces that have been building up, gradually, the valleys to many thousands of feet in depth. The removed material when being transported from its original source and after deposition is commonly called "débris."

Rates of débris movements (where mountain slopes are steep) depend primarily on the condition of natural mountain vegetative cover. Destruction of this protective cover by fires, or otherwise, will permit enormous débris flows to result from rainfall intensities which would create, normally, but small débris movement. This abnormal condition diminishes with re-growth of Nature's protective covering, which is often a slow process, since erosion has partly removed the top-soil capable of supporting vegetation.

HAZARDS FROM DÉBRIS MOVEMENTS

Excessive débris waves first affect the lives and property of foot-hill residents. Run-off from smaller tributaries responds more quickly to rainfall than run-off in main rivers and, consequently, a débris-laden stream, upon entering a larger main channel, deposits temporary débris cones, forming barriers of such proportions that the delayed peak of the main river cannot immediately remove them, and river overflow may result. To design an efficient channel under conditions of annual stream flow varying from 3 to 850% of means, is most difficult; when the problem is complicated by heavy débris flows construction costs increase enormously and erosion control at or near the origin of the débris becomes essential.

RECORDS OF WATER-SHED FIRES

Financial considerations govern in the matter of fire prevention and although Federal, State, and County agencies are entirely efficient, at present (1935), with the funds allocated, far from 100% effectiveness in fire prevention has been attained, as shown by forest fire records during the fourteen years since 1919. Major fire records are summarized[5] in Table 7.

TABLE 7.—BURNED WATER-SHED AREAS—1 000 ACRES OR MORE—1919 TO 1933

No.	Year	Area burned, in acres	No.	Year	Area burned, in acres
1	1919	60 000	10	1925	5 650
2	1919	60 000	11	1925	4 000
3	1921	4 000	12	1927	4 630
4	1921	3 500	13	1927	9 000
5	1921	3 300	14	1927	2 960
6	1921	1 500	15	1928	40 000
7	1922	20 000	16	1930	23 000
8	1924	52 000	17	1933	4 860
9	1924	22 000	....	....	....
Total	....	......	....	....	320 400
Average per fire	....	......	....	....	18 900

What expenditures are warranted for fire prevention varies widely in different areas, depending upon population concentrations and values menaced. The foot-hill water-sheds of Los Angeles County are made up of many hundred individually small catchments, aggregating 285 sq miles. Of this, areas totaling nearly 60 sq miles, as yet not denuded, are located above incorporated territory having a combined population of more than 100 000 persons and assessed values of more than $200 000 000.

---

[5] Rept. on New Year's Foothill Débris Flood, by E. C. Eaton, March 19, 1934.

EROSION WITH NORMAL WATER-SHED COVER

Where water-sheds have not been disturbed by fires, roads, earth-slides, etc., erosion is relatively slight. Quantitative records of erosion from Los Angeles County water-sheds that have a normal cover are not as plentiful nor as accurate as those from water-sheds from which the débris flows are more readily measured; therefore, only estimates are available.

One estimate (cited as ample) of the extent to which the storage on the San Gabriel water-shed would be depleted, was 3 200 cu yd per sq mile annually.[6] This value probably includes assumptions of occasional burnings since the estimate was made in 1927, within the 3-yr critical period after more than 30% of the area was burned in 1924.

The measured débris deposited in Sweetwater Reservoir, San Diego County, is reported as averaging 1 400 cu yd annually per sq mile in 39 yr[7], and Gibraltar Reservoir, in Santa Barbara County, averaged 1 380 cu yd per sq mile in its 11-yr period.[7] A major fire in 1923, burning over most of the water-shed, makes this value high. Twelve scattered records collected by the writer average 190 yd per storm per sq mile, ranging from 30 to 500 yd.

No single rate is applicable to all the catchments of Los Angeles County and, although admittedly based upon insufficient data, it is the writer's opinion that, with a water-shed undisturbed by fires for 10 yr or more, 1 500 yd per sq mile is a maximum quantity.

DÉBRIS QUANTITIES FROM BURNED AREAS

One quantitative example of débris movement is that given by the case of Sunset and Brand Canyons[8] which debouch directly on the streets of Burbank, a city of 16 600 population and more than $28 000 000 assessed valuation in 1931. Brand Canyon discharges on a part of Glendale which has a total population of 60 000 persons and a total assessed property valuation of more than $80 000 000. The catchment area of Sunset Canyon is 1.10 sq miles; its length is about 1.5 miles, and its width $\frac{2}{3}$ mile; and in elevation, it ranges from 886 to 3 126 (U. S. Geological Survey). Brand Canyon has a similar catchment of 1.03 sq miles. A fire that burned a total of 4 600 acres occurred from December 3 to 5, 1927, and included all of Sunset and Brand Canyons as well as adjacent canyons. One year later (October, 1928), the first rains occurred, recording a total depth of 0.40 in. During November, 2.10 in. of rain fell, of which more than 65% occurred in one day; a 0.59-in. rain of November 13 was followed on November 14 by a downpour with a sustained 1-hr intensity of 0.43 in., between 8:30 and 9:30 A. M., making a total for that day of 1.41 in. Intensities of 10-min duration were recorded as high as 0.35 in.

Canyon observers reported the resulting débris flows to have followed closely after the high-intensity period, with two distinct flash flows. The first was composed mostly of water, which rose 3.5 ft in a channel 55 ft wide; and this was succeeded by a second flow estimated, by observers, to flow at a rate of 20 to 30 ft per sec. The débris flow lasted 30 min.

---

[6] Rept. on Flood Control and Conservation, San Gabriel River, by F. H. Fowler, M. Am. Soc. C. E., C. D. Marx, Past-President and Hon. M. Am. Soc. C. E., and C. H. Paul, M. Am. Soc. C. E., March, 1927.

[7] "The Silt Problem", by J. C. Stevens, see p. 207.

[8] Rept. on Sunset and Brand Park Canyons Flood of November 14, 1928, by E. C. Eaton.

From all available information, including cross-sections, it was estimated that 29 acre-ft of combined débris and water flowed from Brand Canyon in a 30-min period, of which 17 acre-ft (or nearly 60%) was débris, and 12 acre-ft was water, an equivalent run-off depth of 0.22 in. The average velocity was computed at about 6 ft per sec. The débris flow was equivalent to 26 000 cu yd per sq mile of water-shed, a quantity that checked closely with records of truck removals from streets and lawns. Débris removal costs by public agencies averaged $1 per cu yd, exclusive of the cost to residents for removals from cellars and lawns.

Another example was afforded by the Arroyo Sequis, on the western County boundary, which has a water-shed of 11.4 sq miles, discharging directly into the ocean. It is roughly triangular in shape and ranges in elevation from sea level to 3 060 (U. S. Geological Survey). An intense fire from October 29 to November 6, 1930, burned 90% of this area, leaving its decomposed granite slopes, of 300 to 500 ft per thousand, exposed to rain.

The nearest recording rain-gauge was 12 miles inland, at Elevation 600. Since storms approach from the west they strike the coast water-shed an hour earlier than the gauge and it is probable that the actual rainfall on the burned area was greater in quantity and intensity than that recorded. Rainfall records are listed in Table 8. Beginning at 1:00 P. M., on January 7, 1931, and continuing to 4:00 P. M., the intensities for 10-min periods, expressed in equivalent inches per hour, are listed in Table 9. The total rain falling in the 170 min. was 1.24 in., or an average rate for the period of 0.44 in. per hr.

1:50 P. M.	0.18	2:50 P. M.	0.45	3:50 P. M.	1.38
				4:00 P. M.	1.15

Quantitative measurements could not be made since much débris passed to the Pacific Ocean, but estimates based on mud marks on highway bridge piers (which were as much as 15 in. higher than adjacent bank marks), gave velocities of between 5 and 9 ft per sec. At least 50% by volume was solid matter and the combined débris and water flow was estimated as 700 cu ft per sec per sq mile of water-shed.

A third example—Delta Canyon, a 0.63-sq mile tributary, of Big Tujunga Wash—has a particularly large cone of débris at its mouth (see Fig. 7). In elevation it ranges from 1 650 to 4 500 ft (U. S. Geological Survey); its length is 1.9 miles from crest to mouth; its average width, 0.3 mile; and the grade increases from the minimum slope of 625 ft per mile at the lower end. The canyon forks $\frac{3}{4}$ mile from the mouth, and at the end of the small fork, running west, is a steep mountain peak which is considered as having contributed the major portion of the débris. A large slip along the entire side of this mountain was first noted in 1913, but some sliding probably occurred previous to that date. The area is badly faulted and the slopes are in an unstable condition.

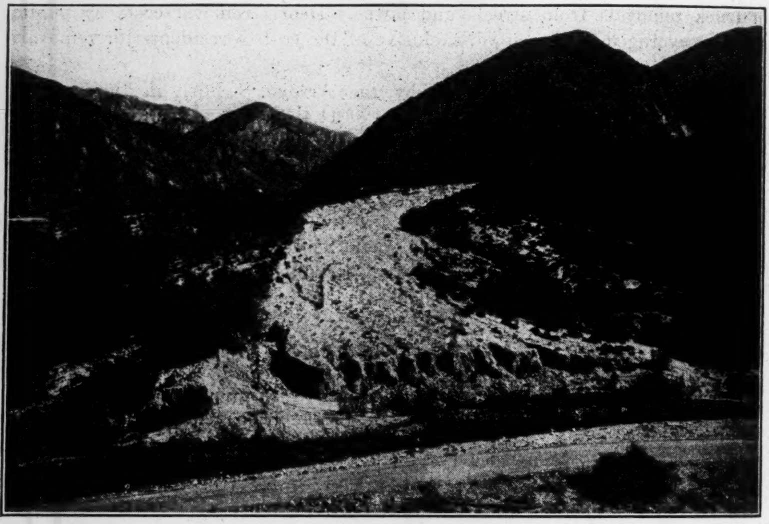

FIG. 7.—DÉBRIS CONE AT MOUTH OF DELTA CANYON.

Fire destroyed 80% of the canyon cover on September 13, 1913, and, during the 1914 flood, débris was deposited at its mouth, shifting the former stream bed to the west. Although slips had been noted prior to 1914 there is no record of débris at its mouth prior to the rains. The heavy rains of 1926 brought down additional deposits. No differentiation can be made between the relative quantities transported by the two débris flows, and a part of the delta has been removed by channel cutting in the main arm of the Tujunga River. However, the volume transported in the two storms is estimated, conservatively, at 123 000 cu yd per sq mile, or more than 60 000 cu yd per sq mile per storm.

The La Crescenta-Montrose débris flow, on January 1, 1934, furnishes the best and most accurate, as well as the largest unit débris flow of authentic record.[5] In this case seventeen contiguous water-sheds have a combined crest length of 6 miles and a total area of 7.5 sq miles. The catchment areas in this region are steep and rugged, rising 2 500 ft in 1.75 miles. The catchments range, in size, from Pickens, the largest, with an area of 1.6 sq miles, to several as small as 0.2 sq mile. They debouch, through sixteen separate channels, on to developed foot-hill, city, and urban areas below the canyon mouths, aggregating about 7 sq miles. The area, which is mainly residential, extends from Tujunga City, the largest and at the western boundary, easterly through the unincorporated cities and towns of Highway Highland, La Crescenta, and Verdugo City to La Canada, the easterly boundary.

The aforementioned water-sheds were completely denuded by fire from November 21 to 24, 1933. They had not been burned previously since 1878. The early storms that began December 14, at 5:00 P. M., and ended on December 15, yielded 4 in. of rain which packed the ash residue into the surface pores of the heavy soil cover, built up during decades of undisturbed brush. Recording rainfall records are given in Fig. 8(*a*) *a*nd Fig. 8(*b*) from Flintridge Fire Station at Elevation 1 325 (U. S. Geological Survey). Following this preliminary saturation, came succeeding storms culminating with December 31, on which date successive 1-hr intensities increased from 0.5 in. per hr at noon to 0.78 in. at 1:00 P. M.; 1.8 in. at 2:00 P. M.; and 1.14 in. at 3:00 P. M. After 3:00 P. M. the rainfall subsided to 0.3 in. per hr until midnight when it increased suddenly to 1.28 in. per hr. A flash, 5-min intensity at a rate of 2.16 in. per hr began at 11:47 P. M. Three separate recording gauges, distributed over the area, registered sustained 1-hr intensities at midnight of 1.28, 0.85, and 0.87 in. per hr, respectively; and it is probable that a 1-in. intensity was representative of the entire area. No particular 1-hr intensity was a maximum, all-time record, but the successive cycles of sustained high intensity were without known parallel.

Beginning almost exactly at midnight on December 31, 1933, and lasting for an hour, the resulting succession of débris flows caused 30 deaths; 483 homes were either completely swept away or rendered uninhabitable; and the total property damage aggregated $5 000 000. All the loss of life and 80% of the damage occurred in the eastern part below Pickens and Hall-Beckley Canyons. The largest city, Tujunga, was completely protected by a débris basin at the mouth of Haines Canyon (see Figs. 9 and 10). Another basin was under construction at the head of Verdugo Wash, the main collector at which the smaller tributaries eventually terminate.

Falling on a completely saturated soil, the rain had caused sheet erosion over practically the entire mountain area concurrently with a slippage of numerous masses from steep canyon sides of weathered rock, into the narrow canyon channels. Mass movements originated from canyon sides as high as 200 ft above stream bed, some of the masses being as much as 50 to 150 ft wide. Trees 2 ft, or more, in diameter slipped with the masses and were swept into the streams. When sufficient run-off was impounded behind the earth barriers thus created, to saturate them, they moved down stream until they either drained sufficiently to retard progress, or were stopped by other slides farther down stream. As these movements were repeated, débris was collected in increasing volumes and the masses moved with increasing momentum. Simultaneously, the side tributaries attained peak flows and the combined effect was to release débris and water from canyons in waves 15 ft or more in height. Reaching open territory these waves flattened to

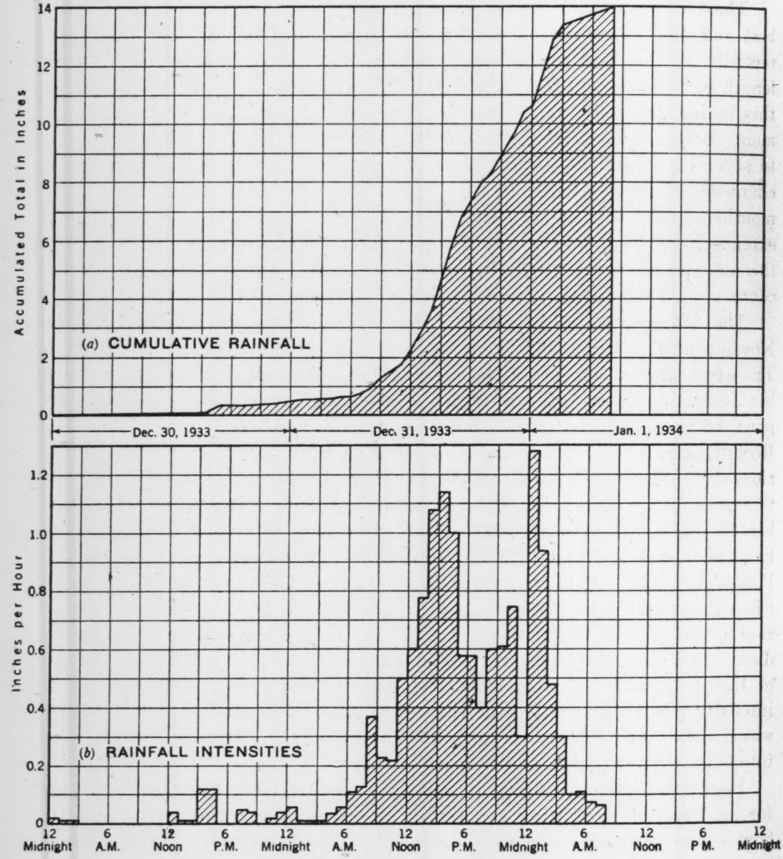

FIG. 8.—RAINFALL RECORDS, STORM OF DECEMBER 30, 1933, TO JANUARY 1, 1934.

5 or 6 ft in height and spread to widths of 100 to 200 ft scouring new channels and thus picking up new débris loads. In canyons velocities were sufficient to carry along many 10-ton boulders. One $59\frac{1}{2}$-ton boulder was rolled on to a paved street at the mouth of Dunsmuir Canyon.

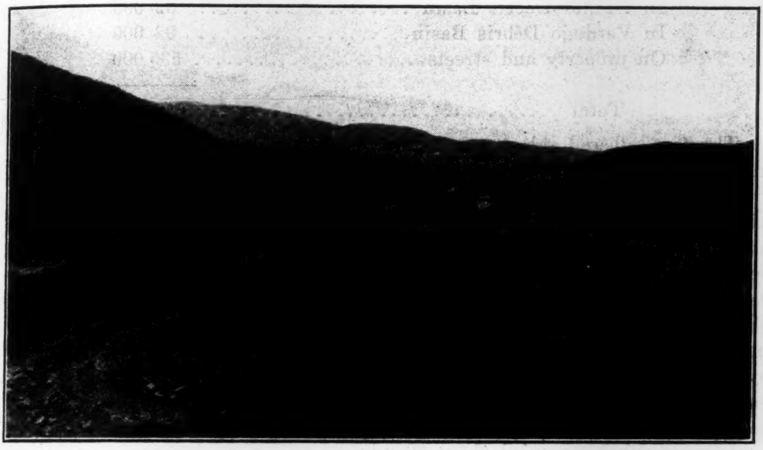

Fig. 9.—View of Haines Canyon Débris Basin, Before Storm of January 1, 1934.

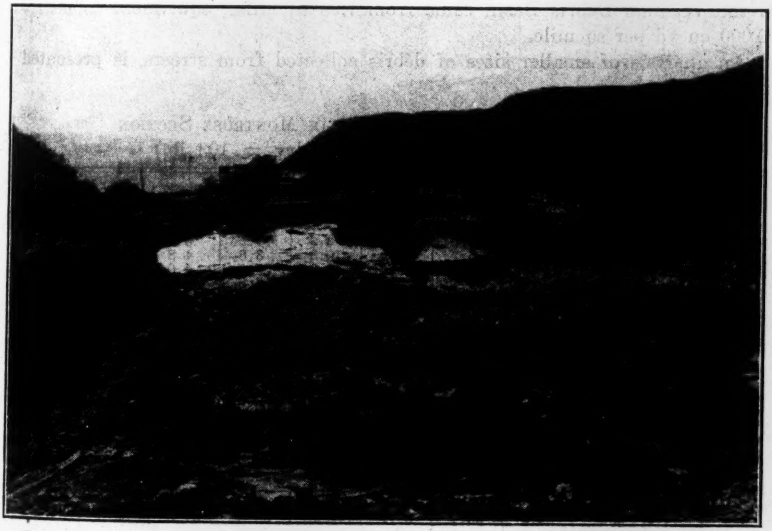

Fig. 10.—View of Haines Canyon Débris Cone, After Storm of January 1, 1934.

Based on carefully computed quantities of deposits in the two débris basins, and on field and airplane surveys, débris deposits on property (in cubic yards) were:

In Haines Débris Basin	32 000
In Verdugo Débris Basin	92 000
On property and streets	535 000
Total	659 000

The foot-hill and urban area below the canyon mouths covers about 7 sq miles; of this area 1 040 acres, or 23%, were affected by débris (see Fig.11).

Practically all the débris was deposited within the 1-hr period after midnight, occurring in a succession of about fifteen sharp débris flows, moving at velocities estimated at from 5 to 10 ft per sec. Canyon velocities were considerably greater. Each sharp peak of major débris flow would be succeeded by a rapidly moving stream which contained less débris, cutting a channel to one side or through the deposited débris masses. In some instances these masses would drain out and, successively, become saturated by stream flow to a point at which they would again begin to move; and, encountering a rapidly moving stream, they would be carried along in a succession of surges. It is estimated that the flows containing maximum percentages of débris occupied about 30 min.

The east half of Haines Canyon (the westerly limit of the burned area) had been denuded. Practically the entire débris movement from this source originated from 0.47 sq miles, indicating a débris rate of 67 000 cu yd per sq mile scoured out by a single storm. Débris on property and streets and in the Verdugo Débris Basin came from 7.08 sq miles, equivalent to nearly 90 000 cu yd per sq mile.

An analysis of smaller sizes of débris collected from streets, is presented in Table 10.

Fig. 11.—La Crescenta-Montrose District; Areas Affected by Debris Flood of January 1, 1934.

Cross-sections were taken, following the flood, of the principal canyon channels. A typical section showing Pickens Canyon is given in Fig. 12. The highest water or mud marks were left at moments when the débris flows were either practically stationary or were moving only slowly; but the final lowest channel sections as left resulted from cutting by the later and receding stream flows of higher velocities, which ground the stream bed far below its original grade and below that at the time of the making of the highest mud marks. Computations of peak flows based upon these highest marks and the final channel cross-sections must be modified by judgment, of course, as gained from those witnessing the flows at the time of their activity.

The writer's conclusions were that a sustained 1-hr run-off occurred, which was equivalent to an average depth of 0.9 in., or 580 cu ft per sec per sq mile, and that the maximum débris flow contained 70% of saturated débris to 30% of water by volume, flowing at an average velocity of 5 ft per sec. The relative quantities of débris and water discharged in the 1-hr period were estimated as 48 acre-ft of water and 55 acre-ft of débris.

DÉBRIS CONTROL

For major débris movements, positive protection requires direct storage. The best protection thus far devised is the débris basin, which is admittedly expensive and not sightly. It is positive, however, and its first cost is often less than that of one débris removal from streets.

A case in point is the Haines Canyon Débris Basin (see Figs. 9 and 10). Its low capital cost of about $0.25 per cu yd was due mainly: (1) To its location in a Federal Forest area, consequently involving no cost for right of way; and (2) to the basin excavation created by an operating rock plant. Immediately after it was filled, the débris was removed with an average 500-ft haul, for a cost of $0.30 per cu yd. Débris basins at more than one hundred locations will be needed ultimately. Their capital costs per cubic yard of débris capacity will range from $0.30 to $1.00 per yd, depending mainly on excavation costs. Their physical locations are closely fixed, between the canyon mouths and the deltas, at points sufficiently toward the canyon mouths to prevent channel-cutting around them and as far down on the deltas as feasible toward the flatter slopes where excavation costs will be least.

Their storage capacity is obtained, in part, by cut-and-fill excavation in which considerable waste is necessary due to the safety requirement that the deepest part toward the outlet or spillway should be in solid cut. The sides of the basin may be leveed from part of the excavated material. Where feasible, side-channel spillways are advisable, thus forcing the débris flows to enter from the upper end and follow circular paths, facilitating maximum deposition of débris. Sufficient adjacent areas should be provided for future deposition of material.

Where water-sheds are unburned, the operating costs of débris basins are negligible, because little or no débris removal is necessary. After a fire and succeeding high-intensity storms, the basins must be emptied promptly.

The necessity of locating the basin largely in cut, results in excavation costs ranging from 50 to 75% of the total, the other costs being for spillways

and auxiliary structures connecting the basin to the head-works of channels. The spillway generally occupies limited space and requires considerable time to construct. On the other hand, the basin excavation covers a large area (1 acre to 2 acres, or more), and thus permits the use of large equipment and rapid construction. Two large power shovels, supplemented by large trucks, can excavate, on a conservative estimate, 20 000 cu yd per three-shift day. Under emergency conditions, a basin for protection from an area of 2 sq miles may be excavated in from 15 to 30 days. Although it is urgently needed during the 3 to 5-yr period following a fire, a débris basin will be inactive over the period of years when no fires have occurred. At best, it cannot be made attractive in appearance and must be located not far from residence property.

These factors suggest the possibility of saving in capital investment by setting aside definite areas, preparing detailed plans, and constructing spillways, channels, and auxiliary structures, but deferring the excavation of pits until fires have occurred. The large excavation equipment can be used later for prompt removal of débris deposits. After mountain cover has regrown, basins may be permitted to fill until fires again indicate that they should be re-excavated.

WATER CONSERVATION INCIDENTAL TO FLOOD REGULATION

Conservation of flood wastes will result from flood regulation for protective purposes.

Increased drafts on local water supplies have been accentuated by decreases in original replenishment due to paving and building activities which have changed former pervious surfaces to impervious surfaces. River channels have been improved reducing thus the original wetted areas. The over-draft from wells tapping the basins between 1914 (the last major flood year) and 1931, has created a present underground storage space of more than 2 250 000 acre-ft. The effects of pumping in excess of replenishment is especially marked in the basins of the coastal plain where serious intrusions of salt water have resulted. Here, water from wells on an area of more than 57 sq miles shows a salt content of more than 15 grains per gal, which is considered to be the limit for human consumption.

SURFACE HOLD-OVER CONSERVATION EXPENSIVE

To provide conservation by surface hold-over storage under Los Angeles County water-shed conditions would run into enormous costs, particularly since hold-over of floods for five years or more would have to be provided. High surface storage costs are here due to the steep slopes and large number of individually small drainages that are characteristic of the mountain territory.

As indicating the costs involved, the twelve reservoirs constructed or under construction by the Los Angeles County Flood Control District will regulate the floods from 400 sq miles, having a combined capacity of 109 000 acre-ft, at an average capital cost of $200 per acre-ft. Under such conditions capacities must be limited to those needed for regulation alone, and, following storm periods, the reservoirs must be emptied progressively at rates permitting percolation into underground basins.

Fortunately, there are available unparalleled natural reservoirs of high capacity. Created by the deposition of sand, gravel, and boulders through the ages, these basins are twenty-six in number. Dikes and geologic faults have created underground barriers, thus forming a series of reservoirs which retard underflow, the water passing over and through these dikes into succeeding basins down stream. Void spaces in the gravels range from 20 to 10%, the larger values applying to the main valley basins, the smaller to the coastal areas.

The logical solution is to conserve the present wastes by regulation and passage into the underground basins. Measured 1931-32 flood-water waste to the Pacific Ocean from 1 841 sq miles of major drainages, was 101 578 acre-ft, indicating conservation possibilities when flood regulation has been provided sufficient for percolation into existing underground basins. The distribution of this flood-water waste is shown in Table 11.

SPREADING TO INCREASE PERCOLATION

Regulated flood flows may be encouraged to percolate in increasing quantities by extending the wetted areas on overlying gravel cones by "spreading." A representative set of percolation measurements made in 1930–31 and 1932 at fifty-three different locations is given in Table 12.

Rates of percolation through surface gravels are mainly proportional to areas wetted and only to a minor degree upon depth of water. Flood flows, even when the main débris has been removed, contain sufficient fine suspended matter, with collodial content, so that a depth of deposit of from $\frac{1}{16}$ to $\frac{1}{8}$ in. is sufficient to reduce the percolation rates 50%, or more, or practically to seal the surface. In stream-bed areas the "scarification" of a few inches is sufficient to increase percolation rates markedly.

Scarification by plowing and harrowing of test sections on the San Gabriel River and Rio Hondo gave results indicated in Table 13.

Increased percolation may be effected by the construction of "spreading works." In their design, ponding alone, or the creation of large shallow basins, does not furnish the complete solution for the percolation of waters containing sediment. It has been proved, however, that by keeping the streams of water moving and by flushing certain areas, the top gravel layers receive a scrubbing action, and high percolation rates can be maintained. The velocities necessary range between 2 and 4 ft per sec and must be supplemented by flushing immediately before, and immediately after, a run. The quantity necessary to waste by flushing should not exceed 5% of the total quantity spread. Spreading works include head-gates from which main and lateral ditches take off through gates in effect similar to an irrigation system. The object of spreading is to provide a wetted area of water in motion covering as large a total area as possible.

2 400	1.91		
6 030	2.72	5.50	102

Under a carefully planned spreading system it is possible to provide a net wetted area of from 25 to 35% of the gross area at construction costs ranging from $200 to $300 per gross acre of spreading grounds. Operating costs will range from $0.15 to $0.50 per acre-ft of water percolated, the quantity varying according to the area, its shape, and the layout of the ditch systems.

As a practical average value, from 0.5 to 1 cu ft per sec per gross acre spreading area may be spread, depending upon the location of the area, and the character and layout of the spreading works.

CONCLUSIONS

Under physical and weather conditions as described the conclusions are, as follows:

Flood Flows.—On the larger mountains with vegetation undisturbed, a total of 10 in. of rainfall will produce sufficient saturation to permit marked run-off. Storms of intensities of 1 in. per hr and more, if closely following the saturation period, will produce floods, their magnitude rising rapidly with increasing intensities. Twenty-four hour intensities may be expected, varying from 3 in. on the coastal plains to 13 in. on the mountains, with sustained 1-hr intensities of 1 in. to 3 in. Under the higher intensities, following saturation, flood flows of 400 acre-ft per day per sq mile are possible. With the characteristic sharp peaks of these areas this quantity will represent a 1-hr peak of 400 cu ft per sec per sq mile. The regulatory storage needed will depend upon the economic balance between channel costs and regulation costs. In Los Angeles County its range is from 150 to 300 acre-ft per sq mile.

On the lower foot-hills and valley areas with high percentages of impervious surfaces, little or no saturation is needed to produce an immediate response of run-off to rainfall. It is necessary to anticipate future development both domestic and industrial in designing drainage channels in such areas and to set aside adequate areas for the ultimately required drainages.

Débris Flows.—After a normal water-shed cover has been destroyed, erosion rates will increase from 50 to 100 times that with undisturbed vegetation. The best protection from débris is the normal vegetative cover. After denudation, any protective program is a secondary, far less efficient, and much more costly, defense. Erosion of a water-shed removes portions of the soil capable of supporting vegetation. Sufficient regrowth to afford protection will take from 5 to 10 yr, depending upon weather conditions and the extent to which the soil has been removed. With vegetation destroyed protection requires direct débris storage; this can be afforded by débris basins at or near the mouths of the canyons. Following denudation, erosion may produce from 50 000 to 100 000 cu yd of débris per sq mile, the quantity depending upon slopes and intensities. The larger quantity may result from intensities as low as 1 in per hr. Little preliminary saturation is necessary and may be as low as 5 in. if occurring in a short period.

In designing débris basins, flows of 75 000 to 150 000 cu yd per sq mile of drainage should be provided for, arrangement should be made for prompt removal, and adjoining areas should be provided for deposition.

Burning of water-sheds is not always of human origin. Lightning is one cause. Even with the best possible fire-prevention measures occasional fires will occur. Even a foot-hill water-shed 1 sq mile in extent may produce sufficient débris to cause heavy loss of life and immense property damage, when it is located above developed territory. In such areas, basins should be at least set aside; complete detailed plans prepared for their construction; and the auxiliaries of spillways, etc., should be built, so that in emergencies they may be constructed promptly.

Conservation.—Provision for flood regulation for protective purposes will give capacities in excess of that required for conservation of the flood waters that will result from increased percolation, which is principally in proportion to the stream-bed areas wetted. Where increased percolation above that of the natural channel is needed, spreading systems may be built at costs of $200 to $300 per gross acre, with percolation capacities of from 1 to 2 acre-ft per day per acre.

ACKNOWLEDGMENTS

The writer desires to express his appreciation to Franklin Thomas, M. Am. Soc. C. E., who made, for the Los Angeles County Flood Control District, the report on the Big Tujunga water-shed, quoted in this paper. Appreciation is expressed to the many members of the District staff who collected the basic data from which this paper has been prepared; and, in particular, to F. H. Hay, Assoc. M. Am. Soc. C. E., Chief Hydrographer, and to R. S. Goodridge and F. J. Cornick, Assoc. Members Am. Soc. C. E., of the Hydrographic Department; also, to Mr. E. C. Kenyon, Jr., in charge of Erosion Control.

DISCUSSION

ARTHUR G. PICKETT,[9] ASSOC. M. AM. SOC. C. E. (by letter).—In the latter half of his paper, Mr. Eaton has demonstrated conclusively that the primary cause of débris flows hazardous to communities of the Los Angeles coastal plain, is the denudation by forest fires of the brush cover of adjacent foot-hill and mountain water-sheds. These fires, if followed by the type of heavy semi-tropical rains that frequently occur in Southern California, result in sheet erosion and débris flows from the mountain sides on to the unprotected communities below. Such flows will not cease until the native brush cover has been fully restored.

No engineer familiar with the topography and geology of these water-sheds, who observed the results of the La Crescenta-Montrose disaster, will question the possibility of a débris flow during such a storm, of from 50 000 to 100 000 cu yd per sq mile of water-shed burned.

Mr. Eaton presents factual data to the effect that the La Crescenta-Montrose disaster resulted in the loss of thirty lives, the destruction of 483 homes, and a total property damage of $5 000 000, all of which was the result of one storm upon a burned area of 7.5 sq miles. To this loss must be added the cost of débris removal and the necessary construction of débris basins and flood-control works adequate in size to prevent similar damage which may occur at any time in the next 5 or 10 yr, or until the native brush cover is sufficiently restored to retard excessive erosion.

Based upon data presented in the paper, the cost of débris removal following the disaster, probably exceeded $425 000, or more than $57 000 per sq mile of water-shed burned. Los Angeles County is admittedly entering a wet cycle, or period of more than average rainfall, during which several storms of greater intensity than the one which caused the disaster may be expected. Consequently, the cost of construction and maintenance of débris basins in the area during the next five years may, according to Mr. Eaton's data, exceed $1 000 000.

The writer is thoroughly in accord with most engineers, who agree that if the mountain water-shed had not been denuded by forest fire, little or no damage would have occurred in the foot-hill communities of this flood area. It would seem, therefore, that the possibility of successful suppression of brush and forest fires adjacent to such communities should receive the primary consideration of engineers interested in flood and débris control.

Similar fires in the Hollywood Hills have been fought successfully by the Fire Department of the City of Los Angeles. R. J. Scott, Chief of the Fire Department, has found that, if trained fire fighters, properly equipped, can reach a fire within 15 min of its inception, and if 10 000 gal of water per min can be placed at their disposal for a short time, they can almost invariably suppress the fire without serious loss of water-shed cover; whereas without this water available, a loss of hundreds or even thousands of acres may be expected. Table 7 of the paper, shows that seventeen fires fought, without the advantage of an adequate water supply, resulted in a loss of 320 400 acres of water-shed in Los Angeles County, an average of 18 900 acres per fire.

---

[9] Civ. Engr., Los Angeles County Surv., Los Angeles, Calif.

Although the personnel of the Federal Forest Service and County Forestry Departments is thoroughly organized and trained, limited appropriations have prevented the installation of water systems, as well as the acquisition of other much needed facilities for forest fire protection. Until recently, such facilities have been regarded by many as an unwarranted expense, even in the relatively small areas, adjacent to heavily populated communities, where more than 90% of such fires originate.

Following the La Crescenta-Montrose disaster, plans and specifications were prepared for the construction of a project, under the work relief program, to provide a water system, motorways, firebreaks, trails, and similar facilities necessary for the fire protection of the extremely dangerous water-shed above the communities of Altadena and Pasadena.

This project was the first unit of a comprehensive plan to provide such facilities for approximately 16 000 acres of valuable but dangerous mountain water-shed, hazardous to the communities of Altadena, Pasadena, South Pasadena, Sierra Madre, Arcadia, San Marino, San Gabriel, and Rosemead, with a group population of more than 300 000.

The only feature of the plan, not included in similar projects now under construction (1935), is the water system. The quick, economical delivery of the large quantities of water required, presented many new and unusual problems which were complicated by the steep grades and topography encountered. These problems were solved, however, and an adequate water system was designed which would enable fire-fighters to reach any point in the area with heavy streams of water under gravity pressure, by the extension of not more than 500 ft of hose.

As designed, the main storage reservoir of the system is located above the highest point in the area to be protected, and will have a capacity of 1 000 000 gal. Water will be delivered to this reservoir, either from a rainfall catchment area, or by gravity flow through 4 000 ft of 6-in. pipe line constructed into Millard Canyon, where an adequate, reliable stream of water is always available.

From this reservoir, 6-in. steel pipe lines will carry the water down the main ridges to eight secondary reservoirs of the system, which are necessary for pressure regulation and additional storage. From these reservoirs, 6, 4, and 3-in. pipe lines will extend to roads, trails, motorways, and other strategic points throughout the area. One hundred and fifty fire hydrants, fitted with adapters to permit instant connection of either the 1½-in. hose used by the Forest Service, or the 2½-in. hose used by County Fire Departments, will be located along the various water lines.

The design will permit full delivery of water from each hydrant, even if all the other hydrants of the system are in operation at the same time. Sufficient water storage is provided to assure an adequate supply for the fighting of fire throughout the area. At points of unusual hazard, where even a city fire stream might not prove effective, small monitors or hydraulic giants have been provided to operate under higher pressures and with larger quantities of water than would otherwise be possible.

Specifications provide that all reservoirs shall be constructed in excavation, lined with reinforced concrete to prevent leakage, and covered to reduce evaporation; and that all pipe shall be Grade A steel, mill-tested to 1 100-lb pressure.

An area of 1 600 acres would be protected in this manner by the project, all of which is located in the "high risk zone," where Forest Service officials expect 90% of all fires to start. The total cost of materials and supplies required for the construction of this unit of the water system is $69 600. Commenting on the project publicly William V. Mendenhall, Supervisor of the Angeles National Forest, stated that with such facilities available, his men would almost guarantee to suppress any fire in the area with a loss of not to exceed 1 acre of water-shed.

In the higher mountains adjacent to this project, the danger of fire being started by human carelessness is reduced materially. If fires do occur, conditions are such that Forest Service officials believe smaller quantities of water will be required for their suppression. Consequently, fewer water lines are required in these areas of secondary risk, and the cost of the water system per square mile is reduced materially.

Before the disaster, the La Crescenta-Montrose water-shed included both "high" and "secondary" risk zones. A similar water system, designed to protect the entire burned area, could have been constructed at any time previous to the fire, at a cost for materials and supplies of $150 000. The cost of relief labor, or that of labor by the Civilian Conservation Corps, could not be considered as a true charge against the project. However, if constructed by contract, the installation of all facilities necessary for fire protection would not have cost as much as the removal of débris immediately following the disaster.

Unquestionably, sites for débris basins should be purchased and other protective measures, as outlined by Mr. Eaton, constructed for the protection of communities from débris flow in case the water-shed is denuded by fire. It would also seem logical to spend an equivalent sum of money to insure against such a catastrophe, by the installation of water systems and other facilities necessary to combat, successfully, the many forest fires that do occur. This is especially true when the chances are 100 to 1 that, sooner or later, the water-shed will be destroyed unless such facilities are provided.

R. W. Davenport,[10] M. Am. Soc. C. E. (by letter).—In studying this paper, the writer has been interested in examining, rather critically, the section entitled "Flood Hydrograph Determination", and some of the incidental observations are submitted herewith.

Fig. 3 shows the run-off for the basin for the years ending September 30, 1903 to 1930, plotted against the respective indices of seasonal wetness, or the estimated mean annual precipitation over the basin expressed in percentage of the mean as determined for the period, 1872–1930. The run-off from 1916 to 1930 was estimated from the record of the Sunland gauging station of the U. S. Geological Survey evidently by application of the drainage area ratio (124.5 sq miles ÷ 106 sq miles), and, from 1903 to 1915, the run-off was deduced from the record of the neighboring San Gabriel Basin. These data give the twenty-eight points plotted in the diagram.

---

[10] Hydr. Engr., U. S. Geological Survey, Washington, D. C.

In undertaking to express a general relationship between precipitation and run-off in a problem of this kind, it is a commonly accepted procedure to consider run-off as a residual after the precipitation has been subjected to losses by evaporation and transpiration, and possibly other losses, usually of relatively minor importance. These losses, like the precipitation, are thus to a large extent the resultant of the operation of meteorological agencies. It is not practicable, of course, to determine the factor representing the losses by direct observation, but it may be determined indirectly by subtracting the run-off of a basin from the precipitation for periods selected so as to eliminate or to minimize differences due to changes in surface or ground-water storage. It is the writer's observation that for humid regions the factor varies in a rather definite and systematic manner, dependent upon latitude, altitude, temperature, and other regional characteristics and that from year to year it has an amplitude of variation corresponding roughly to that for precipitation. In arid regions, where the rainfall is insufficient to meet the potential demands of evaporation, transpiration, etc., the losses, of course, will tend to be smaller and more variable than in regions where the rainfall is ample.

Table 5 has been examined with regard to the indicated losses from 1903 to 1930, and the results, for groups determined by the amount of the annual precipitation, are listed in Table 14. Over the period of years considered, these data show a definite tendency for the losses in the Big Tujunga Basin to increase as the precipitation increases. For rainfalls of 30.1 in., and more, the losses varied from 22.5 to 32.7 in. and averaged 27.4 in.—apparently not much different from what would be expected in any similarly located humid region of similar temperature and similar quantities of rainfall.

The curve drawn through the plotted points of Fig. 3 takes an upward direction, so that for an annual precipitation of 54.6 in. (index of seasonal wetness = 200), the losses would approximate 23.4 in., whereas for the maximum year (1883–84), with a precipitation of 65.8 in., the application of the derived relationship by extrapolation, gives losses amounting to only 18.1 in. However, the facts indicated by Table 14 and the interpretation of general experience elsewhere, as noted, suggest that the losses with 65.8 in. of precipitation would be materially more than 18.1 in. and might well be

TABLE 14.—PRECIPITATION, RUN-OFF AND LOSSES, BIG TUJUNGA DRAINAGE BASIN

Range of precipitation, in inches	Number of years in groups	Mean precipitation, in inches	Mean losses, in inches
20 and less	7	16.9	16.2
20.1–30.0	9	24.1	21.4
30.1 and more	12	35.7	27.4

assumed to be 27 in., or more. This assumption would lead to a reduction of the estimated seasonal run-off for the maximum year from 316 700 acre-ft to probably not more than 250 000 acre-ft. In view of the rather large difference thus obtained, the writer would be pleased to have the observations of the author regarding it.

The writer is especially interested in the forms of hydrographs shown in Fig. 6, because they seem to depart from the forms that he would expect from his experience with comparable streams. The hydrographs seem to show that for four successive days, substantially the entire run-off from rainfall on each day cleared the basin within a 24-hr period. General experience and a superficial examination of the rainfall and run-off conditions of the Big Tujunga Basin suggest that the run-off from the rainfall on a given day will continue in substantial, but gradually decreasing, amounts for two or three days after the time of maximum flow from that rainfall. Studies of characteristics of streams in this respect have been presented by LeRoy K. Sherman, M. Am. Soc. C. E.,[11] and Merrill M. Bernard, M. Am. Soc. C. E.[12] Therefore, the writer is considerably interested to know whether there are conditions in the Big Tujunga Basin that warrant the assumption of hydrographs as shown, which are seemingly somewhat at variance with the indications of experience elsewhere.

The writer has not examined what, if any, difference these considerations might make in the conclusions with regard to flood flows. In general, a momentary peak of 388 cu ft per sec per sq mile for the Big Tujunga drainage basin as adopted seems a reasonable and appropriately conservative estimate for the peak flow of a rare flood.

The compilation of data and experience on flood and erosion control problems in this paper present a most interesting and valuable contribution.

C. S. Jarvis,[13] M. Am. Soc. C. E. (by letter).—Although the problem outlined in the paper may be more nearly representative of extreme conditions than of average or usual flood and erosion control problems to be encountered in the United States, it follows that an adequate solution for the more difficult situation may be applicable, at least in part, for the simpler ones.

The observed and reasonably expected rates of precipitation for the foothill region around Los Angeles, Calif., are far from the maxima observed elsewhere for both long and short periods, particularly along or near the Gulf Coast. Likewise, the rates of run-off per square mile of drainage area thus far observed in that foot-hill region are considerably less than have been recorded for numerous small streams. The outstanding or unique features of the situation described by the author comprise the following: (1) Steep slopes on the windward side of relatively high mountain ranges, and near the coast; (2) warm or moderate all-year temperatures except on the higher elevations; (3) seasonal precipitation occurring mainly during the winter;

[13] Hydr. Engr., Soil Conservation Service, Washington, D. C.

(4) droughts occurring every summer, thus limiting the types of surviving vegetation and resulting in recurrent fire hazards; (5) unconsolidated débris and soil materials depending for their stability, on the steeper slopes, largely on the roots of vegetation; (6) soil surface partly protected by plant foliage, and incapable of maintaining itself without such protection; (7) metropolitan and urban developments on the detrital cones and flood-plains; (8) local water resources deficient, especially during the seasons of maximum demand; (9) justification for storage developments to utilize all the normal run-off, thence to facilitate recovery and repeated use; (10) ground-water supplies heavily overdrawn, with consequent intrusion of salt water to menace and further deplete the remaining ground-water reserves; (11) unusual opportunities for flood regulation by spreading, and by storage in basins partly bounded by loose, permeable strata, for the double purpose of local protection of lives and property and prompt replenishment of underground storage; and, (12) property values capable of supporting a comprehensive program for flood regulation and protection, water conservation, and its maximum utilization.

It is readily granted that other localities may be characterized by one or more of the aforementioned features which occur in combination in the Los Angeles District; but nowhere else in this country are all the factors represented to such a degree. Therefore, the measures economically justified for the Los Angeles situation may be applicable only in part elsewhere.

It has been widely observed among the head-waters of streams in both foot-hill and mountainous regions that minor landslides are going on progressively during any normally wet season, and occasionally during periods of deficient rainfall. The planes of contact between ledge rock and products of weathering are usually planes of weakness and instability; this is also true of rock débris on inclined beds of clay or other relatively impervious material. Water trickling along such planes naturally acts as a lubricant, inducing motion, cleavage, subsidence, and occasionally landslides.

Such surface disturbances among head-waters are so common and so unimportant as to escape prominence. The remoteness from the main channel of the stream, the relatively small volumes of water yielded from the disturbed areas, and the correspondingly small amount of erosion resulting therefrom, all combine to keep such phenomena in the background. However, when they occur along the lower courses of streams, where lives are endangered and property threatened, they assume considerable prominence. It appears that some of the unstable masses on such slopes are susceptible of treatment to insure their permanency in present positions; or, occasionally, to accelerate their stabilization by inducing movement to flatten the slope to a natural grade of repose, corresponding to most severe conditions expected to be encountered.

A parallel is afforded in the treatment of sites for flumes, pipe lines, or other structures near the foot of a slope. It is advisable and customary to clear the upper slopes of boulders or other rock masses that might be loosened or detached by weathering processes; or, occasionally, it is deemed expedient to repair or connect protruding ledges to serve as barriers for the protection of the lower slope.

Recent practice in the construction of trails and access roads among scenic mountain areas deserves more than passing notice. To prevent accumulations of water on the trails or roadways, diverting channels have been constructed to discharge into basin-like depressions, such as the borrow-pits from which surfacing material has been obtained. In such cases, where several feet of depth and potential hydrostatic pressure are provided, and where coarse materials, such as gravel or rock waste and other loose materials are exposed, the rapid percolation and the storage combine to dispose of surface run-off. The ease with which a large number of such percolation and storage facilities may be provided seems to make up for their restricted capacity, taken separately.

Several municipal water supply or irrigation projects, as well as hydroelectric power projects, have proved failures due largely to leakage from the reservoirs. Where comprehensive developments are undertaken for the benefit of all legitimate interests on a river system, it may well prove to be a profitable venture to seek reservoir sites that will feed underground storage by leakage or percolation. Where test borings disclose coarse, pervious materials at reasonable depths below the valley floor, it may be advisable to trench or cut through the more nearly impervious overlying material to induce underground flow and storage.

Modifications or adaptations of the foregoing methods may well be adopted in connection with flood and erosion control problems. Particularly, the provision for many avenues of access to strata of coarse, open texture, and multiple small storage basins for both water and débris may measurably relieve the burden to be sustained by the larger reservoirs down stream, helping to maintain their original capacity and thus adding to their effectiveness.

Doubtless, general recognition of existing facts would prove that nearly every locality is confronted with flood and erosion control problems, each meriting individual treatment and capable of a best solution; or, where misguided by inexperienced or over-confident advisers, a community may appropriate and spend generously without measurable progress toward a satisfactory solution. The author has done much to clarify the view as to potential dangers from those natural phenomena, and as to remedial steps which have proved effective in the Los Angeles District. Mr. Eaton has rendered a distinct service by his able presentation of the subject-matter.

HARRY F. BLANEY,[14] M. AM. SOC. C. E. (by letter).—Some excellent data on débris flows in Southern California are presented by Mr. Eaton. The writer and Colin A. Taylor, Assoc. M. Am. Soc. C. E., made a brief survey[15] of damage resulting from movement of débris out of canyons during the storm of December 30, 1933 to January 1, 1934, described by the author. This incident offers the opportunity to draw several object lessons and to take steps to guard against a recurrence of such losses.

[14] Irrig. Engr., Bureau of Agricultural Eng., U. S. Dept. of Agriculture, Los Angeles, Calif.

[15] Unpublished report, "Damage Resulting from Movements of Débris Out of Canyons During the Storm of December 30, 1933, to January 1, 1934, in Southern California", by Colin A. Taylor.

The movement of large masses of detritus out of mountain canyons as mud flows is not an unusual geologic occurrence. Large débris fans have been built up and are steepest and most rugged at the mouths of small canyons in which the stream flow is intermittent. The increasing development of the country has brought more and more of these areas under cultivation, and many of the most desirable residential sections are located high on the fans. However, in many cases, unregulated subdivision has caused the development of entire fans so that the natural watercourses are encroached on before adequate protection is provided.

In mud flows saturated masses of soil furnish the transporting medium that carries huge rocks out of the canyons. The rocks may originate in the same slide with the soil, or they may be picked up in the canyon bottom when temporary dams formed by slides break loose.

A viscous mass of mud slipping from a canyon wall may contain just enough water to make it flow, and progress may be relatively slow in the flatter slopes of the canyon bottom. In this condition, huge rocks are carried along without rolling and the movement has the appearance of a lava flow, and, in this condition, may move slowly out of the canyon on to the fan.

When a large quantity of surface run-off occurs at the time the saturated soil slips from the canyon walls, the water may first pass over the top of the slower moving mud flow. Water may also pile up behind the temporary dams and then, as they give way, mix with the soil and make the mass less viscous. As the proportion of water increases the mass becomes more fluid and the rocks tend to settle and roll or slide along the bottom, while the finer material mixed with the water moves over the top of the mass with increasing velocity. The puddled mass that moves the larger boulders drains very slowly.

Eight samples were collected at 4:00 P. M., on January 2, 1934, of the fine material in the wash under some large boulders at Foothill Boulevard, north of Montrose, Calif. (see Fig. 11). The average moisture content was 18.4% by weight, and after screening out the material larger than 2 mm in diameter, the percentage of moisture was 27.8, based on the oven-dry weight of the material smaller than 2 mm. The percentage of water in a saturated soil as it lies in place before it first starts to slip would be approximately 25% by weight, or 33% by volume. This saturated fine material acts as a lubricating medium and assists in the transportation of the larger boulders.

In the canyon bottom mechanical mixing with more water takes place, and the percentage of water must be higher except in the slower moving mud flows. The water content of the material must be continually varying through wide ranges so that the evaluation of flows from gauge heights is most uncertain. There is also the further complication caused by the underlying rocks and viscous layers of material moving much more slowly than the more fluid material on top. Furthermore, the churning bores of flood crests also contain air which tends to increase the maximum gauge height or high-water marks. From this, it follows that the estimation of flows of this character by gauge height record at the ordinary gauging station is most impractical as no record is obtained of the water content of the flow, nor can the velocity be considered as a water equivalent.

It would appear that the most practical method of measuring discharge rates under conditions such as prevailed in these canyons is to gauge the rate of rise in the débris basin at the canyon mouth and also to establish a gauging station in the channel below the débris basin.

One of the most important functions of brush cover in controlling run-off is the aeration of the soil. Decayed roots and worm holes furnish channels through which air is readily moved from the lower soil depths. Rain does not ordinarily run down these channels as is popularly supposed, but moves into the soil as capillary water. The function performed by the roots and worm holes is to release air back to the surface as it is displaced by the downward moving moisture. This release of air prevents the development of back pressure, which would materially reduce the rate of infiltration of rain water, particularly in long-continued steady rains.

The burning of the water-shed increases the potential danger many-fold, but mud flows will occur on certain soil types with the vegetative cover still intact as witnessed by the flows from Neusbickel Canyon, near San Dimas, Calif., during the same storm. In this case, the soil is a clay loam and the moisture could not be transmitted into the more compact underlying subsoil fast enough to prevent saturation of the top soil. Slips of the top soil then occurred on the steeper slopes. The soil in Neusbickel Canyon supports a dense growth of mustard that starts each winter and dies the following summer. There are also occasional patches of brush. The canyon sides are very steep—60° and more in many places. A 5-in. rain on December 12 to 14, 1933, filled the top soil to field capacity, and the fresh growth of mustard was less than $\frac{1}{2}$ in. high at the start of the storm on December 30, when 15 in. of rain fell within 30 hr. saturating the top soil so that it slipped down the slopes, at many points forming great arrow-shaped scars on the hillside. In some cases, the movement was slow so that the material was carried away as fast as it dropped into the stream bed. In others, the evidence shows that great masses avalanched down and temporarily blocked the canyon. At the end of the storm, however, the stream bed was swept clean to bed-rock and the débris was deposited in a fan-shaped mass at the mouth of the canyon.

The control of moving masses of detritus has been a serious problem in the Western States for many years, and the protection of the irrigated agricultural areas from floods has been the concern of governmental agencies. The problem has been studied in Utah, and control methods have been devised by engineers of the U. S. Bureau of Agricultural Engineering. The results of the Utah investigations were published in 1933.[16] Similar methods of control might be effective in some areas of Southern California for the protection of life and property in the foothill areas.

Mr. Eaton discusses "Spreading to Increase Percolation" and, in Table 13, contributes some valuable information on the effect of scarification by plowing and harrowing on the rates of percolation in the San Gabriel River and Rio Hondo. In this connection, the U. S. Bureau of Agricultural Engineering has been conducting experiments on water-spreading at the mouth of

---

[16] "The Barrier System for Control of Floods in Mountain Streams", by L. M. Winsor. Assoc. M. Am. Soc. C. E., *Miscellaneous Publication No. 165*, U. S. Dept. of Agriculture.

San Gabriel Canyon for several years. This investigation, which is in charge of Mr. A. T. Mitchelson, has produced some interesting data on the stimulating effect of undisturbed native vegetation by root activity on the rate of percolation. In 1930, an experimental plot of 0.38 acre was diked and water was applied uniformly in such a way as not to interfere with the healthy growth of the vegetation. Continuous measurement was made of the water flowing on to the plot and of the run-off. In 1931, a second plot of like size, shape, and soil type was established adjacent to the first, but from it the vegetation was removed, the roots grubbed out, and the surface plowed, harrowed, and furrowed. It was operated simultaneously with the other plot. In 1932, a third plot was established, which was also adjacent to and of the same size as the first, and was operated simultaneously with the others. The third plot, however, was operated on the basin method, a head of about 6 in. of water being held over the wetted area.

In the season, February to June, 1930, during a continuous run of 87½ days, the plot in native vegetation absorbed water at rates averaging 3.98 acre-ft per acre per day and ranging from 3.03 to 5.33 acre-ft per acre per day. In January to March, 1931, during a run of 82 days, this plot absorbed at rates averaging 6.50 acre-ft per acre per day and ranging from 2.13 to 7.92 acre-ft per acre per day, while on the furrowed plot the daily absorption rates averaged only 2.53 acre-ft per acre and ranged from 1.15 to 4.16 acre-ft per acre. In the season, January to June, 1932, the daily percolation rates for the first plot again were highest, averaging 5.03 acre-ft and ranging from 2.12 to 8.04 acre-ft per acre. On the furrowed plot, the rates ranged from 1.66 to 4.22 acre-ft per acre and averaged 2.93 acre-ft per acre per day, while on the basined plot the minimum, maximum, and average rates were, respectively, 2.22, 5.08, and 3.76 acre-ft per acre per day.

W. P. ROWE,[17] ASSOC. M. AM. SOC. C. E. (by letter).—A very complete outline of the flood-control problems of Los Angeles County is presented in this paper. The information contained in Tables 12 and 13, dealing with percolation rates, is of particular interest as millions of dollars are now (1936) being spent in Southern California on projects designed to increase the supply of the underground water basins. In view of these enormous expenditures the writer believes that the economic side of this problem should receive more particular attention.

The paper contains certain statements relative to quantities of material eroded from mountain sides which the writer can not pass unchallenged. This is especially true in view of the widespread interest being displayed in erosion control and the propensities of certain erosion-control enthusiasts in quoting published data to support their claims without analyzing their accuracy.

In discussing this feature of the paper, the writer will use the author's definition, namely: "Erosion, in this instance, is defined as the washing of loose material from weathered mountains and foot-hill areas, and its deposition upon the lower valley floors." Four quantitative estimates of erosion from burned-over areas are cited by Mr. Eaton and he states: "The La Crescenta-Montrose débris flow, on January 1, 1934, furnishes the best and most accurate, as well as the largest unit débris flow of authentic record." Haines Canyon is included in his treatise on this area. Under "Erosion with Normal Water-Shed Cover", he states: "Where water-sheds have not been disturbed by fires, roads, earth-slides, etc., erosion is relatively slight", and immediately preceding Fig. 8: "Mass movements originated from canyon sides as high as 200 ft above stream bed, some of the masses being as much as 50 to 150 ft wide. Trees 2 ft, or more, in diameter slipped with the masses and were swept into the streams." It is true that the brush cover on the mountain sides was burned, but most of the trees and other canyon bottom growth escaped unharmed by the fire. This is characteristic of most mountain fires in Southern California. If one were to believe evidences of previous earth slippages in this area and the statement in the paper that this area had not been burned over since 1878, one must conclude that similar slippages would have occurred during the storm of January 1, 1934, regardless of the fire.

---

[17] Cons. Engr., San Bernardino, Calif.

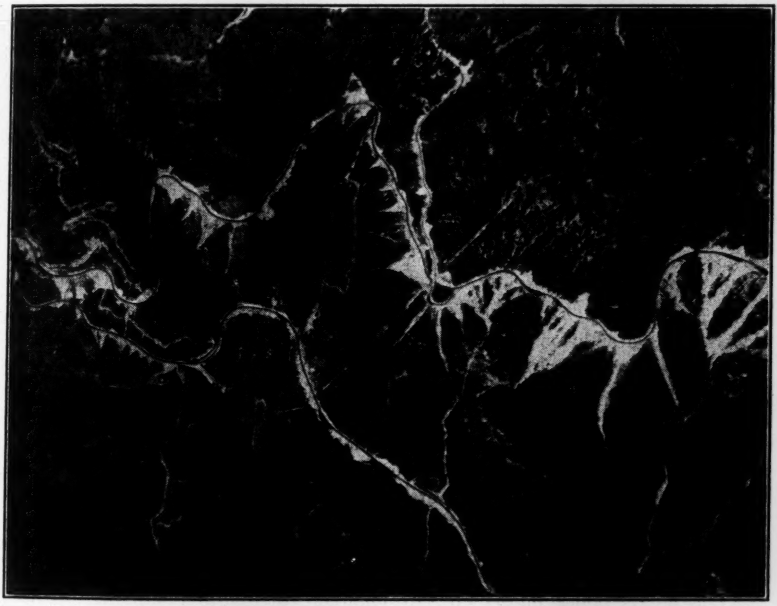

FIG. 13.—EROSION IN THE SAN BERNARDINO MOUNTAINS

It is almost impossible to find a water-shed in Southern California that conforms to the author's description of one on which erosion is relatively light because of the absence of previous "fires, roads, earth-slides, etc." Fig. 13 shows a portion of the San Bernardino Mountains north of San Bernardino. It depicts all the major man-made aids to erosion, namely, earth-slides created by cutting faulted ground, and earth-slides created by the overcast of materials excavated from side-hill cuts, fire-breaks, old roads, and new roads. Most of the area was burned over by fire in 1911 and parts of the same area have been visited by two other fires since that time. The débris removal from the mountain sides by storm waters after the fires was very slight in comparison with that due to the various construction activities. No evil effects from the fires are visible either on the ground, or from the air, and the escape of canyon bottom vegetation from fires is characteristic of Southern California brush fires. The apparent lines of erosion down the canyons is due to the movement of overcast material.

Under "Erosion and Erosion Control", the author states that the forces of erosion are still active and have built deposits of many thousands of feet of débris in the valleys and he apparently ascribes this deposition to the results of burning of water-shed cover. In his analysis of the quantities of erosion from the San Gabriel Canyon area (see "Erosion with Normal Water-Shed Cover"), he shows that the flood of 1927, one of the highest peak flows of record, caused the erosion of only 3 200 cu yd per sq mile, 3 yr after a major fire. With this as a basis one should assume that it is only a combination of heavy rainfall on a burned-over area that causes débris flow from an undisturbed water-shed. The coincidence of a season of heavy rain following a fire which might occur every 56 yr, as in the case of the La Crescenta-Montrose flood, is too remote to account for the deposition of the enormous valley fill in the La Crescenta-Montrose area, unless one were to reverse the old stand-by theory of the Forest Service propagandists and assume that forest cover no longer makes the rainfall, but that lack of forest cover is responsible for heavy rains. The logical explanation lies in a study of the geology of the water-shed by which it will be found that erosion has been active regardless of fires.

Following Fig. 8 the author, describing the movement of peak flows of débris and water below the canyon mouths, states: "Reaching open territory these waves flattened to 5 or 6 ft in height and spread to widths of 100 to 200 ft, scouring new channels and thus picking up new débris loads"; then (preceding Table 10): "Each sharp peak of major débris flow would be succeeded by a rapidly moving stream which contained less débris, cutting a channel to one side or through the deposited débris masses"; and, again (following Fig. 11): "* * * but the final lowest channel sections as left resulted from cutting by the later and receding stream flows of higher velocities, which ground the stream bed far below its original grade and below that at the time of the making of the highest mud marks."

The débris cones on which this channel cutting and shifting occurred are the result of previous erosions and the re-working of this material can not be classed as erosion under the author's definition. Nevertheless, he includes the quantity of this re-eroded material in his estimates of erosion per square mile of water-shed.

The author has failed to mention one very important factor in describing the shifting channels and later cutting on the La Crescenta-Montrose débris cones. Prior to the flood, a series of wire and rock check dams had been constructed across the active stream channels. The crests of these dams in many instances were less than a foot below the top of the banks on either side. When the flood flows from the mountain occurred, they overtopped these dams and scoured out the loose alluvial material below them and deposited it behind the dam next lower down stream. When the small basins behind these dams were filled to the crests of the dams, the water and débris were diverted laterally around the ends of the dams and on to the adjacent territory. The 59½-ton boulder mentioned by the author (see following Fig. 9) was deposited in this manner. It was not carried from the mountain side by this one flood, but rolled down the débris-filled channel until it was diverted by one of these check dams. The remnants of the check dams in this vicinity gave ample proof of this theory. The fact that the active channels on these débris cones usually ride on the highest part of the cones aided in this channel shifting.

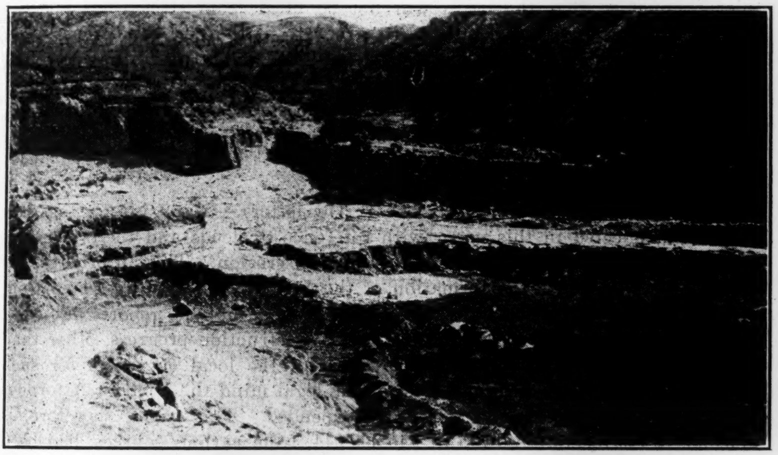

FIG. 14.—DÉBRIS BASIN IN HAINES CANYON ON MARCH 19, 1934.

The writer will agree with the author in the statement as to the effectiveness of the Haines Canyon débris basin in controlling débris flows, but disagrees when he attributes the 32 000 cu yd of débris caught in the basin to erosion from the mountain side under his definition. This basin was the result of the operation of a gravel company excavating at the head of the débris cone of Haines Canyon at its apex within the canyon walls. The original active channel had a slope of 10 per cent. The operations of the gravel company in excavating below the original grade of the stream resulted in a face at least 40 ft high at the upper end. This face was practically vertical and consisted of sand, gravel, and boulders. When the flood occurred, the water poured over this face and started to re-adjust the grade of its bed to fit this new condition. The result was a cutting of a deep channel up stream from the gravel pit, all the eroded material being deposited in the basin.

The classification of all the material deposited in the débris basin as erosion from 0.47 sq mile of burned-over water-shed and the assumption that, therefore, the rate of erosion from 1 sq mile of burned-over water-shed was 62 000 cu yd, would not conform to the author's own definition.

Fig. 14 is a view looking up stream across the Haines Canyon débris basin on March 19, 1934. It shows (1) the re-adjusted stream bed with banks from 15 to 30 ft high; (2) the débris cone deposited within the basin, but above the spillway level; (3) the original high-water line at the top edge of the recent excavation made after the storm of January 1; (4) a re-adjustment of grade on the old cone by stream flow by a storm after January 1; and (5) the extent of the most recent excavation. The spillway is to the right of the photograph, and its crest is about 10 ft below the level of the remnant of narrow-gauge railroad showing at the foot of the bank.

The importance of having the spillway of a débris basin in solid cut has been shown by the author; but of equal importance is the protection of the inlet channel so that the basin will not be filled from stream-bed deposits washing in as the stream re-adjusts its grade to fit the new conditions.

The evils of erosion are bad enough without undue magnification. The writer is probably old-fashioned in his beliefs, but he still maintains that the Grand Canyon was not the result of forest fires, draining of swamps, or any of the other multitudes of natural evils that have been blamed on the activities of mankind.

J. B. LIPPINCOTT,[18] M. AM. SOC. C. E. (by letter).—Many interesting data have been collected in this paper with reference to floods and their resulting erosion. Of these two problems the greater is erosion. This information is of value because, since the formation of the Los Angeles County Flood Control District in 1915, there have been few if any engineering reports published containing the physical data collected, or of construction progress, other than through the daily press, despite the request of the local engineers for such information. By some peculiar twist of the legal mind the District Attorneys ruled that bond funds could not be so expended. This paper, therefore, is welcome to engineers. A total of $46 308 044, from various sources, had been spent on this work prior to the fall of 1935. Since then $10 000 000 more have been allotted to the District from Federal sources.

Since the appointment of C. H. Howell, M. Am. Soc. C. E., as Chief Engineer on January 30, 1935, a comprehensive document entitled "Rainfall and Runoff Report, Seasons 1932–33 and 1933–34" was issued under date of June 1, 1935, which contains hydrographic data for that period. Especially in view of the difficulties of the problems involved it is hoped that, in the future, reports will be currently presented relative not only to hydrography, but also to the engineering features, including the reports of boards of engineers and geologists. This is in accordance with ordinary practice for large public works.

Bonds were voted by the Los Angeles County Flood Control District for two purposes: (1) The prevention of flood damage; and (2) the conservation of water by spreading floods over absorbent valley fills for underground storage. The general plan contemplates regulating reservoirs in the mountains, and flood-control channels across the valleys and plains, supplemented by spreading basins by means of which the water could be saved. The building of the dams has been difficult because of the geological character of the rocks of the Sierra Madre Range. These rocks have been shattered by earth movements and largely decomposed. The foundations and abutments for these dams have been poor. The local engineers are not alone in having difficulties with these adverse conditions. Engineers and geologists from numerous other parts of the United States have been consulted, with much the same experience. Twelve dams have been built successfully but there have been several disappointments. Important features of the general problem are yet unsolved. The dense population of Los Angeles County and the high property values (both of which are threatened) create an insistent demand for protection. Very little has been done in building spreading basins although the Supreme Court of California has pronounced this as one of the main features of the project.

---

[18] Cons. Hydr. Engr., Los Angeles, Calif.

Because of the steepness of the mountain drainage basins, violent, flashy floods are discharged on to the valleys at intervals averaging about once in five years. These floods are followed by long periods of low flow. As described by the author, they carry surprisingly large quantities of débris. During an occasion of this nature the rolling and grinding of the boulders can sometimes be heard for several miles.

The gradient of the San Gabriel River, which is the principal stream of Los Angeles County, indicates the difficulty of the problem of disposing of this débris-laden water. Its smaller tributary basins have stream-bed slopes of from 125 to 400 ft per mile, and the main channel of the river in its mountain section, has a slope of 60 ft per mile. Below the mouths of the canyon the gradient across the San Gabriel Valley for a distance of 12 miles is 25 ft per mile. The river then flows through a pass on to the Coastal Plain where for a distance to the sea of 20 miles the gradient is 6.5 ft per mile. The hydraulic properties of these channels, even when leveed, become more unfavorable at points nearer the ocean. In the case of the Verdugo Wash (north of the City of Los Angeles), the gradients across its débris cones at La Crescenta (Montrose) are 500 ft per mile; thence, through the City of Glendale, the channel has a grade of 80 ft per mile, discharging into the Los Angeles River in the City of Los Angeles, where the channel has a slope of 25 ft per mile. The discharge of mountain floods ranging from 500 to 1 000 sec-ft per sq mile, eroding the shattered and decomposed rocks, has resulted in the building up of débris cones of great volume at the mouths of the canyons, and a general delta plain toward the sea. These débris and delta formations are of universal occurrence. Topographically, many of the cones are surprisingly symmetrical. All the channels are unstable and shifting. The steep slope and the great volumes of the débris cones indicate that the process of their formation has extended through long periods of time and that these deposits will continue.

Because of the commanding elevations of these cones and their attractive climate they have been extensively occupied and improved and, in many instances, towns are located in these exposed locations. The author shows that where the small mountain basins have been recently denuded by fire (which cannot be entirely avoided during the long dry summers) the volumes eroded from the smaller and steeper basins amount to extremes of from 40 000 to 50 000 cu yd per sq mile during single floods. If the floods are diverted at the mouths of the canyons, into lined channels, as is being done, with the foregoing gradients, the place where the débris will be dropped depends on the flattening of the gradient. The deposit must occur somewhere before the flood reaches the sea. As an indication of this last-named process apparently the mouth of the Los Angeles River has changed its position 18 miles, the San Gabriel River, 9 miles, and the Santa Ana River, in Orange County, 10 miles.

Efforts to Solve the Problem.—As stated previously, the population and property value of Los Angeles County is such that efforts must be continued to control both the flood and the débris. The first general plan of attack was made in 1917 when $4 450 000 in bonds was voted for the building of dams on the Arroyo Seco and San Dimas River, together with the diversion of the flood waters of the Los Angeles River from Los Angeles Harbor.

This was followed in 1924 by a plan that was hurriedly presented, without mature engineering study, and against the protest of the Los Angeles Section of the Society. It involved an expenditure of $35 300 000 for building dams, channel improvements, and spreading basins, the announced program being to regulate the floods of the major streams and to put the regulated flows into underground storage.

Despite the recommendation of two boards appointed subsequent to the bond election (relative to the original San Gabriel Dam), the Courts held that the type, size, and location of the structure defined in the bond election proceedings had to be followed rigidly. After foundation difficulties had developed in connection with the construction of this major structure, the California Supreme Court subsequently held that, because of "changed conditions", modification in the plans could be adopted, an essential feature in the decision being that the resulting decreased surface storage should be replaced by an increase in the quantity of water to be stored underground.

Although to date (1936) twelve dams have been built and are performing service of value, other efforts to build large dams have been unsatisfactory in some instances.

As the smaller reservoirs are practically débris basins in which to impound eroded material, the cost of some of them as such is of interest. The costs in Table 15 are high but they are less than the expense of $1.00

TABLE 15.—COSTS OF SMALL RESERVOIRS

Name of dam	Reservoir capacity, in acre-feet	STORAGE COST	
		Per cubic yard	Per acre-foot
Live Oak	250	$0.47	$760
Sawpit	470	0.83	1 340
Little Santa Anita	110	0.79	1 280
Big Dalton	1 290	0.49	790

per cu yd for cleaning up débris that was deposited at the rate of 26 000 cu yd per sq mile of drainage basin in October, 1928, on to streets and yards below the mouth of Brand Canyon, in Glendale, Calif., as stated by the author. His description of these débris flows is especially interesting and presents data that are new. It should be remembered that the great débris flows occur only when the burning of the cover of the drainage basin is followed by torrential rains. Although this combination may occur only at long intervals (say, 10 to 15 yr), the menace is present constantly.

Check Dams.—During the early years of the District there was a popular demand for the building of "check dams." This idea extended throughout Southern California. These check dams at first consisted of dry rock-fills, about 5 to 10 ft in height, built in the mountain channels without being founded on bed-rock. Frequently, they were only a few hundred feet apart, the idea being that their small basins would fill with débris which would absorb the flood water and permit of slow percolation later in the season, and also that they would step down the steep gradients of the channel. These structures promptly failed with the first floods. They were followed by a modified construction, wrapping loose rock in wire mesh; 4 060 of these check dams were built by the Flood Control District. They were also placed a few hundred feet apart in the canyons and on débris cones. The rolling of large rocks by floods cut the wires, and the floods also washed around their ends. To date, approximately 2 000 of these dams have failed under flood action. Accumulated material behind them contributed to débris that was projected on to underlying areas. It was stated that "check dams" had been used successfully in the Alps. Observations in Switzerland and Japan where flood and débris problems prevail, are that such small dams are substantial structures built of cut stone or cement masonry, and are usually founded upon bed-rock. The Los Angeles County check dams were built largely against the protests of the engineers in charge of flood-control work.[19]

Although there are 1 589 sq miles of mountain drainage area in the Flood Control District, the writer knows of no comprehensive estimate of the cost of controlling floods in this area by check dams. Some cost figures, therefore, may be interesting. The flood-control engineers have reported[20] that "the cost per cubic yard of debris stored by check dams varies widely, ranging from as low as 45 cents per cubic yard of debris up to as high as $6.00." If a cost of $3.00 per cu yd for such storage is assumed, this is equivalent to $4 839 per acre-ft of capacity. The following is also given from a report[20] written in 1931: "The actual measurements from a single moderate storm where fires have denuded the watershed have shown over 25 000 cubic yards of débris from one square mile of foothill area with a possible recurrence equal in amount for each storm during the period required for regrowth of vegetation." This re-growth requires fifteen years. Horse Canyon, a tributary of the San Gabriel River having 2.15 sq miles of drainage was completely "check dammed" in the summer of 1932. Twenty-three rock and wire check dams were built, and 137 loose rock dams, which is a total of 160 check dams, or 1 check dam for each 6.25 acres. The cost per square mile of this work was $10 445, and the cost per cubic yard of débris storage, 51 cents. An estimate of the cost of controlling 13.76 sq miles in this basin was $256 082, or an average of $18 610 per sq mile.[n] The conclusion is reached that the concrete dams and reservoirs, such as those referred to previously, none of which has failed, are more substantial and no more expensive than the "check dams." Studies have been made in Santa Barbara County, California, by the U. S. Forest Service for controlling the débris on the Santa Ynez, which confirm these conclusions.

[19] Rept. of E. Courtlandt Eaton, M. Am. Soc. C. E., August 17, 1927.

[20] Rept. by E. Courtlandt Eaton, M. Am. Soc. C. E., and Frank Gillelen, Assoc. M. Am. Soc. C. E., May 22, 1931.

Flood-control work in Switzerland by means of larger and more substantial check dams on Lambac Creek, near Brienze, having a drainage area of 1.66 sq miles, shows an expenditure between 1898 and 1913 of $216 000, of which 60% was for channel construction below the mouth of the canyon. This amounts to a cost of $130 000 per sq mile. At the time of this cost estimate the work had not been completed. Where suitable reservoir and dam sites exist on larger drainage areas, the construction of the larger and more substantial dams is justified.

Débris Basins.—The next effort by the Flood Control District in the development of a plan to control débris from small mountain drainage areas was by means of "débris basins." These basins are excavated in the débris cone, with overflow weirs discharging into lined channels. The basins are built at the mouths of canyons at the apex of the débris cone. The general theory is to obtain a storage capacity of 100 000 cu yd of débris for each square mile of tributary drainage basin. The excavated material consists of sand, gravel, and large boulders. The plan is to discharge the floods through these basins in which the larger débris will be deposited and build concrete-lined channels of large capacity from the outlet of the basin down the slopes to the larger drainage lines and thence through other larger lined channels to the rivers. To January 20, 1936, twenty-three of these basins have been built.

The following is a description by the Flood Control engineers of one of these basins in the Montrose District, called Haines Canyon: The drainage area, in square miles, is 1.50. Of the basin, 60% has been burned. The present water capacity of the basin as built is 24 700 cu yd. Assuming that the débris in the basin itself takes a slope of approximately one-half the natural slope of the channel, its débris capacity is estimated at 87 250 cu yd. It is proposed to enlarge this débris capacity ultimately to 150 000 cu yd. What is termed the "bulked *Q*", of water and débris, in cubic feet per second, is 200% of the maximum peak water flow calculated for the drainage area above the basin. This bulked *Q* is given as 10 000 cu ft per sec. This will allow bulking by débris of 100%, whereas the estimates of débris flow for the January 1, 1934, storm in the La Crescenta area, indicated a bulking of 50% by débris. What is called the "clear-water *Q*" of 5 000 sec-ft is the design *Q*, for the first section of the channel below the basin. In designing the inlet and outlet structure of the basin, the bulked *Q* is used.

---

[n] Rept. by E. Courtlandt Eaton, M. Am. Soc. C. E., October 31, 1932.

As the author well shows the débris brought down by floods is enormously increased when such floods follow soon after the burning of the brush cover of the basins. He states that following a fire, the floods of January 1, 1934, discharged from 7 sq miles of drainage north of La Crescenta (Montrose) 659 000 cu yd on to property and streets, amounting to more than 90 000 cu yd per sq mile. Other instances are given by the author of greater débris flow from other burnt areas. Referring to the cost of these débris basins he states: "Their capital costs per cubic yard of débris capacity will range from $0.30 to $1.00 per cu yd, depending mainly upon excavation costs." It will be noted from these figures that the cost of débris-basin storage does not differ greatly from the costs of similar storage behind the four concrete dams previously cited.

The probable life of the débris basin as well as of the small reservoir will be short. In the case of the débris basins the plan is to re-excavate them when they are partly or entirely filled. When the smaller reservoir is filled the probable plan may be to provide another on the same stream. These figures are presented not in criticism of the plans of the Flood Control District, but rather as indicative of the expensive nature of the problem involved and which should be solved. These great débris flows occur only when floods follow fires, a combination of events that does not occur frequently. Nevertheless, they are a menace that should be provided against.

Assuming maximum flood discharges of 500 to 1 000 cu ft per sq mile delivered into concrete-lined channels having gradients of more than 10%, the further question arises as to whether the exceedingly high-water velocities of fully 40 ft per sec which may occur, will flow around curves in the channels irrespective of their débris. The opportunity to observe this phenomenon has not yet occurred.

Brush and Forest Cover.—The beneficial effect of forest or brush cover in reducing floods and erosion has been amply demonstrated in California by observation on adjacent experimental plots both burnt and unburnt in two mountainous regions, and also by careful observations on neighboring drainage basins of similar exposure some of which have been denuded by fire. These measurements (which are in accord) have been conducted by the U. S. Department of Agriculture. To give the details would be to repeat the views of the writer which have been presented[22] previously. They show in one series of test plots that the run-off from burnt areas, with rain at the rate of 2.4 in. per hr, was 200 cu ft per sec per sq mile and that there was "no surficial run-off measured" from the covered plots. Eroded material from the burnt plots was 3 cu yd per acre and that from the unburnt area was zero. With a 12-in. rainfall during the storm of December 30, 1933, to January 1, 1934, the peak run-off from the Verdugo Wash of 19.3 sq miles (which included the Montrose area, 6 sq miles of which was steep, absorbent, canyon floor and largely burnt over), was 350 cu ft per sec per sq mile and the erosion, 50 000 cu yd per sq mile, whereas, from the unburnt mountainous adjacent Arroyo Seco Basin of 16.24 sq miles with brush cover, the run-off was 58 cu ft per sec per sq mile and the erosion was relatively insignificant. Other basins show greater contrasts.

---

[22] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 330.

These examples show the great value of the dense brush on the Southern California mountains. If this cover can be maintained, it relieves the flood and débris problem. If fires are prevented it affords a much simpler and less expensive process than the building of costly engineering works. This solution resolves itself into the effort to prevent fires. The Federal, State, and County organizations have combined to prevent fires and have succeeded substantially in reducing their hazard. Lookouts with telephone connections have been established throughout the mountains. Fire-breaks have been built along ridges. The system of roads being built, will permit of the rapid transportation of men and equipment to fires. If a fire can be reached in its incipiency, it can be extinguished. If, however, it becomes general, the task is well-nigh hopeless; the effort then is to control it within drainage basins. In the writer's opinion relatively greater benefits can be obtained from efforts to prevent fires than by the construction of engineering works, although both are necessary. A most rigid patrol and control of the use of the Forest Reserve is justified.

The occupation of the menaced débris cones should be discouraged and should have been prohibited. However, they are already (1936) largely occupied. As stated by the author this occupation invites disasters such as that which occurred on January 1, 1934, when 30 people lost their lives and $5 000 000 property damage occurred at Montrose. It is unfair to require the public to pay the costs for their protection which may be at a money cost in excess of assessed values. The location of these improvements in many instances prevents the spreading of flood water for conservation purposes on the cones as originally planned.

Conclusions.—In conclusion, the writer expresses his appreciation of the difficulties involved in the handling of the flood problems of the Los Angeles County Flood Control District. The task appears well-nigh impossible of complete solution on the one hand and a necessity on the other. The presentation of basic data in this paper is valuable. Further reports on the engineering problems of the District should be made generally available in order that the minds of many engineers can give it thought. The engineers in charge of the work are entitled to helpful co-operation. Opportunities for conserving the valuable flood water by its underground storage are yet available in the larger valleys and on the Coastal Plain and should not be neglected as this is one of the main features of the project. It is a cheaper conservation method in Los Angeles County than the storing of water in surface reservoirs. However, each drainage basin requires a separate study and plan.

E. I. KOTOK,[23] ESQ., AND C. J. KRAEBEL,[24] ESQ. (by letter).—A great volume of data on rainfall and run-off relations in Los Angeles County, California, has been accumulated by the County Flood Control District and various Federal agencies. A smaller amount of information on erosion has been similarly gathered. Mr. Eaton has done a signal service in selecting some of the most significant facts and estimates and presenting them with his excellent analyses. The engineering methods described for flood and débris control have not only proved successful where they have been used, but are indicated as indispensable for the protection of communities contiguous to mountain water-sheds which have been denuded of vegetation.

---

[23] Director, California Forest and Range Experiment Station, U. S. Forest Service, Berkeley, Calif.

[24] Senior Silviculturist, California Forest and Range Experiment Station, in Charge of Studies in Water-Shed Management and Erosion Control, U. S. Forest Service, Berkeley, Calif.

In stating that the natural cover of vegetation affords the "best protection from débris", Mr. Eaton expresses a fact which has been so frequently and spectacularly demonstrated in California by the sequence of fire and flood that it is now quite generally accepted. The formulation of adequate plans for water-shed management, however, still requires the obtaining of quantitative data on the degree of influence exerted by different types and conditions of forest cover, not only upon soil movement, but also upon water movement. Such planning requires, furthermore, a study of the effects of manipulating or "improving" the cover by cutting, planting, or otherwise, and the development of methods of restoring vegetative control quickly after accidental denudation.

In these problems the forester's interest is vital, since in California nearly all the major water-sheds lie within National forests. In Southern California where water is the limiting factor of human development, the primary objective of forest management is to produce from mountain catchment areas the maximum annual yield of useful water—with emphasis on the word "useful" and with due regard for the increasingly important secondary use of the forest in this region, namely, recreation.

The California Forest and Range Experiment Station, representing the research branch of the U. S. Forest Service, is engaged in a comprehensive program of studies in water-shed management[35], including both field and laboratory attacks and giving first priority to the aforementioned problems. A large part of this work is centered in the San Dimas Experimental Forest, an area of 17 000 acres within the Angeles National Forest, set aside for research purposes by special order of the Chief Forester, U. S. Forest Service. The area embraces the entire water-sheds of Big Dalton Creek (7.5 sq miles) and San Dimas Creek (18.3 sq miles), situated in the San Gabriel River drainage and shown in Fig. 1, both commanded near their canyon mouths by large dams built in 1928 and 1922, respectively, by the Los Angeles County Flood Control District for flood control and water conservation purposes. During the three years, 1933, 1934, and 1935, with the help of unemployment relief labor, the Experimental Forest has been equipped with approximately 350 rain-gauges, 17 stream-gauging stations, 9 débris measuring reservoirs, numerous climatic stations, sample plots, and the necessary roads, trails, telephone lines, laboratory, and other service buildings. All engineering design and construction has been done under the direction of the Regional Engineer of the Forest Service, and at all stages, the staff has invited criticism and suggestions from local engineers, water officials, and other interested persons, in the effort to make of the Experimental Forest an adequate laboratory of water-shed management and erosion control problems for Southern California.

---

[35] The program is described briefly by Mr. E. I. Kotok, and some representative data are presented by Mr. C. J. Kraebel, in the Report on Progress Conference on Water Conservation, Los Angeles, Calif., March 13–14, 1935, by the Committee on the Conservation of Water, Irrigation Division, Am. Soc. C. E. (mimeographed December, 1935).

In discussing the 1934 flood flow from Pickens Canyon, the auther touches on the difficulty of calculating such a flow from high-water marks and channel sections after the flood. A characteristic of such flows is their scouring action by which the stream beds may be lowered several feet during a single storm. Both the exposed bed-rock of the scoured channels and the roughly stratified structure of the great outwash fans at their mouths constitute evidence that such scouring has occurred periodically through past centuries. A survey of Pickens Canyon made by members of the Experiment Station after the flood revealed soil loss from ½ mile of the canyon bottom at the rate of 20 000 cu yd per lin mile of channel. Fig. 15 depicts a typical section of the channel, photographed after the Montrose flood of January 1, 1934, which illustrates the difficulty encountered in estimating run-off rates of débris-laden flows. The upper tape, *A*, indicates the highest water stage, the middle tape, *B*, the pre-storm channel bed, and the lowest tape, *C*, the present scoured channel as it was left by the flood. Erosion of the stream bottom was progressive. The question, for which there is no definite answer, is: "What was the channel profile when the water surface was at the highest level?". It is quite possible for the maximum run-off to have occurred when the channel was only partly scoured and the water surface had dropped below its highest mark.

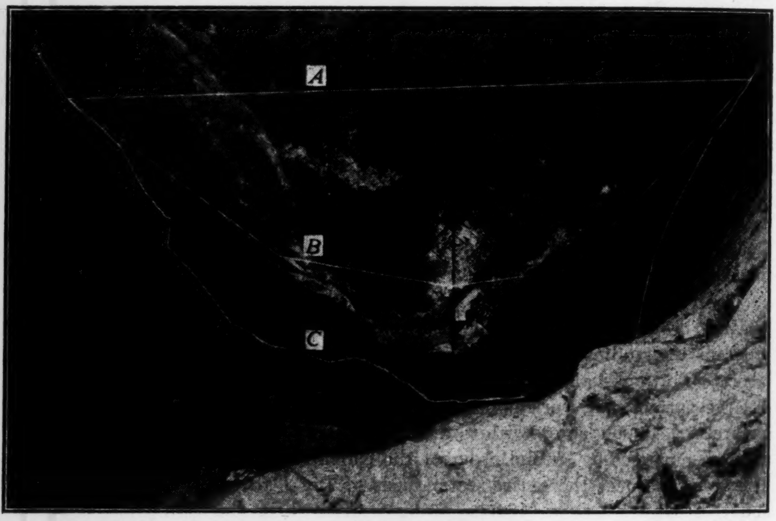

FIG. 15.—CHANNEL OF PICKENS CANYON, AFTER MONTROSE FLOOD OF JANUARY 1, 1934.

In the effort to find a positive means of measuring débris-laden stream flows, the staff of the Experimental Forest Station has found the Parshall flume unsatisfactory and is developing a critical-depth flume with parallel sides and sloping floor. Tests of this new meter have thus far been very encouraging.[26]

Regarding estimates of erosion with normal water-shed cover the author rightly states that information is not plentiful. A probable reason for this lack of data is that débris production from well-covered chaparral water-sheds is so slight that it ordinarily escapes notice. The erosion rates given for the San Gabriel, Gibraltar, and Sweetwater water-sheds (see heading "Erosion with Normal Water-Shed Cover") do not represent erosion from well-covered areas because all these water-sheds had been severely burned over, and the Sweetwater water-shed had also been over-grazed for many years. There are so many variables involved which influence erosion of burned areas and also the recovery of the burned vegetation that it is unwise to generalize about either. The author's estimate of 1 500 cu yd per sq mile annually from areas unburned for 10 yr, or more, seems a generous maximum.

From experience in the Experimental Forest the writers submit some rates of erosion, in Table 16(*a*), based upon actual catchments in tight reservoirs for the entire rain season of 1934–1935. From the great New Year's storm ending January 1, 1934, the rates measured in the same experimental water-sheds were as shown in Table 16(*b*). These extremely low run-off and erosion rates, when compared with the rates cited by Mr. Eaton for the same storm on the Mt. Lukens burned area, indicate that the quantitative influence of good vegetative cover is considerable. The burned water-sheds received an average of 12.5 in. of rain, yielded a maximum run-off of 580 cu ft per sec per sq mile (Pickens Canyon), and an erosion rate of approximately 67 000 cu yd per sq mile (Haines Canyon). Thus, the run-off ratio, as of covered to burned area, is 1:23, and the erosion ratio, 1:1 600.

TABLE 16.—EROSION RATES AND RUN-OFF IN CHAPARRAL WATER-SHEDS, 1934–1935

Water-shed	Area, in square miles	Elevation, in feet	(*a*) THE ENTIRE RAIN SEASON, 1934–35			(*b*) THE GREAT STORM, JANUARY 1, 1934		
			Precipitation, in inches of depth	Erosion rate, in cubic yards per square mile	Condition of water-shed	Precipitation, in inches of depth	Maximum run-off, in cubic feet per second per square mile	Erosion, in cubic yards per square mile
Bell No. 3......	0.097	3 500	33	500*	Burned in 1919	11.8	34	62

[26] "Experiments with Critical Depth Flumes for Measurement of Flow in Débris-Laden Streams", by H. G. Wilm, J. S. Cotton, and H. C. Storey, California Forest and Range Experiment Station, presented at the Pacific Coast Meeting of the Am. Geophysical Union (Section of Hydrology), at the California Inst. of Technology, Pasadena, Calif., February 1, 1936.

Loss of soil by erosion in the burned area shown in Fig. 16 approached 100 000 cu yd per sq mile. The inter-shrub spaces proceeded to form gullies almost unhindered, because of the wide spacing between burned shrubs, their slow sprouting, and the sparseness of ground-cover vegetation between the shrub clumps. Ground-cover plants are lacking because the soil-stored seeds which might have escaped burning, were subsequently washed down the slope by sheet erosion.

The unburned water-sheds cited in Table 16(*a*) may be considered too small to be significant. Erosion measurements for large unburned water-sheds are not available, but run-off records from such water-sheds for the great storm clearly reflect a regulatory influence of vegetative cover similar to that on the small water-sheds (see Table 17). The run-off rates from these water-sheds, lying in the same mountain range as the burned area, receiving the same or heavier rainfall, and having similar geologic structure and topography, nevertheless yielded peak run-off only one-tenth (or less) as high as that from the burned area. The logical deduction that the controlled run-off from the forest-covered areas could have produced proportionately little erosion is substantiated by the fact that the water, observed during the storm, was almost clear of suspended matter.

TABLE 17.—RUN-OFF FROM LARGE UNBURNED WATER-SHEDS, STORM OF JANUARY 1, 1934

Water-shed	Area, in square miles	Rainfall, total, in inches	Run-off, in cubic feet per second per square mile
Arroyo Seco	16.4	11 to 17*	58
Eaton	6.5	13.8	51
Big Santa Anita	10.5	13 to 19*	54
San Dimas	18.3	10.8†	53

* Range of catchment in various rain-gauges.

† Catchment determined by statistical analysis of the catch in 150 rain-gauges distributed over the area.

As a means of reducing sheet erosion from burned water-sheds, the Forest Service has adopted from agriculture the idea of sowing a quick cover-crop and has found the lowly mustard to be the plant best suited to the purpose. The cost per acre, when sown by hand at the rate of 5 lb of seed per acre, averages $1.25. Inaccessible country is sown by airplane at $0.90 per acre, but the work is dangerous and the seed distribution is likely to be irregular. Quantitative data on the soil-holding effects are not yet available, but Fig. 17 shows a typical mustard stand, six months after sowing, in which the mustard with a density of 6 plants per sq ft, has filled the inter-shrub spaces with soil-binding roots, while the tops protect the soil from driving rain and wind. The oven-dry weight of mustard plants, returned as protective litter to the burned soils, ranges from 2 000 to 6 000 lb per acre the first year, and the seed production by this first crop is from 200 to 1 500 lb per acre. It is expected that the mustard will ultimately be crowded out by the recovery of the chaparral. At that stage there is a remote possibility that sufficient seed may remain stored in the soil for many years to produce a protective cover-crop after some future fire.

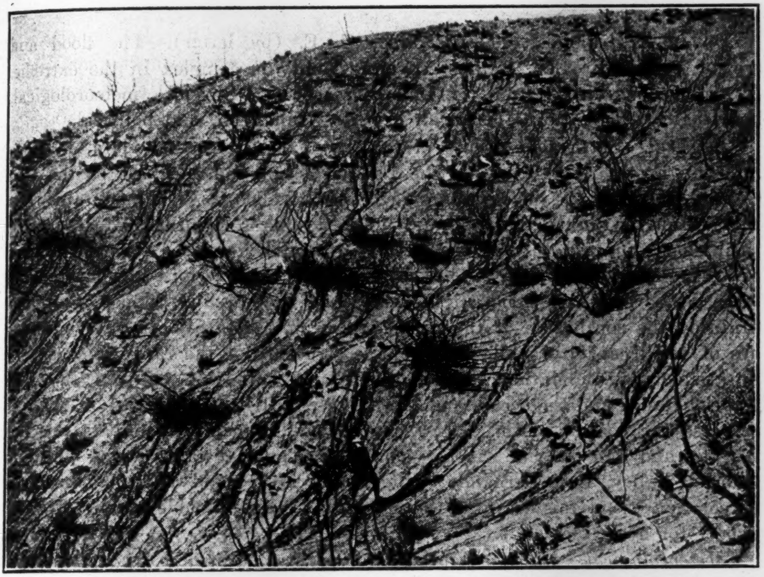

FIG. 16.—LOSS OF SOIL BY EROSION IN BURNED AREA (PHOTOGRAPHED SECOND WINTER AFTER FIRE) APPROACHED 100 000 CUBIC YARDS PER SQUARE MILE.

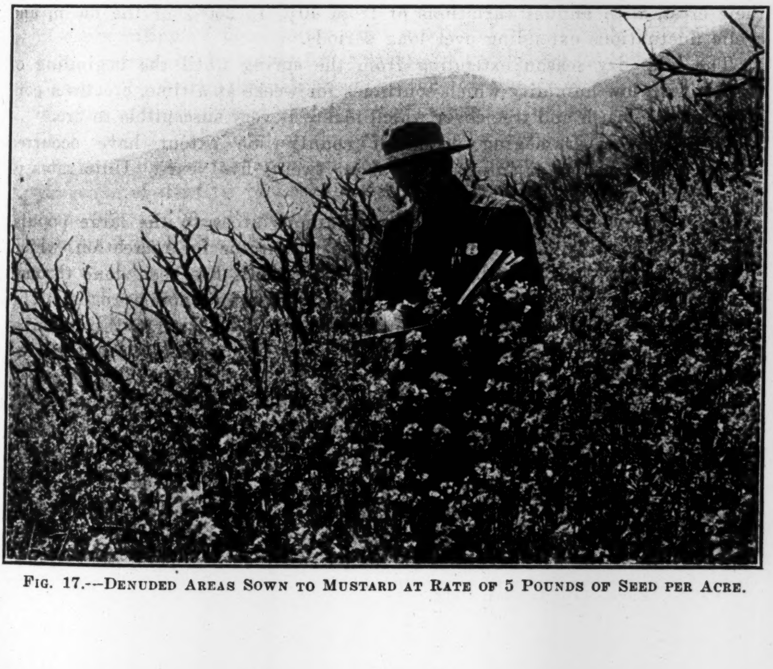

FIG. 17.—DENUDED AREAS SOWN TO MUSTARD AT RATE OF 5 POUNDS OF SEED PER ACRE.

DONALD M. BAKER,[27] M. AM. SOC. C. E. (by letter).—The flood and erosion control problem in Los Angeles County is complex in the extreme. It may be considered from the following aspects: Physical, meteorological, hydrological, recreational, cultural, historical, financial, and political.

Physical.—Settlement occurs principally upon the coastal plain, 1 000 sq miles in extent, lying between the Pacific Ocean and the base of the San Gabriel Range, where the elevation reaches about 1 000 ft. The mountains then rise abruptly within a short distance to elevations of from 6 000 to 10 000 ft, their slopes covered with a deep soil, easily eroded, which supports a cover of heavy brush and timber. This cover constitutes a serious fire hazard, and when destroyed, heavy flood run-off and débris flows result. Slopes of streams draining the south side of the range are steep, and available reservoir sites are of small capacity, while the geologic structure of the range affords very unsatisfactory foundation conditions. About half way between the San Gabriel Range and the ocean, and extending parallel to it, a series of low hills traverse the coastal plain, with two openings, through which pass the Los Angeles and San Gabriel Rivers. Three large ground-water basins—the San Gabriel Valley, San Fernando Valley, and the coastal plain—supplied by percolation of streams draining the mountains, form valuable sources of water supply for overlying lands.

Meteorological.—Mean precipitation, concentrated principally in the period from December to March, inclusive, increases from 10 to 12 in. near the ocean to 20 to 25 in. at the base of the mountains, and to 35 in, and more at their crest, with annual variations of from 40% to 250% of the mean, and cyclic fluctuations extending over long periods.

The long dry season extending from the spring until the beginning of winter, with low humidity which continues for weeks at a time, creates a condition in the brush and tree cover which makes it very susceptible to fire.

Hydrological.—Damaging floods of county-wide extent have occurred singly, or in groups, at intervals of about twenty-five years. Unit rates of run-off from such floods are high.

Recreational.—Proximity of the mountainous areas to the large population on the coastal plain invites use of the mountains for recreation, which, in turn, requires that they be made accessible. This has been done through the construction of many trails and, recently, of automobile roads. This enhanced accessibility has greatly increased the fire hazard with its threat of removing protective brush cover, and many serious fires have occurred, which have further added to the flood run-off and erosion.

Cultural.—The population of the coastal plain has increased from 500 000 in 1916, when the last major flood occurred, to about 2 250 000 in 1936, or 350 per cent. Mr. Eaton's estimate that only 8% of the present population has experienced or has a realization of a major flood is evidence of the difficulty met in obtaining public interest in the problem. Much settlement and development have taken place on areas subject to flood menace without an appreciation of the menace either on the part of the developers, settlers, or of public officials. The average population density of the area is in excess of 2 000 persons per sq mile, and high values of land and improvements exist, many of such values occurring in areas subject to flood menace.

---

[27] Cons. Engr., Los Angeles, Calif.

Historical.—Local attention was focused upon flood-control problems following the 1914 flood, the first to cause serious damage. Major floods occurring previous to that date, in the 1880–90 decade, although greater in magnitude than those of 1914 and 1916, caused far less damage because of the relatively small population and the lack of intensive development. Following 1914, a flood-control district was formed, embracing practically the entire County south of the mountains. The plan of flood control first adopted consisted primarily of channel rectifications and improvement with little attention given to water conservation. A bond issue of about $4 500 000 was voted in 1917 to carry out this plan.

The great increase in population occurring in the 1920–30 decade focused attention upon the need for conservation of local water supplies, and, in 1924, a plan, hastily conceived and prepared without adequate hydrologic and other data, was devised for which a bond issue of $35 000 000 was voted. In this plan conservation of water was emphasized, the bulk of expenditure being for storage dams in the mountains, foremost of which was a gigantic concrete dam in the San Gabriel Canyon estimated to cost $25 000 000. Some of the smaller dams proposed in this plan were built. The large dam in the San Gabriel Canyon was abandoned, due to poor foundation conditions, and plans for two smaller dams with much less storage capacity were substituted. With the advent of a bountiful supply of water from the Colorado River, interest in conservation of flood water has waned, and the present construction program, amounting to nearly $20 000 000 and carried on by the Corps of Engineers, U. S. Army, through the assistance of a large Federal grant, is again directed entirely toward channel rectification and improvement.

Financial.—The cost of the work done by the Flood Control District is met by a district tax upon land and improvements only. Since the assessed valuation of the City of Los Angeles, which is within the District, has ranged from 60% to 70% of that of the entire District, the City has been in the past (and will be in the future) called upon to meet this percentage of the total cost of the program, except that done under Federal grant. Except for some channel improvement in the Los Angeles River and the Pacoima and Tujunga Dams, the bulk of the money spent for construction work has been on structures and projects outside the city limits, although under the present program involving Federal aid, a considerable portion of the funds are allocated to projects within the City of Los Angeles. The latter has a very serious stormwater problem within its boundaries, and until a few years ago it had made large annual expenditures for the construction of storm drains, the costs being raised by local assessment.

Political.—The Board of Supervisors of Los Angeles County acts as the legislative body of the Los Angeles County Flood Control District, and various other County officials, such as the Assessor, Tax Collector, Auditor, County Counsel, also act for the District. The latter has its own engineering personnel which, however, since the District is a separate political entity, is not subject to County Civil Service regulations. This form of organization, originally proposed in the interest of economy, has not been satisfactory, as flood-control administration and policy have been submerged in general County issues, and popular opinion has not found an opportunity to express itself on flood control alone.

Proper control measures group themselves into the following:

(1) Water-shed management, including the preservation of existing vegetal cover, renewal of destroyed cover, and prevention of erosion;

(2) Disposition or conservation of flood waters (or both disposition and conservation), including construction of regulation and storage reservoirs, spreading works, and flood channels; and,

(3) Control of land utilization in flood-menaced areas, including the reservation of land for reservoir and channel easements and the control of land utilization and improvement in menaced areas.

Recently, much excellent work has been accomplished by Federal and County forestry agencies in water-shed management. Motor roads to afford accessibility for fire-fighting have been constructed, and equipment and organization for such fighting have been provided. Work is progressing in restoration of burnt-over areas and in prevention of erosion from bare slopes. An extensive program for collecting basic hydrologic data, lacking at the time previous plans were made and bond issues voted, has been under way for some years past.

An attempt was made in the 1935 Session of the State Legislature to amend the Flood Control Act, creating for the Flood Control District a legislative body separate from the County Board of Supervisors, providing for the preparation and adoption of a comprehensive plan of flood control before any further construction work was done, and placing the personnel of the District's staff under civil service. Although such revision had the hearty support of all civic bodies interested in the subject, political opposition in certain quarters prevented its accomplishment.

Widespread differences of opinion exist among those hoping to benefit by the conservation features of the District's activities as to the title to the water which will be developed by such features, and until this subject is settled and a policy adopted governing the utilization of such water, a threat of extensive litigation will continue.

Nothing so far has been done toward the control of land utilization in flood-menaced areas, although it would appear that, once such areas were designated after proper study and investigation, legal authority probably exists to prevent such development and utilization through regulation of the sub-division of land by the planning commissions of the County and of the various cities within the District.

Neither has any accomplishment been had in the development of a comprehensive plan of flood and erosion control for the District in which all the various phases and aspects of the problem—regulation, conservation, land use, and financing—are considered and co-ordinated. Until such a comprehensive plan has been developed and adopted and the opportunistic and drifting policy which has characterized past efforts to solve the problem has been abandoned, future occurrence of events which are related by the author of this paper may be expected.

E. Courtlandt Eaton,[28] M. Am. Soc. C. E. (by letter).—Mr. Pickett states correctly that fire-prevention methods on water-sheds are the cheapest and best insurance against the débris menace. Next in order of economy are provisions for quick access to incipient fires and provisions for adequate supplies of water to assist the fire fighters. The quantity of water required is not large since modern "fog nozzles", or high-pressure nozzles creating a fine spray as a protection to men and to increase the humidity locally, have been found to be very effective. In line with the plan advanced by Mr. Pickett, it has been proposed to build submerged and covered concrete tanks in the mountains at accessible locations which may be filled from rainfall, by collector channels, or by adjacent paved areas, in readiness for the fighting of possible fires during a succeeding dry season. As stated by Mr. Pickett, limited appropriations have prevented fulfillment of these plans.

If measures for prevention and suppression fail, débris basins must be resorted to as the last line of defense at costs which may reach capital expenditures as great as $150 000 per sq. mile of water-shed.

Mr. Davenport mentions the accepted procedure, in determining annual run-off quantities, of considering run-off as a residual after subtracting evaporation, transpiration, and other losses. This method is entirely proper, of course, where the primary purpose is to establish a relation between rainfall and run-off, and are particularly applicable to localities where rainfall is less flashy in character and water-sheds are not so subject to physical changes as is the case in Los Angeles County.

Under Los Angeles County weather and physical conditions a given quantity of rainfall in a season may produce widely varying amounts of run-off, depending upon the intensities and the previous condition of saturation of the water-shed, and detail study of daily and hourly precipitation must be made. In the studies of Big Tujunga water-shed the problem was mainly that of arriving at the regulating capacity required and the expected peak flows during the critical 4-day period rather than to determine the seasonal run-off. Table 5, therefore, is merely a general and preliminary study based upon the indices of seasonal wetness method and was used as a guide in the selection of a critical season for detailed analysis. It is possible that the total run-off for that season, under normal water-shed conditions, would be close to 250 000 acre-ft. However, there are historical records indicating that the water-shed had not fully recovered from a previous fire so that the actual run-off may have been even greater than that shown in Table 5. Since all historical and rainfall records pointed to 1884 as the year of major flood in a 50-yr period, that year was selected for detailed analysis.

The details of the method used in computing the 4-day peak flows are too long for reproduction herein, but in brief the procedure included: (1) The measurement by planimeter, of sub-areas from a map similar to Fig. 5; (2) the distance from the point of delivery to the next succeeding point down stream was measured and the channel slope computed; (3) times of concentration were determined for the sub-areas; and (4) a coefficient of run-off was selected for the average typical soil and cover characteristics as determined by field investigations.

---

[28] Cons. Engr., Los Angeles, Calif.

The flow was then computed from the rational expression, $Q = C\ I\ A$, in which Q = run-off, in cubic feet per second; C = coefficient of run-off; I = average intensity of rainfall during the time of concentration of the sub-areas, in inches per hour; and, A = area of sub-area, in acres.

The relation between the daily peaks in the maximum 4-day flood period was derived from co-related studies of the San Gabriel River water-shed on which there are considerably longer rainfall and run-off records than on the Big Tujunga water-shed.

Mr. Jarvis states that the conditions in Los Angeles County are extreme and that the County has a combination of physical features and high property values not commonly met elsewhere. The writer agrees. Nevertheless, similar erosion problems to a lesser degree exist elsewhere in the West although, fortunately, high concentration of population and property values do not as yet lie within the paths of débris flows.

Mr. Blaney mentions the excellent experimental work done by Mr. Mitchelson, of the U. S. Bureau of Agricultural Engineering, from which much valuable information has been obtained. The relatively high rates of percolation obtained by Mr. Mitchelson as compared with those of the writer in Table 12 are attributable to the relatively clear water available for Mr. Mitchelson's experiments. The percolation rates given by the writer are in the main those during receding flood-flow periods when the water was cloudy. Were it possible, in spreading operations, to count upon handling a reasonably clear stream flow the "basin" method of spreading could be used at a considerable saving in land costs and spreading works. Under conditions where the water carries considerable suspended matter, the ditch system, in the writer's judgment, is preferable.

Mr. Rowe infers that the coincidence of a heavy rain following a fire is remote. The writer cannot agree. A storm of high intensity, coming any time within a 3-yr, or more, regrowth period after a fire will cause a débris flow; in fact, a second high-intensity storm within that period may produce even a greater débris flow than occurred with the first storm due to the previously loosened water-shed condition. Mr. Rowe mentions check dams as a possible indirect source of some of the débris. A thorough study made of the canyons immediately following the débris flows does not support his theory. Mr. Rowe also attributes a portion of the débris flow in Haines Canyon débris basin to the operation of a gravel pit which formed the nucleous of the aforementioned basin. This theory is borne out neither by the examinations made of the water-shed to trace the sources of débris, nor by the analyses of débris in the basin, much of which consisted of earth and top-soil originating from water-shed slopes.

Mr. Lippincott mentions one of the difficulties under which the Los Angeles County Flood Control District has labored. Although there are in the District's files and on file as public records, many complete reports containing valuable engineering data, legal restrictions have prevented the financing of their reproduction for general distribution and a lack of general knowledge other than that contained in the daily press has resulted.

Mr. Lippincott mentions the publication of a "Rainfall and Runoff Report, Seasons 1932–33 and 1933–34." In fairness to previous administrations many rainfall data were obtained extending back almost as far as the formation of the District and complete rainfall-run-off reports in the aforementioned form, have been issued each year since 1927.

Mr. Lippincott draws a comparison in Table 15 between the four dams of highest unit cost of the twelve constructed by the District. The average cost of all dams built by the District has been about \$200 per acre-ft, ranging from \$35 to \$1 300 per acre-ft. The average is equivalent to about 13 cents per cu yd of débris capacity.

Undoubtedly, dams, even at the highest cost mentioned, are more economical than débris basins. However, dam sites are limited and the débris basin takes its place where no adequate dam sites are available.

Incidentally, considering flood control and conservation features, a statement of cost per acre-foot of storage capacity alone is not indicative of flood-regulating values, since the reservoirs may regulate in a single season amounts three to four times their nominal storage capacity and the conservation or hold-over storage features are present in the underground basins fed by the regulated flows.

Messrs. Kotok and Kraebel have mentioned the work being done under their direction by the California Forest and Range Experiment Station of the U. S. Forest Service. From their results will be obtained invaluable quantitative data that will furnish a basis for future planning of remedial and preventive measures. The writer agrees that his value of 1 500 cu yd of débris per sq mile annually from unburned water-sheds may be high.

Fig. 15 shows graphically the difficulty in estimating rates of débris from the high-water mark, *A*, and taking the cross-section, *C*, after the recession of the flood. The section at the time of maximum flow might be at any place between *B* and *A*.

Mr. Baker mentions the difficulty in obtaining public interest in flood-protection problems. Fundamentally, the Flood-Control Act itself is responsible. Under the Act, the members of the County Board of Supervisors, only a fraction of whose time can be given to flood-control matters, act as directors without additional salary for that service. Furthermore, the Act provides that the County Counsel, County Auditor, and County Purchasing Agent act in their several capacities for the District without additional compensation for this service. Each of these reports directly to the Board of Supervisors. Thus, there is no semblance of centralized control or responsibility. This condition, in conjunction with the failure to finance, legally, the general dissemination of reports and information, or the lack of legal authority to finance a public relations bureau, has placed the District in a defensive position.

Although only partly completed as a completely connected unit, the works built thus far have safeguarded thousands of lives and have prevented, and are preventing, destruction to property that might otherwise mount to sums several times the expenditures made for protection.

Incidentally, a Comprehensive Plan Report was issued by the District in 1931, drawing attention to the menaced areas and outlining needed protective works. As stated by Mr. Baker attempts to amend the Flood Control Act have so far been unsuccessful.

THE RELATION OF ANALYSIS TO STRUCTURAL DESIGN

By Hardy Cross[1], M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Mensch, Russell C. Brinker, Marshall G. Findley, I. K. Silverman, Bruce G. Johnston, Harold E. Wessman, N. M. Newmark, L. E. Grinter, F. P. Shearwood, and Hardy Cross.

Synopsis

Confusion sometimes exists in structural design as to the use to be made of analyses. The designer soon realizes that precision is futile in some cases and important in others, and the experienced designer realizes fully that analysis of the conventional type is frequently a poor guide to proper proportions. That analysis shows a certain member to be overstressed commonly indicates that the member should be made larger; but the over-stress sometimes has little importance and may be disregarded. In some cases where the over-stress is serious, the best solution is not obvious; sometimes the structural layout should be changed entirely.

Critical study soon leads to recognition of important differences between load-carrying stresses and stresses which produce no appreciable resistance to the applied loads. The latter may be due either to external movement of abutments or to internal distortions, or they may be due to deformation induced in one part of a structure as a result of that in another part. The load-carrying stresses may also be divided into two groups. The distinction in this case, however, is based upon response to changes in design; these sub-groups are not always clearly distinguishable, but they have characteristics so widely different in certain cases as to force their differentiation.

A classification is presented herein, with the idea of suggesting a convenient arrangement of certain familiar characteristics rather than with any wish to define the groups formally. The designations suggested, therefore,

---

Note.—Presented at the meeting of the Structural Division, New York, N. Y., on January 17, 1935, and published in October, 1935, *Preceedings*

[1] Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

are for convenience of reference only. The non-load-carrying stresses will be distinguished as Deformation Stresses and Participation Stresses; and the load-carrying stresses as those normal in their characteristics and those which are hybrid.

Deformation stresses are a consequence of strain and strain is a consequence of internal or external movements not due to stress in the structure, such as abutment movements, shrinkage, or the effects of temperature change.

Participation stresses are similar to deformation stresses, but they are due to a quite different cause. They include what are known as "secondary stresses" in bridge trusses and "participation stresses" in bracing systems as special cases. The designation is used herein for want of a better one, but the term is used in a wider sense than usual.

The primary action of most structures is such that the stress in any one part is independent, or nearly independent, of that of the other parts. This is termed normal, structural action. The group indicated includes all structures statically determined and, for good reasons, it includes also most of the forms of indeterminate structure that experience has shown to be useful.

There is a type of structure in which one member cannot be designed separately but must be designed with due consideration for its effect on other members. Such action is referred to as "hybrid," because it has some of the characteristics both of normal structural action and of participation action. The group of structures seems to be quite large and to have characteristics of great importance to designers.

Although the designations assigned herein may be new, the concepts involved are not new. What the writer wishes to do is to classify and arrange certain views of structural design which have an honored tradition in American practice. The paper is not intended to be quantitative, except in so far as quantitative statements may help in defining qualitative action. The classification proposed has some value in reconciling discordant views held by practical designers and those held by theoretical analysts, and seems, further, to have value in reconciling conflicting views held by theoretical students in the field. It is also of value in anticipating the characteristics of proposed structural types.

I.—Types of Structural Action

Deformation Stresses.—The outstanding characteristic of deformation stresses is that the strains in the structure are fixed and that the stresses are deduced from the strains. The stresses themselves are not fixed at all, but depend entirely upon the stress-strain relation of the material.

Another important characteristic is that strength has nothing, or practically nothing, to do with the problem. The strains are fixed by the over-all dimensions of the structure and by the amount of deformation to be accounted for. The designer finds it convenient to predetermine such strains, reduce them to equivalent stresses, and deduct these stresses from the working stresses available for load-carrying capacity.

Participation Stresses.—This term is used to include what are commonly known as secondary stresses in bridge trusses, participation stresses in bracing systems, participation stresses in cross-frames due to unequal deflection of trusses or girders, cross-flexure in the vertical members of trusses, secondary flexure in slender columns of bents, secondary flexure in slender spandrel columns of open spandrel arches, and secondary flexure in slender columns of buildings.

Participation stresses have many of the characteristics of deformation stresses: The strain is fixed; the stress is a consequence of the strain; and the strain, in general, can be affected in an important way only by changing over-all dimensions and not by changing the strength of the member. Thus, it is generally known that increasing the moment of inertia without changing the depth of truss members will affect the secondary stresses only as the primary stresses are affected.

Another important characteristic of these stresses is that they do not increase in proportion to the load up to rupture, but increase less rapidly after the yield point of the material has been passed. They are then clearly somewhat less dangerous than primary load-carrying stresses.

The interest of the designer in these secondary stresses is not to determine their value exactly but rather to be sure that this value is not too high. In order to find what value is too high, it is not sufficient to approach the problem from the analytical viewpoint. The values permissible in design vary with the material used, with the importance of the member involved, and with the type of failure that would result. At present, secondary stresses are accepted as a necessary evil. Try to keep them within a reasonable figure, and otherwise forget about them. Any effort to change this viewpoint represents a radical departure in thinking in the field of structural design. (In 1934, a valuable paper on the "Effect of Secondary Stresses Upon Ultimate Strength," was presented[2] by John I. Parcel, M. Am. Soc. C. E., and Eldred B. Murer, Jun. Am. Soc. C. E. Surely, the idea of discounting secondary stresses is not new in America; but accurate data as to the amount that may be discounted are much needed.)

An important difference between participation stress and deformation stress lies in their relation to the properties of the material. The two are affected in the same way by departures from Hooke's law for, in both cases, it is the strain that is fixed, the stress being a consequence of the strain. In so far as the ratio of stress to strain, however, changes with time (time flow of concrete) the effect is pronounced and direct in the case of deformation stresses, whereas time flow as distinguished from plastic flow has no effect at all in the case of participation stresses because, although the stress for a given participation strain is less as time goes on, the strain itself is in the same ratio greater because of flow under primary stress.

---

[2] See p. 289.

If the participation strain is linear, as in the case of cross-bracing, the designer can control the stress only by changing the length of the member, which usually means that he cannot control it at all. If the strain is angular, the designer can control the maximum participation stress by changing the length of the member (which is usually impracticable), by changing the depth in the plane of flexure, and, to some extent, by changing the form or variation of section along the member.

Participation stresses are dangerous to the extent that they impair the primary load-carrying capacity of the member. Any generalization about them that does not consider the nature of failure from primary load is misleading.

Normal Structural Action.—The term is used herein to describe the action of those structures or structural parts in which it is possible to determine at the beginning the approximate magnitude of the forces in action, and in which the magnitude of these forces is affected comparatively little by the relative stress intensity in the parts of the structure.

The most obvious example is the ordinary statically determinate structure. In this type primary stress in one member is not affected at all by the stresses in any other member. All stresses are determined directly by statics, and the members are then proportioned for the forces which act upon them.

Most of the classical forms of indeterminate structures act normally, although their action is less definite than for structures statically determinate. A good example is the ordinary continuous truss, which, in practice, is often designed at once without any exact analysis being made after the design is complete. The experienced designer knows that for these structures such analyses will not indicate any important changes in his design.

Other examples are ribbed arches and spandrel-braced arches of steel, the so-called "rigid frame" bridges hinged at footings so far as the forces and moments at the knee are concerned. Most cases of continuous girders are included in this type.

In these structures it is possible to follow the procedure recommended in the textbooks. The engineer is told to guess at the sections, analyze, revise, and re-analyze. A bad first guess does not make much difference; the series of designs converges rapidly. In these cases, however, the designer can do much better than a bad first guess. Preliminary studies of pressure lines and of the properties of influence lines will enable him to make a good first guess—so good that the revision is trivial.

Hybrid Structural Action.—The term is used herein to mean structural action in which two or more parts participate in carrying loads to such an extent that if the strength of one part is changed the forces acting on other parts are largely affected. Clearly, there is some interaction in all indeterminate structures; the difference here indicated between normal and hybrid action is one of degree, and the two classes merge into each other. Participation stresses also are directly affected by changes in the primary stresses, but the relation is not reciprocal.

Hybrid structural action may be divided into two classes from the viewpoint of the designer's knowledge: Those in which the nature of the structural action can be foreseen; and those in which it cannot be foreseen. This says nothing except that the designer either does or does not know what he is doing; but the distinction needs to be made.

This type of action may be further divided into two classes, depending on whether the structure can or cannot be designed efficiently as laid out. It is very important to know this at once, but the knowledge depends on the designer's understanding of the problem.

A very simple example of what herein is called hybrid structural action occurs where two parallel beams are connected so that their center deflections must be the same under a single load at the center. If they are of the same span, depth, and material, they share the load in proportion to their strengths, and load can be assigned to one or the other at will. Even if the spans are different, this is still true if the depth-length ratio is the same for the two beams.

In this case the designer can foresee the action. He then designs as he chooses and knows that the stresses will be as assumed without further analysis; the analysis precedes any designing. Moreover, the structure can be designed efficiently since the stresses in the two beams will be the same. If the depth-length ratio is different for the two beams, however, they cannot be designed efficiently. No matter what the designer does, the relative stresses will be proportional to this ratio; but he can still foresee this fact. This case is simple; frequently the action of the structure is not easily predetermined and, in many cases, the efficiency of the design must be considered for several conditions of loading.

Near the center of long trusses having two diagonals in each panel, the designer may predetermine the stress intensities in these diagonals pretty accurately. In any panel the stress intensities in the diagonals are in inverse ratio to the squares of the lengths of these diagonals if there is no stress in the posts and if the stress intensities in the chords are equal and opposite. For dead load, these conditions in chords and posts are nearly fulfilled; for isolated loads, they are only approximately correct.

Knowing this and considering for the present only dead load, the designer can assign areas to the diagonals at will. If the chords are parallel, the diagonals can be designed efficiently; if the chords are not parallel, one diagonal must be inefficient. Influence lines may be helpful, but they fail to furnish at once a very illuminating picture of the essential structural action. For single concentrated loads the effect of the stresses in the posts and of unequal stresses in the chords may be pronounced. If single moving concentrated loads dominate the design, exact proportioning seems hopeless.

In these cases—parallel beams and double diagonals—the textbook recommendation to guess at a section, analyze, and re-design, to convergence will not work very well. If the layout is efficient, analysis will show the first guess to be right—and will show any guess to be right—but if it is inefficient, repetition of analysis and design will eliminate the inefficient member—after many repetitions—and result in a simpler structure.

Similarly, the king post truss cannot be designed for given working stresses in beam and sag rods except for a small range of the ratio of beam depth to sag depth, which ratio can be predetermined. The chief interest in the king post truss is that, goemetrically, it is so obviously the familiar problem of a truss subjected to secondary stresses. Looking at the truss from this viewpoint, the engineer would first design it; then he would reduce the depth of the beam until the secondary stress in it was within safe limits, or he could, by adjusting the sag rods, produce initial stresses to offset the secondaries. If, however, he attempts to utilize these secondaries, to put them to work in carrying the load, an entirely different structural problem is presented, and new methods of study are required.

Hybrid structural action also occurs in the queen post truss, in systems of intersecting beams, in Vierendeel girders, probably in most slabs (at least where variation of depth is involved), in some problems of continuous beams, and in many problems of continuous frames. It is discussed subsequently, in the case of bents, of rectangular wind frames, and of arches integral with their spandrel structures.

Study of a Two-Legged Bent Illustrating the Types of Structural Action.—The distinctions herein presented are well illustrated by studies of a two-legged bent carrying vertical loads. It is assumed that the members are rectangular and homogeneous. It is proposed to study the flexural stresses in the columns. The girder section is assumed to be the same throughout the discussion but first the depth, and then the width, of the column is varied.

If the column is very narrow the girder acts practically as a beam simply supported. The rotation of the top of the column must be the same as that of the end of the girder. The angular strain in the column, therefore, is fixed, and the flexural stress varies almost directly with the depth. If the column is extremely rigid it takes nearly the full fixed-end moment in the girder and the flexural stress varies nearly inversely as the square of the column depth. Between these conditions is one in which the flexural stress in the column is nearly independent of the depth; the column is picking up moment as fast as it can take it.

If the width of the column is increased, it will be found that in the first stage (column slender) the flexural stress in the column is scarcely affected at all; in the last stage (column stiff) this stress varies inversely as the width; and in the transition stage, the increase in width reduces the flexural stress somewhat but not at all in proportion to the increase in strength.

The first stage represents a structure essentially statically determined (post and lintel or column and beam), but with participation stresses in the columns. When the column becomes very stiff the structure—so far as the columns are concerned—is normal in its action, the stresses in the columns being determined for a fairly definite moment. In the transition stage the structural action is hybrid and does not respond readily to ordinary design procedure; increase in depth may either increase or decrease the flexural stress or leave it unchanged; and increase in width (which amounts to increase in moment of inertia) produces comparatively little effect.

Deformation stresses would be produced in this structure by change of temperature. As the depth of column is increased, the deformation stresses at the top of the column would vary at first almost directly as this depth, but later would be relieved by flexure of the girder.

Perhaps the most important fact revealed in this case is that if the flexural stresses indicated in the hybrid stage are dangerously high, there does not seem to be very much that can be done effectively, as long as the girder section is constant. This column may be thrown from the hybrid stage into the normal stage of action, however, by reducing the stiffness of the girder. In the rigid-frame bridge this is done by reducing the center depth of the girder.

II.—General Remarks on Hybrid Structural Action

It is difficult to identify hybrid action in an unfamiliar structural type, but after one has come to recognize the type he begins early to suspect its existence in certain cases. Probably the chief identifying characteristic of the type is that it responds sluggishly or erratically to traditional methods of structural design. Successive cycles of design and analysis may indicate a trend, but produce only slowly a definite and satisfactory conclusion. If there are discontinuities in this design procedure the traditional process may be quite misleading.

Traditional processes are not very helpful in this field, although they still have their place. In these cases there are usually many variables and the curves of variation present maxima and minima. It should not be necessary to point out to scientific men the extreme difficulty—the grave danger—of applying purely empirical methods to such problems. It is impossible, in such a case, to generalize or extrapolate beyond the range of data presented and it is almost impossible to classify the data for study no matter how numerous these data are, unless such arrangement is based on an adequate theory.

It makes a good deal of difference what the designer wants to do. Where the action is normal for given proportions, there is usually only one answer and that is easily approximated at once and easily determined accurately by cut and try. Where the action is hybrid there are many possible structures; the designer must make his choice. In a sense he tells the structure what he wants it to do, and the structure will try to do it. If, however, it is something that the structure cannot do at all, the designer has erred; if it is something that the structure cannot do efficiently, the design is penalized. To apply the more erudite terminology of mechanics to this conception, the fiber stresses desired may involve incompatible strains.

This type of structural action is often best approached from a direct study of the fiber stresses. H. V. Spurr, M. Am. Soc. C. E., has done this in his wind-frame studies,[3] and, without discussing herein whether his method of design is necessary, sufficient, or invariably satisfactory, the writer feels that his contribution to the direct method of attack is of great value.

---

[3] "Wind Bracing", by H. V. Spurr, McGraw-Hill Book Co., 1930.

Rigid-Frame Bent Subject to Vertical Loads.—Consider a bent of the so-called rigid-frame type sometimes used for building frames consisting of a roof girder, curved or polygonal, carried by two columns. The pressure line for dead load in this structure may lie anywhere between that for a simple curved beam supported on columns and that for a three-hinged arch (hinges at the center of the girder and at the bases of the columns).

The action of the structure may be studied by either of two methods. Choose some pressure line which is expected to give a good distribution of material, determine the moments for this pressure line, and then vary the moment of inertia along the section so as to satisfy the conditions of continuity. The depths of the sections may then be varied by choice. By this method the designer tells the moments where he wants them and then decides whether he likes the result.

As an alternative procedure which has some advantage, he chooses the desired pressure line, selects working stresses along this line, and then varies the depths to provide the requisite conditions of continuity. This requires judgment, but may be done quite well by eye. The moments of inertia may then be determined for these moments, stresses, and depths. The important fact is that the design may be predetermined—and predetermined over a wide range.

If at three points of the structure the moments of inertia are intentionally reduced compared with the sections elsewhere, the structure now becomes a normal structure (a three-hinged arch) with participation stresses at the weakened sections, which now act as hinges.

Rectangular Wind Frames.—The problem of analyzing rectangular frames for horizontal forces due to wind or to earthquake accelerations continues to occupy an important place in structural literature. It seems particularly illuminating to discuss the problem from the viewpoint proposed herein. It is assumed that the columns have been designed for vertical loads and that their sections will not be changed; discussion, then, is directed entirely to the design of the girders. The effect of offsets is not considered.

It is not intended to discuss the participation stresses induced in the girders of upper floors by departures from planarity at floor levels. The writer's studies indicate that the problem is neither so important nor so difficult as some have indicated.

Assume that the girders have been designed by some of the conventional methods. An analysis is now made and it is found that some girders are overstressed and some under-stressed. Tradition indicates re-design by increasing the size of the overstressed girder and decreasing that of the girder understressed. However, analysis will show in many cases practically the same stresses as before; in other cases, it may show a slight improvement in the stress distribution which will be further improved by repeated re-design to a certain point; but numerous cycles of re-design may be necessary to produce much improvement.

The girders of a symmetrical rectangular frame, carrying horizontal loads, may be designed on the following assumptions: (*a*) Points of inflection are at the mid-points of all members; (*b*) column shears are proportional to moments of inertia of columns; and (*c*) design stresses in girders are proportional to depth-length ratios of girders. If so designed, it will act as designed except near the fixed base. The analysis precedes and dictates the design; after design, no analysis is needed.

If points of inflection in the columns and distributions of column shears are assumed throughout the building, the designer can, by working from irrotational footings, determine relative stiffness, or K-values for the girders all the way up the building. Negative values for K would indicate impossible assumptions and positive values of K might be unsatisfactory because, for a given working stress, too deep a girder would be indicated or, for a given depth, too great a fiber stress would result.

The object is not to recommend this method of design, although it has value, but rather to indicate that as an alternative to the procedure, now popular, of assuming a structure and, by analysis, determining the stresses in it, presumably with a view to re-design, the designer may predetermine the function that the bracing is to perform, design directly, and then see whether the design is satisfactory as regards girder depths or working stresses. Of the two procedures, the second is often the more satisfactory. Each method is useful for certain purposes.

Note that the sensitiveness of the procedure depends upon the relative stiffness of columns and girders. If the columns are very stiff relative to the girders the moments can be applied almost anywhere without disturbing the desirable condition of inflection points very near the mid-points of the girders; the moments in the girders will be proportional to their K-values.

It seems futile to ask which of several conventional methods of analysis most nearly conforms to the results of so-called exact analysis; the answer depends on the proportions of the structure. Special attention is directed, therefore, to the dangers of induction from specific data whether obtained by computation, from models, or from tests in a laboratory, unless the range of the data covers all variables.

Arches Integral with Their Spandrel Structures.—An important example of hybrid structural action occurs in arches that are integral with their spandrel construction. It has long been recognized that there is interaction of the rib and the spandrels, but such interaction is commonly neglected in design.

In special cases applying to such structures, the engineer can see certain controlling relations. If the columns of an arch having open spandrels are quite flexible and very closely spaced, angular changes along the arch rib must be the same as those along the deck girder, since the vertical deflections of the two are every where the same. In this case, then, the entire structure could be designed at once as an arch made up of two members placed side by side as in a flitch beam. The relative flexural stresses in the rib and deck can be predicted and may be controlled by varying their relative depths.

Clearly, in this case, the designer may put all flexural resistance in the rib, or in the deck girder; or he may divide this flexural resistance between the two members at will; arches have been built of all three types—a stiff arch without stiffening girder; a flexible arch with stiffening girder; and a stiff arch reinforced with a stiffening girder. Of course, in any case, there must be some flexural resistance in the flexible member and some flexural resistance in the columns. These, however, will have the well-defined characteristics of participation stresses.

If the columns are not closely spaced the simplicity of the picture is marred both because the flitch-beam picture is less simple and also because the deck girder now has primary stresses as a continuous beam.

As the columns become quite stiff, however, the picture becomes very complicated. Such a structure is clearly hybrid in its action and the nature of the inter-relations is not at once apparent. Methods of studying such cases have been developed by Nathan M. Newmark, Jun. Am. Soc. C. E.[4]

It is important to question whether it is good practice to change from normal structural action with participation stresses to hybrid action with obvious reduction in the factor of safety of the rib, with little promise of economy, and with much complication and uncertainty in design. There is little, if any, evidence that the participation stresses in these structures are dangerous or even objectionable. The idea of putting secondary stresses to work is not usually very promising.

III.—General Remarks on Indeterminacy

Thirty-four years ago Mr. Frank H. Cilley presented a paper under the title "The Exact Design of Statically Indeterminate Frameworks. An Exposition of Its Possibility but Futility."[5] The main thesis was that "statical indetermination in a structure is always to be regarded as self-interference with efficiency." The paper followed a previous paper by the same author,[6] and revived a discussion of long standing as to the relative advantages of determinate and indeterminate systems. Two discussions of the paper were presented by distinguished American engineers and several by foreign engineers.

There is little question that Mr. Cilley's views represented those of many, and probably of a large majority, of the leading American structural engineers of his day. To-day, on the other hand, literature contains numerous articles extolling the virtues of indeterminacy and some writers even go so far as to attribute to indeterminate structures virtues which appear to be contradictory. They are referred to as "reservoirs of resilience," their rigidity is praised, as are their economy and their strength.

Since 1900, many indeterminate steel trusses have been built in America with claims, apparently well supported, of considerable economy. More important still, a new material—concrete—which is more conveniently made continuous, has come into general use.

The rather awkward methods of analysis current at the beginning of this century undoubtedly delayed the development of continuous structural types.

---

[4] Some phases of Mr. Newmark's extensive studies are reported in "Interaction Between Rib and Superstructure in Concrete Arch Bridges", by Nathan M. Newmark, Jun. Am. Soc. C. E. Thesis presented to the University of Illinois in 1934, in partial fulfillment of the requirement for the degree of the Doctor of Philosophy.

[5] *Transactions*, Am. Soc. C. E., Vol. XLIII (1900), p. 353.

[6] "Some Fundamental Propositions Relating to the Design of Frameworks", by Frank H. Cilley, *Technology Quarterly*, June, 1897.

At that time the analysis of some of the more complicated types now proposed was impracticable. The profession has made progress in this field. It may be well now to divert the attention of structural designers from the endless elaboration of analytical technique to the more important matter of interpretation of analyses.

It appears that Mr. Cilley's paper was directed too much to a consideration of what is herein termed hybrid structural action. The degree of self-interference in normal structures is quite negligible. Each normal indeterminate structure usually has a determinate analogue in comparison with which it has certain virtues and which has certain virtues in comparison with it. No generalization is possible, but the indeterminate structure has won consideration and is often indicated.

Structures in which hybrid action predominates are also sometimes indicated. If their action can be clearly foreseen and if they are designed for one controlling load condition, they may be designed economically. Often they are indicated for reasons entirely apart from structural efficiency, as in the case of rectangular wind-bracing; but where their action cannot be clearly visualized, conventional procedures of analysis by computation or by model may furnish little help.

IV.—Concluding Remarks

The paper has indicated four types of structural action the characteristics of which make their separate discussion worth while. These are (*a*) the action that produces deformation stresses; (*b*) that which produces participation stresses; (*c*) normal structural action; and (*d*) hybrid structural action. Deformation stresses and participation stresses have many characteristics in common, but are essentially different in cause and sometimes in action. Hybrid structural action represents a transition stage between participation stress and normal structural action.

Deformation stresses cannot be avoided except by avoiding the deformation that produces them. They may be slightly modified so that a little more strain takes place at one point and a little less at another, but about the same total strain—angular or linear— will inevitably occur. Linear strain due to angular strain may be reduced by decreasing the depth.

The designer's interest in participation stresses is that they shall not be too high; he does not want their exact values. If they are too high, he changes either the over-all dimensions or the details of construction. What is "too high" will always remain a matter of judgment. In normal structural types only is the traditional procedure, of first computing the forces and then designing for them, applicable.

Hybrid structures may be designed in many ways. In order that analysis may guide to design, it should precede design so that the designer may see in what ways the structure can act. Then, in a quite literal sense, he tells it how to act and makes it act in that way. The difficulty is that he may blunder in trying to have it act in a way in which it cannot possibly act or that, of the many ways in which it can act, he chooses an inefficient one.

Structures characterized by hybrid action are difficult to design and are often inefficient in any case. Study of them is made difficult by the inadequacy of traditional methods; it is almost hopeless, and may be dangerous, to study them by emprical methods.

Generalizations as to relative advantages of determinate and indeterminate systems are difficult in any case. Some conflicting opinions in the literature may be reconciled by recognizing the distinction indicated.

DISCUSSION

L. J. Mensch,[7] M. Am. Soc. C. E. (by letter).—The gradual increase in scientific observations of engineering structures has led to an increasing attention to details of theory. The normal action, or what may be more correctly termed the idealized action, of structures as described and taught by engineering textbooks occurs rarely, and very often other influences cause deformation and participation stresses that becloud the issues in actual practice.

A good illustration of this point is afforded by tests made by Dr. F. von Emperger on a large number of girders for the Austrian Concrete Committee.[8] In Fig. 1, (*a*) represents girders loosely supported on brick walls; (*b*) represents girders well embedded in brick walls; (*c*) represents girders with brackets loosely supported on brick walls; and (*d*) represents girders with brackets well embedded in brick walls. All girders had the same span of about 13 ft, all had the same cross-section of $6\frac{1}{2}$ by $8\frac{1}{2}$ in., and the same reinforcement, except that some beams had brackets at the ends, as shown. Girders (*c*) failed at 75% more load than Girders (*a*), although according to the normal action as defined by textbooks the ultimate strength should have been the same. Girders (*b*) failed at 250% more load than Girders (*a*); and Girders (*d*) failed at 575% more load than Girders (*a*). The participation stresses as classified by Professor Cross were of a favorable nature in this case.

A similar effect was observed[9] by the writer in 1934 when having tests made on dowels connecting concrete blocks, as shown in Fig. 2. The stresses in the dowels at ultimate load, when computed by the formula, $s = \frac{P\,a}{2}$, were from 150 000 to more than 200 000 lb per sq in. As the re-rolled steel was probably of less strength than 100 000 lb per sq in., the effect of the friction at the supports was to increase the strength of the dowels 100 per cent. Both favorable and unfavorable participation and deformation stresses are found in concrete pavements, due to friction on the subgrade. Friction causes the concrete to crack when the pavement shortens, due to temperature and moisture variation, but when a concentrated load deforms the under side of the slab, the friction causes a moment of opposite direction to the moment of the concentrated load.

[8] "Mitteilungen über Versuche". Heft IV. 1913.

[9] "Joints for Concrete Pavements", by L. J. Mensch, 1935, p. 33.

A very thorough investigation of a similar nature may be found in the report of the French Committee on Reinforced Concrete[10] The Committee tested to destruction, a reinforced concrete floor of the Science and Art Building of the Paris Exhibition of 1900. As shown in Fig. 3, the girders were of 23-ft span, placed 10 ft on centers; they were connected by small beams of 6 by 8-in. stems, and covered by a 4-in. slab. Concentrated loads of from 10 000 to 42 000 lb were pulled on a small truck in the center line of the building, and the deformation and deflection of one girder were observed when the concentrated load was at various distances from the longitudinal axis of the girder under observation. At a distance of the concentrated load from the girder of 30 ft, 20 ft, and 10 ft, the deflection of the girder was 1%, 10%, and 47% of the deflection observed when the concentrated load was exactly over the girder, and the Committee concluded from its many observations that the stresses produced in the last case were 50% of those of a single girder, disconnected from the adjoining girders.

One can readily infer from these examples that secondary stresses often help the structures to carry higher loads, and so-called inventors have often misled the public by taking advantage of this fact.

The writer cannot agree with Professor Cross that the post and lintel structure is a statically determinate system. The lintel will bend under load and throw the upper inside edges of the posts into heavy compression, thus producing an eccentricity of the load on the posts for nearly one-half their depth. As a consequence, the columns may and may not bend sufficiently to produce at the top an inclination equal to the rotation of the lintel at the ends and thereby offer an even bearing to the lintel. The analysis of such a system has been given by the writer elsewhere[11].

All properly designed bents with either slender or stiff columns may be classified as good engineering if they can be defended on architectural or economical grounds. One may consider all deformation and participation stresses, the deflections of the girders and columns, the flow of concrete due to dead weight, the flow of concrete due to the interaction of concrete and steel during shrinkage, temperature effects, active and passive earth pressure, and possible movements of the abutments. Nevertheless, to make a structure lasting and free from serious blemish, there is still lacking a very important point to the beginner, and this is practical experience and critical observation of existing, similar structures.

In ordinary reinforced building construction engineers are accustomed to design the highly indeterminate girders and slabs by the bending moment formulas: $M = \frac{wL^2}{8}$; $M = \frac{wL^2}{10}$; $M = \frac{wL^2}{12}$; and $M = \frac{wL^2}{16}$, as given by the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete[12]. This Joint Committee did not give any rules for determining the bending moment on inside columns, and, therefore, many engineers believe that it is good practice to omit them from consideration. Exponents of scientific analysis of indeterminate structures may object to such formulas, violating as they do every rule of continuity and compatibility. They may object, furthermore, on the ground that such formulas do not seem to be based on logical reasoning; if they were logical, the coefficients would be different for dead load and for live load and would depend on the relative stiffness of the adjoining members. It is a fact, however, that only in rare cases (especially when there are very large differences of spans in the adjoining members) will a so-called exact analysis make a great change in the moments at the supports and the moments in the center of the girders will be found considerably smaller than those given by the Joint Committee. No great harm is done when the girders are made stronger than necessary in the central section and the adoption of these formulas has saved hundreds of millions of dollars to building owners. The introduction of this type of formula is to the credit of F. Hennebique, and dates from 1894. Structural steel engineers did not have such a leader and they are not in the habit of reducing the bending moment in girders of skeleton buildings from the moment of a freely supported girder.

---

[10] "Experiences, Rapports", etc., 1907.

[11] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1682.

Unless similar simple formulas are offered to engineers for the design of statically indeterminate structures such as those with two or more legged bents, rigid frame, and continuous bridges, old and new types of arched bridges, and single and multiple-arched bents for roof constructions, the writer is convinced that no truly great progress will be made in this field in the United States. The writer has seen designs of that nature which cost considerably more than statically determinate structures. Collections of such formulas have appeared in handbooks in Europe and represent the labors of many conscientious workers, but they need much elaboration before American engineers will have sufficient confidence to use them often. The fact that only uniform sections are used for the various members works against their use for long spans; deflections are not given; proper details and examples are presented only sparingly and theoretical spans instead of clear spans are used in order to facilitate the computations. The work of A. Strassner, published more than twenty years ago, marks a great progress as it shows how to deal with members of varying sections. It marked the first attempt at improvement; it is still very theoretical, and the assumptions and the tables still contain errors. These tables have been used by American engineers for the construction of tables of other coefficients; the latter may contain additional errors and caution is necessary in using them.

Such a handbook as the writer has in mind cannot be written by a single expert or a college professor and his most capable assistants, but must be the work of a great many experts and their associates, and each problem must be investigated by at least four men, working, independently, in groups of two. There is no question but that the solution of statically indeterminate structures requires much tedious work. The most skillful mathematician is likely to make many errors, but two men working together can save time and avoid most errors. At present, only two methods are known for the solution of statically indeterminate structures: The mathematical theory of elasticity and the mechanical solution by apparatus such as those of Professor Beggs, Gottschalk, Nubupest, and others. The mathematical theory of elasticity states neither more nor less than that: Every particle of the interior of a body must be in equilibrium; every particle of the boundary surface must be in equilibrium; stress must be compatible with strain in every point; and, of course, the entire body must be in equilibrium under the action of the loads and other forces such as reactions and surface tensions (frictions and shear from adjoining bodies). It is practically impossible to solve the simplest case of a structural member according to the strict theory, and simplifications are necessary. A particle is in equilibrium when the sum of the components of all forces (stresses) acting on this particle parallel to the X, Y, and Z axes are zero. One simplification most often used is to disregard the stresses parallel to the Y and Z-axes and to confine the investigation to the stresses parallel to the X-axis, which may be assumed to be in the longitudinal direction of the member. Another simplification which is often necessary is to investigate the stresses or conditions of equilibrium at only one or two sections of the member, and to hope and believe that nothing of a dangerous nature will happen in other sections or directions which are not investigated according to the rules of elasticity. A good example is Clapeyron's theory of continuous girders. Clapeyron established the conditions of equilibrium at sections over the supports by making the stresses parallel to the direction of the girder on both sides of the section equal and of opposite direction. In Professor Cross' language he established the principle of continuity, but committed the inexcusable error of not considering the stresses due to the width of the support, which error changes the result by 20% in most cases.

---

[12] *Proceedings*, Am. Soc. C. E., October, 1924, Papers and Discussions, p. 1153.

In the traditional treatment of a fixed arch, the conditions of statical and elastic equilibrium are generally applied to only one section, and most easily to one abutment. The arch is considered as a cantilever fixed at the other abutment, and, under the assumed loading, the other abutment which is being investigated is assumed to deflect horizontally a distance, h, and vertically a distance, v; and it is assumed to rotate through an angle, b. The problem is find the horizontal force, H, the vertical force, V, and the moment, M_a that would cause the deflections, h and v, and the rotation, b, to vanish. In order to find H, V, and M_a, the cantilever is treated as a common girder and the horizontal and vertical deflections and the rotation of the free end abutment are computed for the loads and the unknown forces H, V, and M_a. Then, the so-called elastic equations are formed by: Equating the sum of all horizontal deflections to zero; equating the sum of all vertical deflections to zero; and equating the sum of all rotations of the end to zero.

Not many careful tests have been made to establish how correct the designer is when he uses the formulas for the deflection and rotation of a straight girder of uniform section for the computation of the deflections and rotations of girders of curvilinear form with markedly varying section, knees-braces, or other irregularities. In extreme cases the error is probably of the order of 25 per cent. The identical equations can be obtained by the theory of least work, by the principle of virtual velocities, or by Maxwell's equations. The latter are simply rules for obtaining deflections and rotations; intrinsically they are not more scientific than the foregoing procedure and do not imply an "exact" theory of elasticity.

There are many methods of obtaining the deflections: By arithmetical summation, by integration, by the moment-area method, the slope-deflection method, and the shear-area method, to name only a few. These methods are not new theories of elasticity as some writers would like to have them called, but are more or less cumbersome methods of finding deflections. New methods are re-invented by every new generation of engineers in the desperate search for finding the nearly impossible—a simple method of computing deflections. Statically indeterminate structures would be used more often and more scientifically and would be much better understood if only one method had been taught in the last seventy years, and if that method had been thoroughly elaborated. The many methods described recently in literature are only a confusion to engineers.

In order to shorten the analysis of typical structures, engineers have computed the deflection and rotation of certain points on these structures for unit loads placed at various positions and have presented the results of their labors in the form of diagrams and tables, which are not yet simple enough to be of great use.

In the case of highly indeterminate systems with hybrid action, as termed by Professor Cross, such as trusses with double diagonals, skeleton girder and column constructions, and series of curved roof bents, the designer must deviate still further from the teachings of the theory of elasticity before he can find a way to analyze the structure. He must make new guesses or assumptions, and one of the oldest and best is that of Saint-Venant, who assumed that the local disturbance caused by a load at a particular point (or member) dies out at a short distance from the point of application. This guess, rule, or principle (some even call it a theory), when applied to a girder of a skeleton building, can be expressed as follows: Consider the girder to be analyzed as connected only to the adjoining spans and columns, the next adjoining spans and stories being considered as having no influence on the girder. The far ends of the adjoining girders and columns may be considered fixed or rotated at an angle suitable to the case. The surprisingly simple results were given by the writer many years ago.[11]

The mathematical difficulties imposed by the exact theory of elasticity (and very often by its simplified form) being insuperable, the analysis of most statically indeterminate structures is beyond the realm of science and becomes an art, in which experience, skill, imagination, guesses, and hypotheses, often of obscure origin, play a greater rôle than calculus, and where charlatans may run riot and false prophets may shine to the utter confusion of the student. A properly conceived handbook would elevate the art, which is still at a very low ebb.

RUSSELL C. BRINKER,[13] JUN. AM. SOC. C. E. (by letter).—A logical classification of the types of structural action and the stresses producing the different types is presented in this paper. Further emphasis might easily be placed upon the question of when secondary stresses may or may not be lightly neglected. The "dishing out" of floor-beam webs and the cracking of stringer-connection angles on some old railway bridges give evidence of secondary stress effects neglected in their designs.

The factor of safety, or more often the "factor of ignorance", allowed in the spread between the specification stresses and the elastic limit in steel bridge design to cover secondary stress and other effects could be put on a more rational basis if the secondary stresses were given greater consideration. Members having low percentages of secondary stresses compared to their primaries, are heavily penalized by giving them the same basic allowable unit stress as those members having high percentages. The fact that the secondary stresses have little effect on the ultimate strength of members does not mean that they should be allowed to produce greatly unbalanced total stresses below the elastic limit because this is the range of usefulness of most structural members. Truly more data on the question of when—or how—to discount these secondaries are needed.

Much refinement in analysis has been made in the decade, 1925–1935, but needed improvements in specifications covering unit stresses appear to have received little attention. It is obvious, that analysis is directly tied up with design stresses, as is the question of details (which is also somewhat behind in progress). In 1923 there was considerable discussion as to the validity of the unit stresses being proposed in specifications for railway bridges[14]. Many prominent engineers looked with disfavor upon the policy of using the same low unit stress for dead load as is used for live load to cover future increases, uncertain impact, etc., but little was accomplished. It is to be hoped that, delving into the types of stresses involved in structural action, Professor Cross will also revive interest in how to evaluate them in terms of more applicable design stresses.

MARSHALL G. FINDLEY,[15] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper Professor Cross has made a notable contribution to the literature of structural design. The problem discussed is not one of detail method, but of general balance, of plan of action, and of criteria for determining the choice of method. It might almost be said that the author presents a pragmatic conception of structural design. The problem involved needs discussion. So much literature of structural analysis has arisen that any one supervising design work is continuously faced with the need for decisions as to how far to go in the use of analytical methods. There is no question but that, on the one hand, certain practical problems are analyzed by mathematics too completely and too well. On the other hand, other problems are too little analyzed—solved too much by rule-of-thumb methods. Only rarely is analysis checked by common sense so as to keep it within bounds while making full use of its possibilities. The personal element complicates the practical problem, one designer enjoying the mathematics of theory too much, while another relies too much on experience, which may be imperfect and misleading.

[13] Easton, Pa.

[14] *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), pp. 532 *et seq.*

[15] Structural Engr., Water Purification Plant, City Engr.'s Office, Milwaukee, Wis.

The term, "hybrid", as used by Professor Cross, however, is very unfortunate. The writer refuses to use this term, and will use instead "monolithic" as being more appropriate. The criticism is that monolithic action is natural and fundamental in some structures, whereas the term, "hybrid", suggests that it is a combination of two types of action. Professor Cross has recognized that the basic nature of monolithic action is his method of moment distribution, wherein every computation starts by assuming perfect fixation at each end of each member. At the same time, the use of this inappropriate term, "hybrid", seems to be bound up with a fundamental misconception. In general, scarcely a structure has been built in which true and natural action is not in some sense "hybrid". It would be impossible to avoid the design of structures that do not somewhere, or in some manner, deserve this term of opprobrium. The real point at issue is not whether "hybrid" structures can or cannot be avoided; it is rather how best to take account of actual monolithic action and its effects.

The criticism of this term is only incidental, of course; but in order to clarify the misunderstanding that it suggests, and also to lead the way to an examination of certain detail problems, the writer presents first some general considerations. These thoughts are partly a development of ideas expressed in Professor Cross' paper—one concerning the need of reconciling discordant views held by practical designers and by theoretical analysts; the other that the designer often tells a structure what to do, and then must see to it that it can do it efficiently. Professor Cross makes a division and then pays very little attention to deformation stresses, to participation stresses, or to so-called normal structural action. He stresses the increasing importance of monolithic action, and in this point all will agree. It is because of this increasing importance that structural analysis is becoming more widely used and, at the same time, more complex.

Two Conceptions of Structural Analysis.—Structural analysis is often considered an exact science. The aim under this conception is to secure an exact picture, by means of computation or of graphic analysis, of action of the beam or structure under stress; of its deflection at each point; of its tension, compression, or shear at this point; or of its dangers of cracking, twisting, or crushing, etc. This conception is very commendable within limits, but its limits are narrow. Only beams simply supported, simple continuous beams, deep trusses, simple frames, and a few other structures can be analyzed in this complete and thorough manner; and, usually, these structures will not be so analyzed for a practical reason—that is, the lack of time. Where such complete analysis is possible, imagination and experience usually make most of it unnecessary.

A larger conception of analysis must be sought, partly on account of current lack of knowledge, and partly on account of one's inordinate ambition to build complex things and to meet complex situations. Columns—simple and compound, flat-slab systems, complex frames, and various other structures that cannot be completely analyzed at present—must be designed. Design cannot wait for perfect analysis; as a matter of fact, it never has done so. Design has always led the way for analysis. Properly understood, design requires the larger conception of analysis. Analysis is no longer a complete and exhaustive prophecy of stresses and deformations. Instead, it must be relied upon as a basis of rational comparison whereby complex and unusual conditions may be assimilated to simple and ordinary conditions.

As a matter of fact, the actual progress of structural analysis is such that even approximate prophecy of action in many structures is impossible. Especially is this the case where pressures against, or produced by, earth are involved. No one knows exactly what happens in a complex footing or in a wharf bulkhead. Only on the larger conception of design is it reasonable to use mathematical analysis in connection with such structures. Analysis is then a guide to rational comparison between a proposed design and an existing structure somewhat similar. Such structures include columns, footings, flat-slab floor systems, steel and timber sheet-piling, and monolithic frames of concrete. The computation is a guide to design, but cannot be considered exact prophecy.

This larger conception of analysis, as the basis of comparative design, as the rational method of transfer of experience from shorter spans to longer spans, from narrow panels to wider panels, from light loads to heavy loads, from static forces to moving forces, etc., needs discussion and elaboration. The outmoded prejudice against indeterminate frameworks, still often expressed verbally, is clearly a consequence of the conception of analysis as exact prophecy. The current interest in frame analysis, in shrinkage and secondary stresses, and in soil mechanics, is a sign that the conception of analysis as a basis of rational comparison is in the ascendency. This interest sometimes leads to the assumption of impossible tasks, with resultant discouragement. Perhaps a discussion of certain definite problems, from the broader point of view, criticizing methods in the light of purposes, may be of some benefit.

The Simple Beam.—The outstanding case of "normal structural action" is perhaps the beam of one span simply supported at each end. In this case when loads are given, shear and moment and deflection diagrams can be drawn quickly, and, superficially considered, prophecy of action might be considered quite definite. Theoretically, however, prophecy is not at all exact, and even practically there may be some question.

The fundamental assumption of beam theory, that a plane section before bending remains plane after bending, is only approximately true. In a rectangular metal section, it might be quite accurate, but in steel I-beams or channels, in timber with its grain and flaws, and in reinforced concrete with its two different materials, this assumption is only justified by the practical need for it. Shear computations are very rough. Even in a homogeneous rectangular section, it is necessary to use an approximation to estimate the relation of maximum unit shear to average unit shear. Furthermore, deflection computations usually neglect shear deformation entirely, whereas in some types of beams it is of greater magnitude than moment deformation; that is, even in a simple beam all the computations for shear, moment, and deflection are based on assumptions which are usually approximately true, but which, in exceptional cases, may be very far from the truth.

This fundamental assumption of beam theory is only supposed to hold true when no stresses exceed the elastic limit of the materials. This elastic limit is itself a more or less uncertain value, more variable in some materials than in others. Hooke's law of elasticity, that stress varies as strain, may become invalid in particular cases for various reasons, such as: (1) Overloading a member; (2) heterogeneity of a material (as in timber); or (3) a gradual departure from the straight-line ratio (as in concrete).

Certain practical conditions may also arise where the difficulty is more serious. Consider particularly the matter of lateral stiffness. Girders carrying rails across track hoppers, for instance, require more attention to lateral bracing than to routine moment and shear computations. From the designer's point of view the lateral forces acting are due to chance and cannot be estimated except empirically. Cross-bracing or diaphragms introduced to stiffen such girders make them "hybrid" structures, which must act monolithically. In an ordinary floor the beams are braced at their top flanges by the slab. That this occurs is recognized in practical design by certain rule-of-thumb devices (cross-bracing, tie-rods, top cross-bars, etc.). The effect of these devices is to make a "hybrid" structure of even ordinary floors.

Thus, in general, even the simplest types of structure may exist under conditions that make them complex in action, and unsafe to design as by "normal structural action". Eccentric loads, the mechanics of buckling, and the relation between shear and tension, are not very well understood in fundamental theory, and must be dealt with by constant watchfulness on the part of the practical designer. "Hybrid" action which must be taken into account in some manner exists in many unsuspected details. With this warning in mind, moment, shear, and deflection diagrams serve as very satisfactory guides for the design of simple beams. However, they are only approximations. Materials do not conform thoroughly to the assumptions of design, even in the most favorable cases. Lack of homogeneity in material may result in eccentricity and, therefore, in so-called "hybrid" action, where the assumptions are practically perfect in every other element, and the designer must be on the lookout for such possibilities, even in the simplest cases.

Even a strut or tie designed for axial stress only presents many uncertainties when examined inch by inch (who knows the exact details of internal stresses in a tension member around the rivet holes, for instance?); so that, in general, in plain tension or compression members, as well as in simple beams, there are uncertainties of fundamental assumption, uncertainties of homogeneity, uncertainties of rigidity, uncertainties of local stress, and uncertainties of perfect elasticity which make the theoretical part of the design very imperfect, considered as exact prophecy. In this case a generalization may be made. Even in the simplest cases, theoretical structural analysis may be considered successful only when, and because, it is a guide to safe, economical, and efficient design.

The Long Column.—The foregoing uncertainties apply to complex structures just as surely as to simple structures; but there are also other uncertainties of many kinds. One of these uncertainties appears in the case of the long column. Briefly, the best method of analysis seems to be an indirect one; namely, the selection of a section such that under chance small eccentricity, the tendency to bend does not increase with time. Other methods of analyzing long columns are not truly methods of analysis, but rather methods of empirical design.

In this case the rational purpose of design is that chance deformation stresses shall be controlled so that they do not essentially tend to increase with time. Here, clearly, if one small part of a column is weakened unduly, the result will be to throw enormous stresses into other parts of the column. Returning to the Cross definition of hybrid action, then, one may conclude that any long column is a "hybrid" structure, which, of course, is simply another way of stating that prophecy is difficult, as regards the exact action of a long column.

The Monolithic Frame.—The uncertainty of prophecy is complicated by an entirely different type of difficulty in the case of the monolithic frame. Assume for the present that all external forces are definite, known, and static (which is rarely the case, as, for instance, on a track culvert). The argument as to whether clear opening or center distance shall be used for each span will perhaps never be decided finally. Theoretically—that is from the point of view of prophecy—this is a very vital question. If one decision is made, end moments and shears will be computed, which are very large and which cannot possibly develop; and, consequently, the ends of the moment and shear diagrams must be adjusted or neglected. If the other decision is made, the question must be more or less arbitrarily settled as to the treatment of certain axial and eccentric forces acting on frame walls.

Practically, this question is not such a serious one, but only because the point of view of prophecy must necessarily be abandoned. Whichever decision as to method he makes, the designer follows that method through various structures, and learns what adjustments to make in order to obtain a satisfactory design. His analysis is of value as a basis of comparison, not as a prophecy. Enough structures of the kind have been designed, built, and tested to serve as a starting point for the comparison.

Deformation Stresses in Concrete.—Setting, shrinkage, and temperature changes normally affect all concrete structures; ordinarily, of course, the object is to distribute deformations, assigning them by definite joints to definite locations.

In certain cases, however, such changes cause participation stresses, thereby approaching "hybrid" action. Such a case arose in the design of certain structures for the Water Purification Plant, at Milwaukee, Wis. In this case, water-tightness requires continuity of certain walls and slabs, whereas the fact that certain slabs frame into a wall at different elevations means that temperature changes in the slabs will throw bending stresses of considerable magnitude into this wall. Only by a systematic comparison of some kind between temperature deformations in these slabs, and unit-moment deformations in the wall, can the resulting moment in the wall be determined. The stiffer the wall, the greater will be the resistance to temperature deformations, and the greater the moment in the wall and the tensile stress in the slab.

The principle involved, that of comparison of deformations, of course, is fundamentally the principle of all monolithic action. All methods of indeterminate structural analysis, whether graphic or algebraic, whether based on conjugate joints or the slope-deflection principle or the theory of least work, are methods of discovering distributions of stresses for which certain deformations are equal and consistent. If the writer understands correctly, Professor Cross looks upon simple and obvious uses of the principle of deformations as cases of "normal structural action", whereas more complex uses of this principle are covered by the term, "hybrid action".

To this point, elements of uncertainty that must be taken into account by structural analysis, even including the so-called "hybrid action", have been discussed; but all the cases examined thus far have assumed known and definite loads acting on the structures in question. Other elements of uncertainty exist, which the writer wishes to include in this discussion, in which external loads are increased or decreased by the action of the structure analyzed. Every designer has analyzed some of these cases, sometimes by guess, sometimes by rough assumption, sometimes by more careful analysis which, however, is always open to question as to its meaning. The writer believes that analysis of these cases is usually practically possible, and, in general, should be undertaken; but such analysis is clearly wasted time and effort if considered as exact prophecy.

Simple Footings.—The assumption commonly made is that earth pressure is uniform over the entire area of the footing (for centered loads) or that it varies uniformly from one corner or side to the opposite one. In the design of footings this assumption is nearly always on the safe side, so it is used very often although known to be erroneous. The more accurate assumption, that intensity of earth pressure varies as the deformation of its surface plane, is difficult to use in many cases, starting as it does with a differential equation of the fourth order. Practically, extreme theoretical accuracy is not required. Consider, for instance, a simple wall footing, with a centered load. The theoretical curve of earth pressures is a sine curve, but a parabola or an ellipse may be used without serious error; that is, the resulting shear and moment curves will be the same for practical purposes. In fact, a straight-line diagram may be drawn, which is also sufficiently close as an approximation.

In more complex cases, with two or more columns on a footing, or the introduction of wind or impact forces, an exact earth pressure diagram becomes practically, although not theoretically, impossible to draw. In some cases, practical approximations for design purposes can be made quite satisfactorily; in other cases apparently no amount of study and discussion will obtain even approximate earth-pressure diagrams, and the designer must analyze the structure by the method of limits, assuming several possible worst cases.

The situation is further complicated, of course, by the difference in action between sand, clay, hardpan, and rock, and by the usual lack of homogeneity in the foundation material. In this case, the essential point is that stress in the footing and stress in the foundation material are related to each other by means of deformation. The stress in each is affected by the capacity of the other to take stress, and not in small degree, but vitally. Thus, the load distribution cannot be known until the design is settled. This is really another type of structural action not included in the paper, and should be given a separate name in generalized discussion. Perhaps the term "reactive" action might be coined for this type of structural action.

The footing is by no means the most complex form of "reactive" action. There are at least two definite forms in which design analyses are being carried on where such "reactive" action exists in more complex form.

Sheet-Piling.—Especially as used in anchored cantilever bulkheads, for quays, and slips, the sheet-pile is loaded by active horizontal forces due to water and earth pressures, and is held in place by the passive resistance of the earth near the bottom, and by an anchorage at the top. The anchorage at the top, in turn, often is held in equilibrium by developing passive earth pressures. Separating the items of loading and of structural action, then, the following items remain to be considered: (1) Water pressure, which is perfectly definite, and can be computed without appreciable error; (2) active earth pressure, which is definite but more difficult to determine exactly, and nevertheless can usually be approximated sufficiently well for practical purposes (like water pressure, this pressure exists independently of the deformation of the movement of piles); (3) passive earth pressure, usually greatest near the bottom of the sheet-pile (in some cases passive earth pressure can be estimated very closely by the conditions of static equilibrium, and, in other cases, it depends on Item (4)); (4) bending action in the sheet-pile, which must be considered because only by deformation or movement can passive pressure be developed; (5) deformation at the top of the pile, due to give of anchorage, axial stress in anchor rods, and bending of wales; and (6) passive pressure developed by the anchorage, which mutually depends upon and affects all these other items.

Theoretical methods have been proposed, which take certain of these items into account. Empirical methods have been used, which take all of them into account, although often by the cut-and-try method. It is clearly a difficult type of analysis, because pressures that can themselves be estimated primarily only by methods of indeterminate structural analysis determine, and in turn are modified by, pressures in which a secondary analysis by means of deformations must be made.

The term, "complex reactive" action, may be applied to this type of action. Design analysis of this type might be considered an attempt at prophecy of action, but as such is certainly not exact.

Roadway Slabs.—An element of contingency enters into the design of tall buildings to allow for lateral resistance in regions subject to hurricanes and earthquakes, or in the selection of sizes for culvert drains in regions subject to heavy rainstorms. The heaviest conceivable winds or earthquakes cannot be resisted economically; and the heaviest rains must be expected to cause floods. First, the designer must decide where to draw the line between high cost and awkward structure on one hand, and greater convenience and economy with less safety on the other.

A similar element of contingency occurs in the design of roadway slabs, in addition to the consideration of moving loads, impact, and "reactive" action. If all sub-grades were compacted perfectly and remained so, there would be little bending stress in any roadway slab. Modern construction methods attempt to produce a perfect sub-grade which will remain perfect. Consequently, although the designer may feel very sure that there will be failures of sub-grade, as a matter of experience, he cannot prophesy where a failure will occur, or how far it will extend. The assumption usually made is that a circular failure of a certain diameter will occur in the sub-grade, and that the slab should be reinforced to carry expected concentrations across such holes, whether central or at the edge of a slab.

In the selection of the diameter of assumed sub-grade failure, the designer is again drawing the line of contingency. In this case design analysis must cope with a third type of "reactive" action which might be termed, "contingent reactive" action. Such design analysis is not prophecy even approximately, but only a basis of comparative design which may be standardized after testing by use.

Criticisms.—After consideration of these rather ordinary cases, it is obvious that Professor Cross' very excellent introduction to the subject needs some modification. He emphasizes two points about which there can be no question, and which are very enlightening and suggestive. The first is the generalization as to participation stresses, which, if not new, is certainly worded effectively, so that deductive reasoning can draw out again from it the fruits of experience which have gone into its formation. The second is the pragmatic conception of design where so-called "hybrid" action exists. Of course, the personal element enters in; nevertheless, it often occurs that the designer "tells a structure what he wants it to do, and the structure will try to do it."

It is because of the characteristic of monolithic and complex structures herein indicated, that safety in structural design can be obtained so often without lengthy theoretical analysis, and with only slight loss in economy. By the method of limiting cases, which is an attempt to prophesy several of the worst conditions that might occur at opposite extremes, it is often possible to design, safely and quickly, a very complex monolithic structure.

The writer has previously criticized the author's use of the term, "hybrid". Now, it seems in place to comment upon another use of words, namely, "normal structural action". This phrase is not so much of a unity as it seems because the author includes in it not only statically determinate structures, but also monolithic structures of varying degrees of complexity, similar only in that the experienced designer can approximate their true action without much study. In other words, design analysis as a method of prophesying actual action is applicable.

Conclusion.—In summary the writer wishes to emphasize several points which have been raised. The first is that "normal structural action" is not a convenient term; even the simplest static action includes many elements of uncertainty. Furthermore, it should be subdivided into static action, and simple monolithic action, which are quite different in their essential nature. "Hybrid" action is perhaps an excellent term for complex indeterminate action when a definite load is divided according to relative stiffnesses of two or more independent or partly independent structures or systems of members.

Certain new classes have been proposed which should be included, resulting in a revision of the classification by Professor Cross, as follows:

I.—Stresses Determined by Strains:
   (*A*) Deformation stresses; and,
   (*B*) Participation stresses.

II.—Types of Action for Supporting Known Superimposed Loads:
   (*C*) Static action;
   (*D*) Simple monolithic action;
   (*E*) Complex frame action;
   (*F*) Hybrid or interactive action; and,
   (*G*) Empirically analyzed action (columns, flat slabs).

III.—Type of Action in Which Loading Is Affected by Action ("Reactive"):
   (*H*) Simple reactive action;
   (*J*) Complex reactive action; and,
   (*K*) Contingent reactive action.

The writer agrees with the author very heartily in his suggestion that further distinctions are needed in the general discussion as to the relative advantages of determinate and indeterminate systems; and hopes that Professor Cross will concur, at least in a general way, with the further distinctions suggested herein.

I. K. SILVERMAN,[16] JUN. AM. SOC. C. E. (by letter).—Character of stress rather than its magnitude is the subject of this paper. Since most of the papers concerning structural analysis appearing in the technical literature of the last ten years have dealt with the technique of stress determination, this paper deserves special attention.

From the author's point of view structural analysis is suggested as a measuring device for efficiency. Thus, if loads were fixed, a statically determinate structure which was built along the pressure line corresponding to the given loads would be as efficient as possible as far as structural action was concerned.

The fundamental assumption made in structural analysis is to the effect that under the action of loads the geometry of the structure remains unchanged as regards span, depth, angles, etc. Under this assumption both statically determinate and indeterminate structures are analyzed for their primary stresses. In the analysis of a statically determinate system it is unnecessary to know the make-up of the members or their physical properties, except to be sure that they are such that deformations caused by the loads do not have an appreciable effect on the dimensions of the structure. It would be difficult, for instance, to determine by ordinary methods the stresses in a structure made of rubber if the loads were such as to cause large deformations. For indeterminate structures with constant moduli of elasticity the make-up of the members must be known since "hybrid" action is present in practically all cases. The writer is acquainted with a truss, continuous over three spans, in which the make-up of the lower chord members adjoining the intermediate piers had a marked effect on the stresses in other members.

[16] Care, U. S. Bureau of Reclamation, Denver, Colo.

The fixed arch, which is a very common structure, exhibits hybrid action (as defined by the author) to a high degree. Under the action of temperature the stresses at the springing are greatly effected by the thickness at the crown. Fig. 4 illustrates the case in which an increase in the depth of the crown of an arch did not necessarily lead to a reduction in unit stress.[17] This structural action is one which ordinarily cannot be predicted. In a circular arch it is found that temperature stresses can be reduced more effectively by increasing the central angle than by changing the strength of the member.

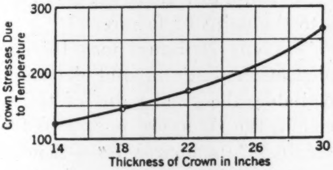

FIG. 4.

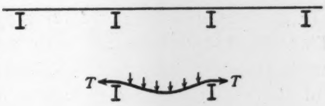

FIG. 5.

A type of action that may be classified under participation stresses, although the stresses produced are load-carrying stresses, is that which is illustrated by the modern suspension bridge in which advantage is taken of the increase in the sag of the cable in computing the maximum cable pull. Another case of the same type of action is shown in Fig. 5 for the continuous plate subjected to a normal load and supported as shown.

A study of the development of structural forms furnishes a fertile field of illustrations of the types of action classified by the author, and the history of the development of these forms illustrates how structural analysis has helped in the production of frames that have primarily normal structural action. A study of this development would be as valuable a part of the curriculum of engineering schools as are those parts which deal with the technique of stress determination.

BRUCE G. JOHNSTON,[18] JUN. AM. SOC. C. E. (by letter).—A logical and concise classification of the factors underlying the relation between structural analysis and design has been presented by the author. The paper deals principally with determinate and indeterminate frames, but the same logical thought applies as well to the study of any structural part, or detail, however small. The "participation stresses", as defined by the author, become somewhat analogous to localized or concentrated stresses in a structural detail, to which increasing attention has been drawn in recent years.

[17] "Design of Symmetrical Concrete Arches", by Charles S. Whitney, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 998.

[18] Instr., Dept. of Civil Eng., Columbia Univ., New York, N. Y.

Every structural element is designed to perform a definite service without failing or deflecting too far under the working load that it carries. Obviously, the safe working load on the structure should be a specified fraction of the load at which the "limit of structural usefulness" is reached. The "limit of structural usefulness" is usually not a function of the maximum stresses alone, although it may be so in special cases. Many studies have been made with regard to theories of failure under combined stress at a point[19], with none as yet generally satisfactory; but the results of such a theory, even if available, would usually have only an indirect relation, if any, to the general failure of any particular type of structure as a whole.

Studies of the stress distribution in a mathematically idealized elastic body present varied and interesting mathematical problems. Although solutions of many of these problems form the basis and historical background of structural analysis, the continued search for new solutions leads often into byways of small practical significance, and the subject of "stresses" may receive disproportionate attention at the expense of a more complete consideration of general structural behavior up to the point of failure.

The "limit of structural usefulness" of any structure may be determined experimentally by plotting the load-deflection diagram and determining, by one of the various arbitrary means available, the yield point of the structure as a unit. If every element of material in the structure is still in the elastic range as the "limit of structural usefulness" is approached—then an exact and complete mathematical analysis gives a close approach to the solution of the particular problem. However, in many types of structures, made wholly or in part of a ductile material such as structural steel, a slight "giving" of the material in local parts often effects a favorable redistribution of stresses. In such cases the local deformations may cause a relatively negligible permanent deflection in the structure as a whole. Although this fact is well known among structural engineers, its importance is sometimes lost sight of by those who may be interested only in elasticity or photo-elasticity. In some cases, however, as exemplified by both the first and second failures in the design and erection of the Quebec Bridge, the neglect of secondary factors caused failure. The conclusion must be that mathematical analysis and engineering judgment are inseparable factors, one without the other being of no great use.

The following outline gives examples of some of the principal zones of elastic, or plastic action within which the limit of structural usefulness may fall:

A.—Limit of structural usefulness reached within, or at the limit of, the elastic range of the material:

(1)—Limited by elastic stresses;
(2)—Limited by elastic deflections; and
(3)—Limited by elastic buckling.

---

[19] "Failure Theories of Materials Subjected to Combined Stresses", by Joseph Marin. Jun. Am. Soc. C. E., see p. 1162.

B.—Limit of structural usefulness not reached until after parts of the structure have passed the elastic limit:

(1)—Plastic yielding localized and not significant;
(2)—Plastic yielding localized at a critical point, leading to failure; and,
(3)—Limited by plastic buckling.

Numerous examples of different structural types may be found to fall under each of the preceding headings.

Both the allowable working load and the limit of structural usefulness may be further conditioned by any of the following:

(1)—The hazard and type of use to which the structure is to be put;
(2)—The type of loading—static, dynamic, repeated, or alternating;
(3)—Physical properties and uniformity of quality of material; and
(4)—Precision of fit and type of fabrication.

Continued research is needed to further the correlation of these factors by studying the entire "load history" of all types and variations of structural elements which are used in current engineering practice. Further development of the theory of elasticity in combination with a consideration of plasticity will greatly increase the effective usefulness of many precise theoretical analyses.

HAROLD E. WESSMAN,[20] ASSOC. M. AM. SOC. C. E. (by letter).—Many readers accustomed to looking for strings of equations and tables of numerical data as earmarks of distinction will fail to realize the value of the structural classification proposed in this extremely important paper. It is well to keep in mind that the paper although qualitative and philosophical in nature, betrays extensive quantitative research of a high order. Such research, involving both analysis and design, must necessarily support the significant conclusions reached by the author.

The inclusion of definite numerical data might confuse or minimize the importance of the basic philosophy. Nevertheless, in view of the conclusions about analysis made by the Committee of the Structural Division, on Wind-Bracing in Steel Buildings[21], the writer hopes that the author will reinforce his remarks on rectangular wind frames by specific examples. In certain types of statically indeterminate structures, analysis and design cannot be considered apart from one another with any assurance of intelligent conclusions. Structures are generally built in accordance with design specifications that impose certain controlling conditions. Moreover, grades, clearances, construction methods, connecting details, and variations in the physical constants of the material, also establish limitations that must be considered in analysis if one wants a structure to act the way it is figured to act.

[20] Assoc. Prof. of Structural Eng. and Mechanics, Coll. of Eng., Univ. of Iowa, Iowa City, Iowa.

[21] *Proceedings*, Am. Soc. C. E., March, 1936, p. 397.

As the author states the concepts involved in his classification of types of structural action are not new. Nevertheless, the profession is greatly indebted to Professor Cross for proposing a logical classification that tends to clarify the relation of analysis to structural design. Regardless of a difference of opinion as to terminology or designation, one cannot help but feel that the author has given structural engineers a "shot in the arm" that will lift many of them out of the rut of conventional thought.

Undoubtedly, experienced designers have sensed the existence of "hybrid" structural action, but for the most part they have had neither the time nor the inclination to go into that phase of analytical research which brings out the full significance of interaction between various units. More often than not the practicing engineer is hurried in the preparation of plans for a definite structure. If computations show that certain members are over-stressed, the tendency is to increase areas or moments of inertia in proportion to the over-stress, without taking time for a final check analysis. This is quite satisfactory if normal structural action emphatically predominates. Unfortunately, many indeterminate structures are of such a nature that a change in area or in moment of inertia of a member also means a change in the load or in the moment resisted by that member.

The writer recalls difficulties encountered in the design of some of the columns supporting the continuous plate-girder viaducts built by the South Park Commissioners over the Illinois Central Railroad tracks along the Lake Front, in Chicago, Ill. The maximum width of the columns in a direction parallel to the longitudinal axis of the bridge was limited by horizontal track clearances established by the Illinois Central Railroad Company. The minimum width was limited by the slenderness ratio for primary compression members in the governing specifications. The columns were rigidly connected to the continuous girders and were subject to dead and live load reaction, dead and live load moment, temperature moment, traction moment, and a transverse wind moment.

A preliminary design section based upon a preliminary analysis was found to be overstressed when all factors were combined. Conventional procedure indicated that more section was needed. The area was increased in proportion to the over-stress, but when a check analysis was made, the column was still overstressed; therefore, the effect of the various factors was then studied separately.

When area was added to the cross-section the unit stress from normal dead load plus live load was decreased; but the unit stress from the bending moment caused by dead load and live load remained practically the same, because increasing the area increased the stiffness, thereby drawing more moment to the column. Moreover, as long as the width of the column was kept constant, the unit stress from temperature moment remained constant regardless of any change in the area of the column. The effect of traction was very small. Decreasing the width of the column was considered. This decrease would have lowered the unit stress, but on the other hand it would also lower the allowable limiting stress because of an increase in slenderness ratio.

Evidently, curves showing the relation between unit stress and area, moment and moment of inertia, or unit stress and width of column, are important aids in selecting the final design. Other relationships may be dictated by the needs of the particular problem.

The author points out the existence of hybrid structural action, particularly in two-legged bents, rectangular wind frames, and reinforced concrete arches integral with their spandrel structures. The writer wishes to add the two-hinged suspension bridge of the usual type (not self-anchored) to the list. It may seem a far cry from a suspension bridge to a flitched beam; nevertheless, the two have much in common.

The cable and the stiffening truss participate in resisting total external bending moment at any section. If an unstiffened cable is used, the external bending moment at any section due to dead load and live load is equilibrated by $(H_w + H)$ $(y + \eta')$, in which $H_w + H$ is the total horizontal component of cable stress and $y + \eta'$ is the total cable ordinate to the deflected cable at the section considered; η' represents the deflection of the unstiffened cable away from normal position. Since the cable itself is flexible, the cable shape must conform to the equilibrium polygon for the load acting on the span.

When a stiffening truss is added to the cable, the deflection, η', at any section is reduced to a value, η, depending upon the stiffness of the truss. If the truss has infinite stiffness, the cable will be forced back through the entire distance, η', to the normal position under dead load and mean temperature. The change in moment at the section is then $(H_w + H)\,\eta'$. To preserve equilibrium at the section, this expression will then be the moment in the stiffening truss—if the truss is infinitely stiff.

For a flexible truss, the cable will be forced back only a part of the distance, η', and the moment in the truss will be some proportion of $(H_w + H)\,\eta'$. If cable stretch and side-span interaction are ignored, the proportion is given by Equation (1):

$$M = \frac{M_t}{M_t + (H_w + H)\,\eta'}\,(H_w + H)\,\eta' \quad \ldots\ldots\ldots\ldots\ldots(1)$$

in which M_t is the moment that would be induced in the stiffening truss if it were bent to the deflection curve of the unstiffened cable. In general terms, M_t is given by Equation (2):

$$M_t = C_1\,E\,I\,\eta' \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

in which C_1 is a constant depending upon loading conditions.

The moment given by Equation (1) does not include the moment in the truss caused by cable stretch from stress and temperature and change in center sag due to side-span interaction. This additional moment is expressed by Equation (3), also in general terms:

$$M = C_2\,\frac{E\,I}{l^2}\,df \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

in which C_2 is a constant depending upon the variation in suspender loading, and df is the change in center sag due to cable stretch from stress and temperature, and to side-span interaction.

From Equations (1) and (3), quite accurate values of the maximum moment in the stiffening truss at the quarter-point and at the center may be found for preliminary design purposes. The derivation and application of these equations are not given in this discussion.

Equation (1), particularly, emphasizes the existence of hybrid action. As the stiffness of the truss is increased, the moment taken by the truss increases. If greater stiffness is obtained by keeping the chord area constant and increasing the depth of the truss, the unit stress may actually increase. This seems paradoxical but computations bear it out. Note what happens to the maximum positive moment in the main span truss of the Manhattan Suspension Bridge when the moment of inertia of the truss is varied.

Fig. 6 shows this graphically. The abscissa labeled, I, corresponds to 43 900 $\text{in}^2\text{-ft}^2$, the equivalent moment of inertia of the main span truss as designed. The corresponding moment is 119 000 000 ft-lb. If the value of I is doubled, the maximum moment increases. On the other hand, if I is halved or quartered, the moment decreases rapidly. The relation is not linear, however.

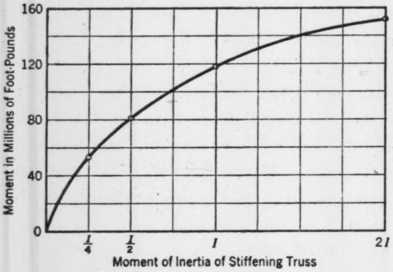

FIG. 6.—RELATION BETWEEN MAXIMUM POSITIVE MOMENT AND MOMENT OF INERTIA OF MAIN SPAN STIFFENING TRUSS OF MANHATTAN BRIDGE.

If the chord areas are kept constant and a variation in I is obtained by changing the depth of the truss, the curve in Fig. 6 may supply the basis for a new curve in which unit stress is plotted as an ordinate and depth of truss as an abscissa; or, depth may be kept constant and a variation in I obtained by varying the area of the cross-section. A curve of unit stress against chord area may then be plotted.

Fig. 6 emphasizes the fact that the most economical stiffening truss is no stiffening truss whatever. What shall be done about local grade changes and curvatures in the roadway, however? The question "stares one in the face"; so a stiffening truss is put on the cable. How stiff shall it be made? What is the limiting grade change or curvature? Who knows? Here is a field for extensive research.

Fig. 6 reveals that there is no one design for the stiffening truss of a suspension bridge. There are any number of possible designs. Conventional analysis fails almost completely as a guide to proper proportions. Studies such as these and the author's "Conclusions" reinforce a growing conviction on the part of the writer that one of the most fertile fields of research in structural engineering is the development of accurate and rapid preliminary design methods. It is most certainly a field that appeals to the practicing engineer.

N. M. Newmark,[22] Jun. Am. Soc. C. E. (by letter).—Perhaps this paper by Professor Cross will serve to divert attention from the elaboration of analytical technique to the development of a technique of design. Certainly the author is to be commended for raising the question of the proper interpretation of analyses and for pointing out a practical and useful philosophy of design. The classification of structural action presented in the paper is the first attempt of which the writer knows to establish a basis for a rational design procedure.

Whether or not the traditional process of structural design is practicable depends on how the forces and moments in a member are affected by revisions of the dimensions of that member and of other members in the structure. For example, a typical relation between strain (angular or linear) and size of member, for a particular member of a given structure under a constant condition of loading, is shown in Fig. 7. Curve (*a*) shows the relation for one set of given constant dimensions of all other members, and Curve (*b*) that for another set.

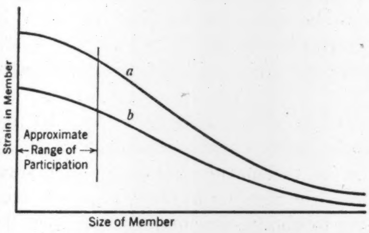

Fig. 7.—Typical Relation Between Size of Member and Strain in Member for Given Condition of Loading and for Two Different Sets of Dimensions of Other Members in the Structure.

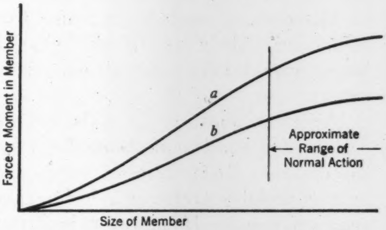

Fig. 8.—Typical Relation Between Size of Member and Forces Acting on Member for Given Condition of Loading and for Two Different Sets of Dimensions of Other Members in the Structure.

In Fig. 8 are shown curves for the relation between total force or moment in the same member under the same conditions as those for which the curves of Fig. 7 were drawn. The approximate ranges of "participation" and of "normal" action are indicated in the diagrams. Action in the intermediate range is characterized as "hybrid" action.

If, for practical variations in other members of the structure, Curves (*a*) and (*b*) are close to each other, the structure as a whole may be considered a "normal" structure; otherwise, it is a "hybrid" structure. The matter of efficiency or inefficiency depends upon whether or not the members in the structure can act together at the desired working stresses. This generally depends on the over-all proportions of the structure as well as on the sizes of the individual members.

For a condition in which the structure is constrained to undergo a fixed deformation, a set of curves somewhat similar to those in Figs. 7 and 8 are obtained, but in general the "deformation" stresses are of a type corresponding to "participation" stresses. The fundamental difference between load stresses and deformation stresses may be stated as follows: For given applied deformations, the strains throughout the structure are independent of the absolute values of the modulus of elasticity; and for given applied loads, the forces in the individual members are independent of the absolute values of the modulus of elasticity.

---

[22] Research Asst. in Civ. Eng., Univ. of Illinois, Urbana, Ill.

Importance of Sources of Stress.—The relative importance of the various sources of stress must be considered in any attempt to revise the proportions of a structure or of its members. As an interesting example consider the case of a filled-spandrel arch bridge. Any effect of the spandrel walls may be ignored since this is purely an illustrative example. In general, dead load is by far the most important source of stress in such a structure. If the arch axis fits the pressure line for dead load, the dead load forces at any section of the barrel are practically independent of the variations in depth of the barrel. The structure is then a "normal" structure for dead loads; it remains "normal" even when the live load effect is considered, since the variation in depth to account for the live load stresses will be fairly small, and the effect of such variation on the maximum total stress will be practically negligible.

However, if such a structure were to be designed for live load only, it would very likely be "hybrid" since a variation in depth in one part of the barrel would effect the stresses in other sections to a fairly considerable extent.

Another question in this connection is worth raising. Consider the design of a continuous beam for relatively heavy concentrated live loads. If the designer limits himself to the choice of prismatic sections in each span, he may possibly arrive at a design in which the maximum fiber stresses in each span are equal. If, however, he attempts to choose proportions such that the maximum stresses at all points in all spans are equal to the design stress, the problem of design, by any existing procedure, becomes almost hopelessly complicated.

Significance of Over-Stress.—The significance of over-stress in a structural member is a matter which has not received as much attention, perhaps, as it deserves. Certainly the literature contains few references to this topic. The author's classification seems to offer a basis for the study of the question. Professor Cross suggests that over-stress due to participation or deformation is not always dangerous. In some hybrid structures, also, over-stress loses its significance when the ultimate strength and nature of failure of the structure are considered, as in the case of the trussed beam discussed subsequently. Apparently, a great opportunity is available in this field for experimental research.

The classification offers a convenient method of estimating the possibility of the significance of chance factors in the properties of the materials, and in the manner of construction. In a "normal" structural type such factors have comparatively little influence. In a "hybrid" structure, they may be of considerable importance. Studies of the effect in an arch rib of chance variations of modulus of elasticity have been reported by Professor Cross.[23] The results seem to show that there is only a relatively small effect of chance factors on the stresses in an arch rib for the usual case in which the dead load is comparatively large. When the dead load is very small compared with the live load, chance variations might cause some concern. However, the effect of chance variations cannot be discussed independently of the significance of over-stress.

The Trussed Beam.—The problem of the trussed beam is of interest in throwing light upon some of the aspects of the use of the classification in design. Certainly, if the sag rods are quite small, the structure is "normal", with the beam "carrying the load", and with "participation" stress in the rods. Again, if the beam is very shallow and has an area of the same order as the sag rods, the structure is "normal", and acts as a truss with secondary or "participation" stresses in the beam. For intermediate cases, the structure is "hybrid."

For the case of a concentrated load at the center of the beam, the hybrid structure is "efficient" when the sag depth is approximately 1.5 to 2 times the beam depth (for the beam and sag rods both of the same material). For lesser sag depths, the sag rods will be understressed compared with the beam for all proportions of the structure. For greater sag depths the sag rods will be overstressed compared with the beam unless the beam is so small that the structure approaches a truss. When the beam is fairly small, it will be overstressed compared with the sag rods unless its depth is adjusted so as to reduce the flexural stresses. If the beam must carry loads at other points than at the center, the foregoing results are changed quantitatively but not qualitatively.

Of course, actually, the stresses in beam and truss may be adjusted either by putting initial tension in the sag rods or by slacking off on them, when the sag depth is less than, or greater than, the efficient sag depth, respectively.

Merely as an illustration, consider the case of a 30-ft beam carrying a concentrated load of 44 000 lb at its mid-point. It is desired to truss the beam to help support the load. Adjustments of the sag rods or stresses due to dead load are not considered. It is assumed in the following calculations that the vertical post is fairly large so that it does not deform appreciably under the load.

Problem 1.—The beam is an 18-in., 90-lb **I**-beam; and the sag depth is chosen arbitrarily as 36 in. from the center of the beam. What area of sag rod is required for working stresses of 18 000 lb per sq in.?

Discount about 2 000 lb per sq in. in the beam for direct stress. At a flexural stress of 16 000 lb per sq in., the beam will carry about 56% of the load. Designing the sag rods for the remaining stress, one finds that the area required is about 2.75 sq in. A review with this design indicates that the total stress in the beam is 17 600 lb per sq in., and in the rods, 18 200 lb per sq in. Evidently, an efficient sag depth was chosen.

Problem 2.—Under the same conditions as in Problem 1, the sag depth is taken as 54 in. A first estimate of the area required in the sag rod is 1.67 sq in.; but a review indicates a stress of 23 900 lb per sq in. in the rods, and a total stress of 14 800 lb per sq in. in the beam. Apparently, the sag depth chosen is inefficient.

By use of the traditional design procedure, the next trial design is an 18-in., 70-lb I-beam, and an area of 2.22 sq in. in the rods. This combination, if moments and forces are not changed, should give a stress of 18 000 lb per sq in. in the rods, and 20 100 lb per sq in. in the beam. However, a new analysis gives stresses of 21 900 and 15 900 lb per sq in. in rods and beam, respectively.

Repetitions of the traditional procedure lead very slowly to a balanced design. The preceding results suggest for a next trial a 54.7-lb I-beam and an area of 2.70 sq in. in the rods. Limiting the depth to 18 in. the designer finally ends with a 48.2-lb beam, and rods of an area of 3.0 sq in., for which the stresses are calculated to be 18 600 and 16 200 lb per sq in. in rods and beam, respectively.

If the problem had been to reinforce the original beam, the designer would have found eventually that approximately the same rod area would have been required as in Problem 1, namely 2.7 sq in. The beam, however, would have been working at a stress of 12 300 lb per sq in., compared with 17 300 lb per sq in. in the rods.

In this problem the question may well be raised as to the significance of over-stress in the sag rods when the beam is understressed. If the stress in the rods reaches the yield point the beam will begin to take a larger share of the load. The structure might adjust itself in a manner analogous to slacking off the tension in the sag rods by increasing their length slightly. The writer does not believe that it is well to depend on such stress relief in general, but the question does deserve some consideration.

Problem 3.—With other conditions the same as in Problem 1, consider a 24-in., 79.9-lb I-beam, and a sag depth of 36 in.

In the same manner as in Problems 1 and 2 a first estimate of the area required in the sag rods is 1.57 sq in. The calculated stresses, however, are 18 800 lb per sq in. for the beam and 16 000 lb per sq in. for the rods. If the rods are reduced in area and the beam is increased in size, as is indicated by the traditional procedure, the ultimate effect will be to eliminate the rods entirely, and the entire load will be carried by a larger beam.

If it is a matter of reinforcing the given beam, the designer will have to resign himself to the use of a lower working stress in the rods than in the beam. With an area of 1.90 sq in. in the rods, the stresses will be 15 000 and 18 200 lb per sq in. in rods and beam, respectively.

One could have anticipated the final designs obtained in these three problems, however. It is not difficult to estimate what simultaneous stresses are required for continuity with given dimensions of sag rod and beam.

Arches Continuous with Their Superstructure.—Certain limiting cases of the arch with integral spandrel structure are "normal", but practically all such structures of the proportions usually built are hybrid.

An arch with a comparatively heavy rib and flexible columns and a deck supporting relatively light live loads is a normal structure with participation stress in the deck and columns added to the normal stress in these members due to their action in the continuous deck frame.

Another normal type is the structure consisting of a flexible rib with a stiffening girder. There will be flexural participation stress in the rib, in addition to the normal stress due to the direct thrust in the rib.

A third type of structure having "normal" characteristics in certain cases is what might be termed an arched Vierendeel truss. This structure must have quite rigid columns. The corresponding simply supported Vierendeel truss would be normal, but fixing the supports introduces some complications. In this connection, it is important to note that the fixed arch rib has hybrid characteristics for live loads, as was pointed out previously.

Other normal arch structures may be secured in various ways by the manner of construction or design involving the use of articulations and flexible sections. Such structures have well marked participation stresses at such articulations and pseudo-hinges. Of course, not all structures with hinges and points are "normal."

In special cases applying to certain other arch structures the controlling relations are comparatively clear, as Professor Cross has indicated. The flitch-beam concept applying to the structure with flexible columns has considerable value. Use was made of this concept by Rankine[24] and Considére.[25] An analysis preliminary to design may be developed along the lines suggested by Professor Cross' treatment as follows: The deck girder will have primary stresses due to its action as a continuous beam. These stresses are due to the dead load of the deck only, and the entire live load. The arch rib will take all the thrust, most of which is due to dead load. Then the difference between the working stress and the primary girder stress is available to resist interaction flexure in the girder. The difference between the working stress and the stress due to direct thrust in the arch rib is available to resist flexure in the rib. The stress due to interaction flexure in the girder is to the flexural stress in the rib approximately as the depth of the girder is to the depth of the rib. The rib and deck resist the moment, except for primary moments, approximately in proportion to their moment of inertia.

A few rough figures will enable an estimate to be made as to whether a tentative combination of depths of girder and rib is efficient or inefficient, and will give some idea as to what can be done about it. For example, if the girder is found to be overstressed, it must be remembered that increasing the depth of the girder may increase the interaction stress although it decreases the primary stress.

For the general case in which the columns must be of intermediate stiffness there seems to be no convenient method of estimating in advance whether the structure can act as it is assumed to act in a preliminary analysis. Use of the traditional procedure of successive analysis (usually by means of a model) and design does not appear to be very promising. Such a procedure might easily be misleading, particularly where a re-design is based on an analysis which is not repeated for the new design. It is open to question whether a better structure is obtained by such a procedure than by neglecting interaction entirely.

Other Problems.—The fundamental philosophy presented by the author has wide applicability. Some of its possible uses have been mentioned, but there are many other cases in which it is useful. As an illustration consider the problem of the stresses in a bearing-plate supporting a concentrated load on an elastic solid.

If the plate is very flexible compared with the solid, the latter deforms in the same manner as under a load directly applied. The stresses in the solid are of the nature of "normal" stresses. The plate, in conforming to the configuration of the solid, has stresses of the nature of participation stresses. If the plate is very stiff, the pressure between it and the solid approaches a certain limiting distribution, and the stresses are "normal" in both plate and solid. If the bearing-plate is neither very flexible nor very stiff, the pressure distribution under it varies considerably with any change in thickness, and the stresses are certainly "hybrid."

The classification has applicability to many other problems concerned with what is sometimes called "internal stress", as well as to problems concerning so-called "frame" structures.

Concluding Remarks.—The profession is indebted to the author for his presentation of a practical philosophy of design. It is to be hoped that his paper will awaken interest in methods of design. Perhaps in the future more energy will be devoted to securing quantitative data for the design of structures rather than to the development of variations in existing procedures for their analysis.

L. E. Grinter,[26] Assoc. M. Am. Soc. C. E. (by letter).—To his important contributions on the theoretical analysis of continuous frames, Professor Cross has added an enlightening paper concerning the relation of analysis to structural design. His subdivision of all structures into normal and hybrid types cuts ruthlessly through the field with little regard for the classical arrangement into statically determinate and statically indeterminate groups. This point of view is at least refreshing, and it seems to be considerably more than that.

Statically Determinate Structures.—The writer has often wondered whether he has ever actually seen a practical structure that could be properly classified as statically determinate. Simple beams are decidedly unusual. What is commonly termed a simple beam (that is, a steel floor joist or roof joist) is frequently encased in concrete poured continuously with other beams through the connection of a reinforced concrete floor-slab or roof-slab. Thus, this structure, which is analyzed as statically determinate, may be one of the most complex of all statically indeterminate constructions—a continuous flat slab with partly discontinuous stiffening ribs supported in part by the columns and in part by restrained edge beams. A search for a statically determinate cantilever structure will not lead to much more satisfactory results since in common with three-hinged arches they become not only statically indeterminate, but mathematically indeterminate when corrosion produces an unknown pin friction. They, too, are usually constructed so that there is partial continuity through a floor system.

---

[26] Prof. of Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

This comparison of structural types could be carried on indefinitely. Surely the lower chord of a pin-connected through truss ought to be a statically determinate member; but, instead, the writer recalls making a railway bridge test for live loading for which numerous strain-gauge measurements on the eye-bars of a lower chord member showed an average stress of little more than one-half the theoretical value. One could explain this phenomenon in part by the self-evident fact that the floor system was functioning as a part of the lower chord, but this general observation would be of little value in an attempt to analyze or to design a similar structure. The fact is that this simple span truss was acting in a most complex manner, that it was internally statically indeterminate, and that the manner of fabrication and erection had a most important effect upon its stresses.

From these and other observations, one might conclude that the classical distinction between statically determinate and statically indeterminate structures has its main justification in the classroom where its value is largely a matter of convenience to the student and the teacher. For the practical designer this distinction is dangerously convenient and, therefore, of questionable importance. Hence, the subdivision suggested by the author is at least worthy of consideration.

Impressed Distortions and Induced Distortions.—Professor Cross has made a division between what he terms deformation stresses and participation stresses. A comparable physical distinction that the writer has been in the habit of making depends upon whether the corresponding distortion is impressed upon the structure or induced in the structure by its own action. Evidently, temperature effects are impressed upon the structure from an outside source. Similarly, the tower of a suspension bridge may have a bending deflection impressed upon it because of a reduced sag of the cable in the side spans when the center span is loaded. At least, this action is external to the tower itself and may thus be classified as an impressed distortion. On the other hand, ordinary secondary stresses in truss members are caused by joint rotation in the plane of the truss which is an induced distortion. Apparently, however, the division line is less clear when one considers such effects as rib-shortening in arches. This action is quite clearly the same as temperature effect or spread, both of which are produced by impressed distortions. Nevertheless, rib-shortening stresses are secondary flexural stresses produced by the shortening of the rib from primary compression, and thus should be designated as "induced stresses." Hence, one observes that impressed and induced distortions merge one into the other.

Professor Cross has attempted to clarify the aforementioned difficulty by observing that time flow will eliminate or reduce a deformation stress (the consequence of an impressed distortion), but that a participation stress (the consequence of an induced distortion) will be unaffected by such plastic flow. In general, this distinction holds true although it may be desirable to add that the distribution of all stresses can be affected by such plastic flow.

These observations explain the writer's preference for the terms, "induced stress" and "induced distortion", as more descriptive of the physical picture than the terms, "participation stress" and "participation strain." Certainly these secondary stresses participate very slightly in the job of supporting the loads; instead, they are induced by primary strains much to the designer's disquietude.

Two statements of the author will be repeated for study: (1) "Thus, it is generally known that increasing the moment of inertia without changing the depth of truss members will affect the secondary stresses only as the primary stresses are affected"; and (2), "the designer finds it convenient to predetermine such strains [impressed distortion], reduce them to equivalent stresses, and deduct these stresses from the working stresses available for load-carrying capacity." Although the writer thinks that Professor Cross has been too generous in concluding that the information referred to in Statement (1) is generally known, he certainly agrees to its importance. Statement (2), although simple in itself, must be complicated by the fact that only the total distortion is evident and that the unit strain is dependent upon the shape of the axis of the member and upon the variation of its cross-section. Hence, for the general case one must admit that even final deformation stresses (impressed distortions) cannot be found until the design is completed. This is just another of those cases in which the designer cannot "foresee the action" and falls back upon a cut-and-try procedure.

Visual Structural Action.—The writer would mention another classification of structural action which in many points agrees with the subdivision suggested by Professor Cross. However, a few structures will be found to have been shifted from the complex to the simpler classification, or *vice versa.* A comparison of the two points of view seems particularly useful since each presents factors for consideration that the other misses.

The subdivision to be suggested is made dependent upon a criterion which can be stated forcefully in the words of Professor Cross, "that the designer either does or does not know what he is doing." In the writer's words this becomes a subdivision into "visual structural action' and "non-visual or concealed structural action." As another criterion that will be of some use, it may be stated that this classification of visual structural action will include all academic statically determinate types and, in general, those indeterminate types that involve, at least theoretically, no more than three redundants. In some few cases a structure having more than three redundants may possibly be arranged to fit into the simple classification of visual structural action. Examples will be given.

The limitation of three redundants is suggested because it is quite evident to the instructor that the limit of visual study commonly is reached when three interacting influences exist. The interaction of two redundants is relatively simple but the number of possible interwoven patterns is about tripled with three redundants. A visual study of the interplay of four influences is not ordinarily within the grasp of other than a highly trained mind. As an example of the usefulness of this classification, one notes that the problem of two crossing beams (deflected equally) which were placed in the complex subdivision by Professor Cross fall into the simple subdivision in this discussion. The analysis and design of such beams, although not feasible by the "guess and revise procedure", is possible in a direct manner, as suggested by the author.

Non-Visual or Concealed Structural Action.—In this classification is found those structures and parts of structures for which an adequate design procedure does not now exist. It is no great credit to the profession, however, that it includes so many ordinary structural types. Hence, it is worth calling attention to the fact that in this subdivision there is included many concrete arches, most tall building frames, flat slabs, continuous footings, bridge abutments built continuously with their wing-walls, arched dams, and even many of the so-called statically determinate structures because of the partial continuity introduced by common methods of construction. In other words, with few exceptions, an adequate design procedure to-day is available only for those structures in which the interaction of the structural parts can actually be visualized. The designer will do well to select and construct structures within this classification until direct procedures for the design of complex structures are made available. When he cannot do this, he should "go slow" in making his design.

Parallel Beams.—Two cases of parallel beams seem worthy of investigation. In wind-stress studies, parallel beams of different depths and perhaps even of different lengths may be forced to rotate through equal end angles. Then, since θ varies as $\frac{M\,L}{E\,I}$ and $M = \frac{S\,I}{c}$, it is evident that for equal θ-values the relative stresses in the two beams are defined as follows:

$$\frac{S_1}{S_2} = \frac{\dfrac{L_2}{c_2}}{\dfrac{L_1}{c_1}} = \frac{\dfrac{d_1}{L_1}}{\dfrac{d_2}{L_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which $\frac{d}{L}$ is the depth-length ratio of the beam. Evidently, the only geometrical shape that will permit such beams to be stressed equally is that of equal $\frac{d}{L}$ - values.

When the deflections rather than the end slopes are identical for the two beams, the deflection varies as $\frac{M\,L^2}{E\,I}$ and the relative stresses in the two beams are defined as follows:

$$\frac{S_1}{S_2} = \frac{\dfrac{L^2_2}{c_2}}{\dfrac{L^2_1}{c_1}} = \frac{\dfrac{d_1}{L^2_1}}{\dfrac{d_2}{L^2_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Hence, these beams must have equal $\frac{d}{L^2}$ - values in order to be stressed equally. This would be the writer's definition of efficient design. In any case such beams furnish an illustration of a statically indeterminate structure properly classified as hybrid under the author's subdivision, but as visual structural action by the writer.

The Vierendeel Truss with Parallel Chords.—This is another structure properly classified as hybrid by Professor Cross, but still easily analyzed and readily designed because of the visual characteristics of its structural action despite the fact that it is highly indeterminate. A few common sense basic assumptions can be made for the purpose of a preliminary analysis and design by statics. Then, in the usual case, an analysis will show that the first design was satisfactory. The few necessary revisions are easily determined because of the visual characteristics of its structural action.

The distinction between the Vierendeel truss and a building frame is that the truss is essentially a regular structure, whereas the building frame is in most cases irregular. Commonly, there are no reasonable assumptions that can be made to lead to a preliminary design of a highly irregular wind-frame that will not necessitate serious revision of sections subject to the difficulties inherent in the revision of any structure the action of which cannot be visualized. Of course, the Vierendeel truss can be hopelessly complicated by the use of a floor system such that the resultant structural action will be beyond visualization. A curved top chord will introduce additional complications.

Rectangular Wind Frames.—The author proposes an interesting design procedure for a regular wind frame. His discussion apparently is intended to apply to a building of medium height since it is assumed that the column cross-sections will be unchanged by the effect of wind. If such a building frame has been designed by a conventional method, it is likely that overstresses will be found when an analysis is performed by a more exact method. However, one need not run headlong into the difficulty pointed out by Professor Cross. Naturally, an increase in size (depth and moment of inertia) increases the stiffness of the overstressed girder, causes it to resist more wind moment, and increases its fiber stress still more. One frequently finds it necessary to reduce its depth, thus reducing the fiber stress for a given moment. At the same time, it may be desirable to stiffen adjacent girders to relieve the overstressed girder of its excess moment.

Of course such a procedure is difficult to apply to a highly irregular structure, but there is no particular reason why the design of a structure as complex as an irregular tall building frame should not consume considerable time. The author's proposal that the design should be based upon assumed points of contraflexure, assumed shear distribution, and design stresses proportional to the depth-length ratios of the girders (equal end slopes) would be practicable for a very regular frame. However, the important need is for a design method that will make the design of an irregular building frame less tedious.

Conclusion.—The writer has found in this paper much material that will require slow digestion. The inference is clear that direct design is the ideal toward which one should strive. The cut-and-try or guess-and-check procedure fails in many cases unless applied with more than ordinary intelligence. Finally, hybrid structures, in which the type of structural action is concealed, in which "self interference" exists, or in which one attempts to "put secondary stresses to work", offers little promise of economy, but far more promise of confusion and poor design.

F. P. SHEARWOOD,[27] M. AM. SOC. C. E. (by letter).—Practical designers, who are called upon to plan for structures on a commercial basis will find this paper of great assistance, since it helps them to visualize the function of the strains and stresses that are caused by the multitudes of indeterminate and unnoticed strains that exist in almost every structure.

When an exact stress analysis of almost any riveted frame is contemplated, the designer is faced with the problems of its irregular secondary lacing, its eccentric connections on all planes, its varying areas of cross-section at the splices and other points, the stiffening effect of the gusset-plates, the participation of the bracing, floor system, and many other resistances which custom allows to be neglected or overlooked. With all these problems to solve (or to overlook), he is likely to be thankful for the fact that he works to a liberal factor of safety. If he strolls through the fabricating shop and watches the straightening rolls, the "bull dozers", the punch shears, and other tools straining the material, he is again grateful that steel is ductile. In his final survey he watches the latest type of fabrication—fusion welding—and reflects on the strains that must be set up by the cooling of that thin molten streak; he then asks himself if there is any margin left between the temperature strains that are set up and the elastic limit. These facts appear to conflict with the rigid limitation placed on the unit stresses and strains allowed in the calculations for proportioning the material, and they suggest that designers may have allowed the fascination of mathematical exactitude, based on assumptions and on Hooke's law, to outweigh and over-awe actual engineering experiences.

It is likely to be forgotten that, although the ultimate strength of steel is 60 000 lb per sq in, its ultimate strain, as measured in calculating stresses from distortion, is about 6 000 000 lb per sq in. (that is, 20% elongation with a modulus of 30 000 000). Since the ductility of steel is utilized during fabrication, why has it been ignored by designers when proportioning steelwork which has more than one path of resistance, and in which the loading is more or less constant? There are many continuous spans, trusses with several systems of web-bracing, rigid frames, as well as many other forms, which, in the event of some part of one path of resistance becoming strained above its elastic limit, will bring the other paths into proportionately greater resistance, and thus insure a redistribution of the combined resistance before the weak member is strained to a dangerous degree.

The ductility of structural steel can be relied upon to provide safely for far more strain from secondary distortions than is usually allowed by standard specifications; moreover, the relative participation of the various paths of resistance to these deformations, is not always wholly dependent on the modulus of steel, but is frequently influenced and relieved by the cross-bending of connection angles, the slip of the rivets, and other relieving deflections. These deflections, although very minute, are relatively great when compared with the direct elastic deformation of the steel. They will alter the distribution materially, therefore, and relieve the extreme fiber stresses.

---

[27] Chf. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.

Limiting the strain in structural steel (after fabrication) to a value below the elastic limit is in sharp contract to the common practice in reinforced concrete, in which the concrete is actually allowed to fracture, and the steel reinforcement is still counted on to function by adhesion to the fractured concrete.

With mature judgement, appropriate calculations for guidance and the knowledge that, in structural steel, the strain increases much faster than the stress when overloading occurs, designers should count, to a greater extent, on the sum total strength of the several resisting paths in indeterminate structures, rather than limit their use to the calculated stress of the weakest member.

HARDY CROSS,[28] M. AM. SOC. C. E. (by letter).—Discussion of the paper may be divided into that dealing with the adequacy or correctness of analysis and that dealing with the use to be made in design of an analysis assumed to be correct. It is generally recognized that flaws may be found in many conventional analyses and most designers understand that assumed conditions of loading or of restraint may not exist. The writer, however, did not attempt to discuss these matters but restricted himself to the question of the interpretation of analytical procedures.

The discussion by Mr. Mensch points out the uncertainties inherent in structural analyses. It also suggests the confusion existing as to the procedures used in analysis. The writer may remark that he does not understand in what sense "the analysis of most statically indeterminate structures is beyond the realm of science and becomes an art"; it seems necessary to accept analysis as a science and design as an art. The procedures of analysis and design are different; that the science is defective and the art often clumsy is another matter. Probably neither analysis nor design will be much improved by more handbooks.

Mr. Mensch discusses the statical determinacy of post and lintel construction. The writer stated that a girder resting on narrow columns "represents a structure essentially statically determined (post and lintel or column and beam), but with participation stresses in the columns." Surely most engineers will agree that a girder resting on two relatively narrow studs should be designed as simply supported. A better example of the difference between the point of view of the analyst and that of the designer would be difficult to find.

In connection with the remarks of Mr. Brinker as to the relative importance of secondary stresses, attention may again be called to the paper by

---

[28] Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

Messrs. Parcel and Murer.[2] Mr. Brinker clearly points out that a uniform stress cannot be chosen and applied indiscriminately to the sum of all stresses from whatever source, and the writer heartily concurs; in fact, to bring this out was one of the main purposes of the paper.

The very interesting remarks of Mr. Findley deal chiefly with the uncertainties rather than with the interpretation of analyses. He puts his finger on the main purpose of the paper, however, when he refers to what he calls the writer's pragmatic concept of structural action. To a considerable extent the attitude of the writer toward design is pragmatic. His point of view may be briefly re-stated as follows: Omit from the picture certain stresses of the type described as participation and deformation stresses—accept for the present the fact that they do not and are not intended to carry any appreciable portion of the load. Assume, now, the pragmatic attitude that when one tells the structure what to do it will try to do it. Questions now arise: Can it do it? Can it do it efficiently? How can the designer determine how to make it do it? Sometimes repeated analysis gives a clue to the action of the structure; often it does not. It is not a question of monolithic construction or of statical determinacy, but of normal response to successive analysis and revision. The term, hybrid, was chosen for those types which do not normally respond because these types partake of the action in part of those which respond at once and in part of those exposed to participation. The writer would like better designations than "normal" and "hybrid", but "statically determinate" and "monolithic" will not serve the purpose.

Mr. Newmark clearly states the main thesis. If a member is overstressed, what can be done about it (the superstructures of arches)? How is the condition best remedied (the trussed beam)? Can anything at all be done about it except to change the type of structure?

Mr. Grinter also wishes to modify the terminology. The writer holds no brief for the terminology chosen; but the discussion by Mr. Grinter brings out clearly the importance of an understanding on the part of the designer of the responsiveness of the structural type to revision—of its response to persuasion.

Mr. Silverman calls attention to temperature stresses in an arch as an example of deformation stresses. Although convenient because it fits into routine conceptions, the treatment of temperature stresses usually given is rather misleading. It is the temperature strains that are fixed, and in arches (and suspension bridges) the most important factor in fixing them is the ratio of depth of rib to rise of arch.

Mr. Wessman discusses the hybrid action of rectangular bracing frames in buildings, a matter discussed also by Mr. Grinter. The writer finds himself puzzled by the attitude of some writers as to the so-called "exact" analyses of wind stresses. The problem of how best to go through the analysis which purports to give the exact moments (and which would give them for given wind loads if it were not for the interaction of partitions, of girder encasements and floors, and for the uncertainty of bracket action and rivet slip), seems a study appropriate for the graduate seminar rather than for the design office. In cases of regular framing the designer knows pretty well how his moments go. In cases of irregular framing he does the best he can, telling the moments in any story where he wants them to go. Analysis will now give some indication as to whether they are likely to go where directed; but analysis—conventional analysis—will not tell at once what allocation of moments is impractical, or within what limits other allocations are satisfactory. In the writer's opinion, this is the important field of research in wind-bracing.

It is scarcely possible to choose a better illustration of the utility of the point of view presented in the paper than the field of suspension bridges to which Mr. Wessman calls attention. In large bridges where the cable has great resistance to distortion the stresses in the truss due to live load on that truss are a function chiefly of its depth and not very largely of its strength; in some trusses the action is "hybrid", both depth and strength are factors; relatively light bridges are "normal" in their action, and the "elastic theory" gives at once a pretty satisfactory design. However, note that, in any case, temperature stresses are of the nature of deformation stresses, the strains being a function of the ratio of truss depth to cable sag, as in arches.

A comparison of the curve (Fig. 6) given by Mr. Wessman, showing variation of moment in stiffening truss with moment of inertia, with a corresponding curve showing variation in moment in one partner of a two-part flitch beam, is very illuminating.

Mr. Shearwood clearly points out the uncertainties produced in steel by fabrication methods and the basis for valuing their importance. His statement of the strength of mild steel in terms of ultimate strain expressed as equivalent strength seems especially happy, emphasizing the importance of ductility. Ductility plays a very different part in participation stresses—where the strain is fixed—and in normal structural action--where the desired strength is approximately fixed; but in many of the complicated structural types it plays a rather complicated part. The total strength is fixed but, at the same time, there is an inter-relation of strains. Perhaps this may serve to justify to Mr. Findley the term "hybrid."

Mr. Johnston and Mr. Newmark have discussed the significance to be attached to over-stress. The question has special interest in the case of hybrid structures—structures in which the load is "carried" in several ways. In this connection Mr. Johnston uses the term, "limit of structural usefulness." The subject needs extensive discussion. To quote from the paper, "The values of stress permissible in design vary with the material used, with the importance of the member involved, and with the type of failure that would result." Thus it has often been argued that it is not very important how moment is distributed between the positive and the negative in concrete beams if provision is made for the total moment. Some engineers seem to overlook the danger of secondary failure in bond or in diagonal tension if the negative steel is seriously overstressed.

The writer appreciates the courtesy of those who have discussed the paper. Their comments open up many fields of research in structural design which are being neglected in the current deluge of algebraic investigations.

TUNNEL AND PENSTOCK TESTS AT CHELAN STATION, WASHINGTON

BY ELLERY R. FOSDICK, ESQ.[1]

WITH DISCUSSION BY MESSRS. W. A. HILL, S. P. WING, J. N. BRADLEY, AND H. P. EVANS, JR., W. S. MERRILL, AND ELLERY R. FOSDICK.

SYNOPSIS

A thorough and detailed analysis of flow-line losses was computed from data obtained by tests on the unusually long flow line leading to the hydro-electric generating plant at Chelan, Wash. This paper contains the results of that analysis, and includes:

(1) The losses that occur in each part of the flow line;

(2) The coefficients of roughness that are applicable to the large concrete and steel lined pipes of this installation;

(3) An unusual and complete analysis of the losses that occurred in the wye-branch; and

(4) A segregation of the diversion losses (see heading, "Definitions of Symbols") in the wye-branch and lower penstock bends from the losses due to frictional resistance, as a means of checking laboratory tests and research work that was being conducted along this line.

The tests were made and a report was prepared as a means of facilitating the most economical operation of the generating station and to supply additional data in the furtherance of engineering knowledge and its application to future designs involving these features.

INTRODUCTION

In 1927, after the hydro-electric generating plant at Chelan, Wash., had been completed and put into service, it was found desirable (because of the unusually long flow line) to conduct a series of tests to determine the flow-

---

NOTE.—Published in October, 1935, *Proceeding*.

[1] Asst. Engr., State of Washington, Dept. of Public Service, Spokane, Wash.

line losses. By means of these tests it was expected to obtain more or less detailed information concerning: (1) The total flow-line loss from which it would be possible to compute, easily and accurately, the water consumption of the turbines; (2) coefficients of roughness that apply to the flow of water in large concrete and steel pipes; (3) an analysis of the losses that occur in the wye-branch; and (4) the laws governing diversion and eddy losses in the pipe bends.

Item (1) was desired for use in operating the plant and Items (2), (3), and (4) were for the purpose of adding to the available knowledge of hydraulic losses that occur in large conduits, thereby facilitating their future design. Practically nothing of a definite nature had been done at the time these tests were made toward analyzing the losses that occur in a wye-branch and little more had been done toward an understanding of the losses in pipe bends.

DESCRIPTION OF THE CHELAN DEVELOPMENT

The Chelan hydro-electric development utilizes Chelan Lake as a storage reservoir, the potential head between this lake and the Columbia River being about 400 ft. The lake has been formed by a glacial fill across the lower end of the former Chelan Gorge. Its outlet, the Chelan River, flows through what now remains of the Chelan Gorge for a distance of about 2.5 miles to the Columbia River.

The dam that regulates the level of Chelan Lake, is built across the river about 0.5 mile from the lake. The intake of the flow line leading to the power house, situated near the junction of the Chelan and Columbia Rivers, is incorporated in the dam.

Fig. 1 is a profile drawing of the flow line and penstock from the intake to the tail-race. The intake to the flow line is of a commercial, draft distributor type from which the water enters a concrete pressure tunnel, 14.00 ft in diameter, constructed to a 0.312% grade for a distance of 10 578 ft. (The concrete tunnel was cast around steel forms which produced a smooth regular finish on the interior surface.) At the end of this distance the tunnel lining is changed from concrete to a double-butt, strap-riveted, steel shell and the grade is changed to 35% for a distance of 397.79 ft, at which point a 14-ft steel-lined pipe rises vertically to the surge tank. Square-edged butt-straps and button-head rivets were used to fasten adjoining sections of steel together, as may be seen in Fig. 2. The interior surface was protected only with the customary factory coat of red lead paint. Consequently, the surface was somewhat rough at the time these tests were run because the steel began rusting soon after the flow line was filled with water. Since the tests were run the interior has been cleaned and repainted with a bituminous enamel, but no observations have been made to ascertain what effect this has upon the losses. The penstock grade continues the same as before, for 604 ft more, to the wye-branch, the diameter converging in this distance from 14.00 ft to 12.50 ft, where it divides through the wye-branch into two 8.83-ft, double-butt strap-riveted, steel-lined, penstock pipes, as shown in Fig. 2. At a point 40 ft below the wye-branch the two diverging penstocks bend in opposite directions through an angle of 29° 13′ 26″, so that they are parallel to each other in a

horizontal plane. The total length of each penstock branch is 138 ft, the lower end connecting to a hydraulically operated needle-valve from which the water passes through a reducing section which converges to a diameter of 6.50 ft at the point where it connects to the turbine scroll-case.

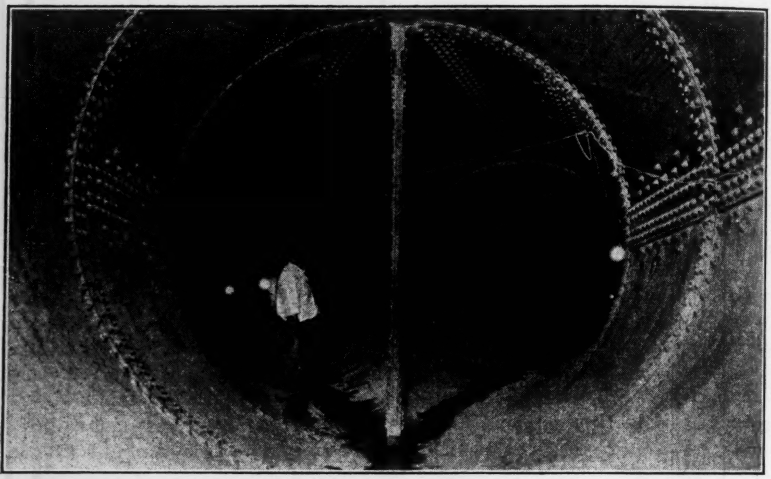

FIG. 2.—INTERIOR VIEW OF PENSTOCK AT STATION 117 + 20, SHOWING THE WYE.

The water from each turbine flows through a spreading draft-tube and out into the tail-race in the Chelan River. The two turbines are identical, each being of the vertical reaction type rated at 34 600 hp, and each using approximately 1 100 cu ft per sec of water when operating with the turbine gates wide open.

EQUIPMENT USED FOR TESTS

Data for the tests were obtained from pressure elevations recorded at eight different observation stations situated at critical points along the tunnel and penstocks from the forebay to the tail-race. The elevation of the water in the forebay, and also in the vent in the tunnel a short distance below the intake, was recorded with specially-built, high-speed, water-level recorders. These instruments were commercial, curve-drawing recorders with the driving mechanism rebuilt to give a chart speed of 0.1 in. per min, which is sixty times faster than normal.

Mercury manometers to be used for recording pressure heads were fastened to piezometer connections in the tunnel at two places between the vent and the surge tank in adits that were excavated for access to the tunnel during construction, at the surge tank, and on each of the converging sections just ahead of the turbine scroll-cases, and a staff gauge was used for reading the elevation of the tail-race. Each of the manometers, and the staff gauge in the tail-race were read by observers during the tests at predetermined intervals corresponding to different stable conditions of flow in the conduit, although it was not necessary to use the data obtained from the readings in the adits as the tunnel lining is concrete throughout the distance from the vent to the surge tank and the total losses for this section were the only data required.

Instead of using the conventional U-tube manometer at the observation points on the turbine scroll-case in the power house, it was necessary (because of the high head which, in some instances, supported a mercury column approximately 28 ft high), to use a single riser for each manometer, which was connected to a specially designed mercury pot in which the water pressure was transmitted to the mercury. The mercury pots were constructed so that a relatively large surface of the mercury was exposed to the water, resulting in a relatively small change of the surface elevation of the mercury in the pot for relatively large changes in water pressure.

TEST RUNS

The test runs were varied so as to cover the three following conditions of load distribution between the two units: (1) One unit operating with the turbine gates wide open, the other increasing its load by steps until it was wide open; (2) two units with balanced loads decreasing the loads by steps to zero; and (3) one unit only, increasing its load by steps until wide open.

To prevent governor hunting and the attendant variation of flow, the governors were cut out, and the turbines were controlled manually throughout these tests.

DEFINITION OF SYMBOLS

The symbols introduced in this paper are defined as follows:

e = a subscript denoting "due to eddies";
h = head loss; h_e = head loss due to eddies above the wye-branch tie-plate; h_a = loss of head that occurs in flowing water when the stream is diverted laterally from a straight path, as in the case of water flowing through a pipe bend or a wye-branch (referred to as "diversion" head loss); h_v = velocity head in Q when measured in the main penstock above the wye; h_{v1} and h_{v2} corresponding to Q_1 and Q_2; Δh_v = velocity-head difference between the flow in the main penstock and in Branch No. 2;
v = a subscript denoting "velocity";
C = Chezy's coefficient; C_w = the Williams-Hazen coefficient of roughness;
H = total head loss;
K = a constant = $1.668\ C_w^{1.852}\ R^{1.167}$;
Q = rate of discharge = total combined flow to Units Nos. 1 and 2; Q_1 and Q_2 = rate of flow to Units Nos. 1 and 2, respectively;
R = hydraulic radius;
V = average velocity at a cross-section;
a = a subscript denoting "due to diversion of flow";
Δ = "difference between".

COMPUTATION OF RESULTS

The pressure heads observed at the various points were increased to total energy heads by adding the velocity heads existing in the conduit, after which the total energy heads were converted into equivalent energy-head elevations for comparison with the forebay, vent, and tail-race elevations.

The elevation of Chelan Lake was disturbed by a seiche while these tests were being run. It was necessary, therefore, to correct slightly, all the observed elevations for this disturbance, except those in the tail-race. In addition, the manometer readings at the surge tank were corrected for an error introduced by the angularity of the riser to the penstock; and the manometer readings at the turbine scroll-cases were corrected for an error in the value of the density of the mercury. The latter errors were determined from an evident displacement of the origin on the loss curve of the wye-branch, the cause for which would not otherwise be explained.

The curves in Figs. 3, 4, 5, and 6 are plotted, therefore, from the observed losses after they have been adjusted slightly to compensate for certain inherent errors, making it possible to draw smoother and more accurate curves through the test points.

The water consumption of the turbines for different loads when operating under various heads had previously been determined by means of tests using the Gibson method.[3] These data were used in determining the flows corresponding to the loads which were carried by the units during the tunnel and penstock tests.

Entrance and Tunnel Losses

The observed losses that occur through the gathering tube and trash racks have been plotted in Fig. 3 and as may be seen are very small, reaching a maximum of only 1.75 ft for the maximum flow of 2 200 cu ft per sec. The total losses in the flow line between the vent and the surge tank, a distance of 10 578 ft, are shown in Fig. 4.

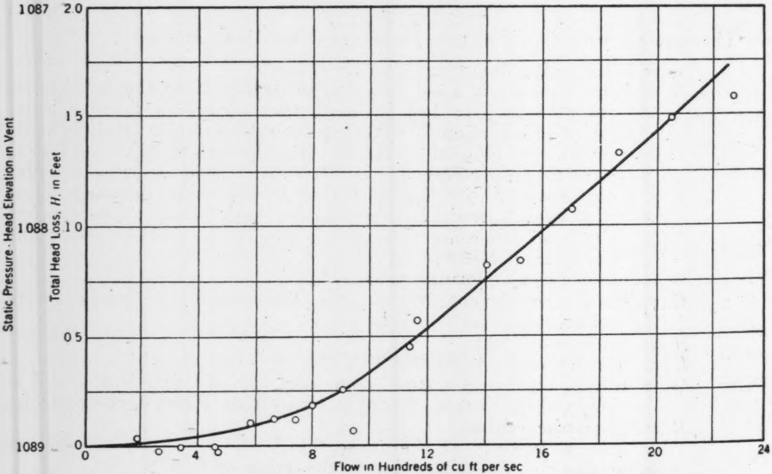

FIG. 3.—ENTRANCE LOSSES THROUGH THE GATHERING TUBE AND TRASH RACKS.

[3] "Pressures in Penstocks Caused by the Gradual Closing of Turbine Gates", by Norman R. Gibson, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 707.

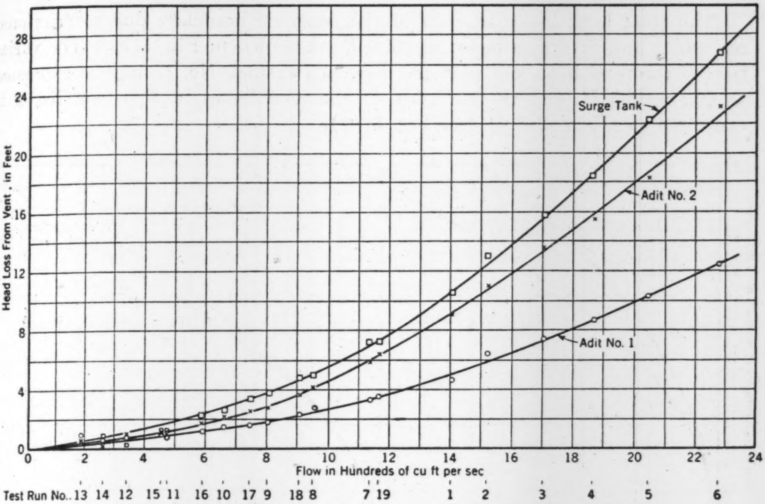

FIG. 4.—CORRECTED FLOW LINE LOSSES FROM VENT TO SURGE TANK.

BRANCH PENSTOCK LOSSES

From turbine tests which were previously conducted using the Gibson method,[2] the losses through the lower part of each penstock branch had been determined by differential pressures. In order to determine the total head loss through each penstock branch the frictional resistance component of this loss was increased proportionately to obtain the head loss due to friction for the entire length of each penstock branch. To this was added the diversion loss component which was present as a result of the bend in the lower part of each penstock branch and which obviously remained unchanged since the additional section of pipe was straight. Thus, the total loss in each penstock branch was the sum of the proportionally increased frictional resistance and the unchanged diversion losses.

Fig. 5(*a*) shows graphically the variation of the diversion losses in each of the lower penstock bends. The fact that the diversion losses through Branch No. 1 are less than in Branch No. 2 is probably due to the unsymmetrical arrangement of the spirals in the turbine scroll-case with reference to the angles through which the penstocks turn. The branches separate as they leave the wye; that is, they bend in opposite directions from the axis of the penstock above the wye whereas both the scroll-cases are spiraled in the same direction.

The equations for the curves of diversion losses in the two penstock branches are similar in character, which demonstrates that in each case the same basic laws govern these losses, although they are different in each penstock for identical flows. The equation for diversion losses in Branch No. 1 is $Q^{2.20} = 330\,H$, whereas that for diversion losses in Branch No. 2 is $Q^{2.20} = 210\,H$ (see Fig. 5(*a*)).

The total head losses in each of the penstock branches, due to frictional resistance and diversion losses combined, are shown in Fig. 5(*b*). The variation of the total head loss with the flow, in Penstock No. 1, may be expressed as $Q^2_1 = 45.5\ H$, and the variation of the total losses in Penstock No. 2 is expressed by $Q^2_2 = 40.8\ H$ (see Fig. 5(*b*)).

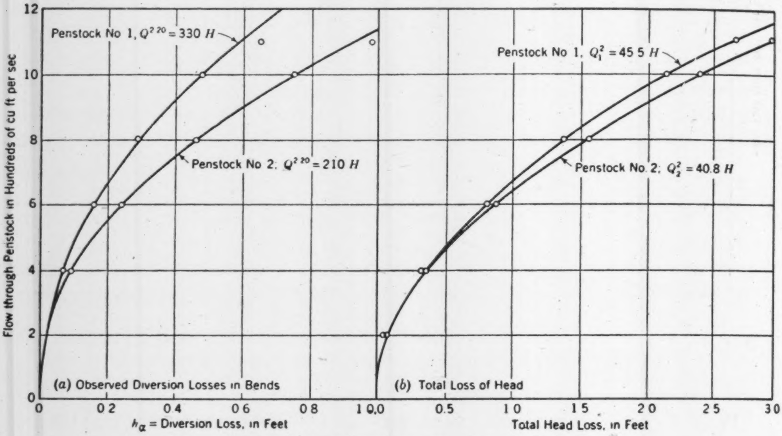

FIG. 5.—BRANCH PENSTOCK LOSSES.

The loss in head that occurred between the surge tank and points in either penstock just below the wye-branch was obtained by subtracting the head loss between the wye and either scroll-case from the corresponding total loss between the surge tank and either scroll-case.

LOSSES FROM THE SURGE TANK THROUGH THE WYE

For the purpose of studying the characteristics of the losses in the wye and penstock branches, the test loads were varied as follows:

Group (1): Unit No. 1 wide open; and Unit No. 2 increasing its load by steps until it was wide open, as shown by Test Runs 1 to 6, inclusive (see Fig. 6);

Group (2): Unit No. 1 and Unit No. 2 carrying balanced loads and decreasing loads by steps to zero as shown by Test Runs 7 to 12, inclusive; and,

Group (3): Unit No. 2 shut down and Unit No. 1 increasing its load by steps until wide open, as shown by Test Runs 13 to 19, inclusive.

To simplify the discussion that follows, these three groups of test runs will be considered in the order of Items (3), (1), and (2), instead of the order in which they actually were run.

Observed losses from the surge tank through Penstock Branch No. 2 to a point just below the wye during Group (3) of the tests, were composed of penstock friction losses from the surge tank to the wye and eddy losses that occurred above the tie-plate in the wye. It is evident that there could be no diversion losses in this branch since no water except that which leaked through the turbine gates was flowing through it. These losses are shown by the curve in Fig. 6 passing through Test Points 13 to 19, inclusive, for Wye Branch No. 2 the ordinates of which are h_{e1} distant from the curve of friction losses that were present between the surge tank and the wye. The manner of determining the position of this latter curve and the resulting values of eddy losses, h_{e1}, will be discussed subsequently herein.

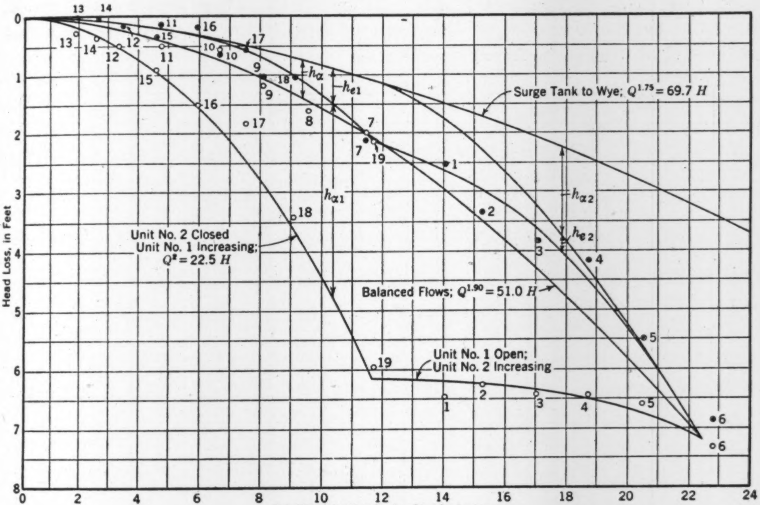

FIG. 6.—LOSSES FROM SURGE TANK THROUGH BOTH WYE BRANCHES.

During this same group of tests the observed losses through the penstock and Branch No. 1 to a point just below the wye, as in the case of losses through Branch No. 2, include (1) penstock friction losses from the surge tank to the wye; (2) eddy losses in the wye-branch above the tie-plate; and (3) the losses incurred when the water from the main penstock was diverted through an angle of 22° 30′ into Branch No. 1. The curve in Fig. 6 that passes through Test Points 13 to 19, inclusive, for Branch No. 1, with the ordinates, $h_{e1} + h_{a1}$, distant from the curve of friction losses from the surge tank to the wye, shows these losses.

It becomes evident, then, that the difference between the observed losses in Branch No. 2 and Branch No. 1 is the result of diversion losses that occur in Branch No. 1. These losses have been replotted in Fig. 7 and their relationship to the flow in Wye Branch No. 1 has been found to be $Q^{1.75} = 18.5\, h_a$.

Observed losses from the surge tank through Branch No. 2 during Group (1) of the tests, with Unit No. 1 open and Unit No. 2 increasing its load, as in Group (3), consist of (1) penstock friction losses between the surge tank and the wye; (2) eddy losses above the wye; and (3) diversion losses that occur in Branch No. 2. Diversion losses occurred during this group of tests because Unit No. 2 was running.

In Test Run Group (3) the eddy losses increased as the unbalance of flow increased between the two penstock branches, reaching a maximum at Test Run 19 when Unit No. 1 was wide open and Unit No. 2 was shut down. As the eddy losses increased when the unbalance of flows increased, during Test Run Group (3), so likewise did they decrease when the unbalance of flows decreased during Test Run Group (1). They became zero when the flows became balanced, which occurred with a flow slightly less than that at Test Run 6 when both units were wide open.

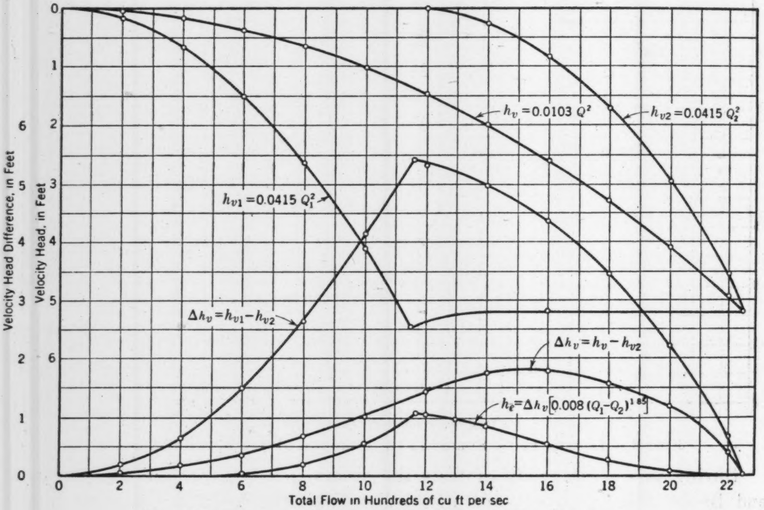

FIG. 7.—EDDY AND DIVERSION LOSSES IN WYE BRANCHES.

Diversion losses in Penstock Branch No. 2, during Group (1) of the test runs, were considered to be the same as those observed for corresponding flows in Branch No. 1 during the test runs in Group (3). The curve of observed losses from the surge tank through the wye in Branch No. 2 for Group (1) of the tests is shown on Fig. 6 as having ordinates of $h_{a2} + h_{e2}$, below the curve of friction losses from the surge tank to the wye. This curve passes through Test Points 1 to 6, inclusive, for Branch No. 2.

Observed losses from the surge tank through Wye Branch No. 1 during Group (1) of the tests are shown in Fig. 6 by the curve passing through Test Points 1 to 6, inclusive, for Branch No. 1. This curve is a continuation of the one that is distant, $h_{e1} + h_{a1}$, below the curve of friction losses from the surge tank to the wye. It slopes downward from Point 19 by an amount equal to the difference between the rate at which the friction losses between the surge tank and the wye increase with the flow of water through the penstock and the rate at which eddy losses (h_{e1}), above the wye decrease as the flows in the two penstock branches approach a balanced condition. It is evident from the downward slope of the curve that, with the unbalance of flows that occurred during Group (1) of these tests, the friction losses from the surge tank to the wye increased more rapidly than the eddy losses above the wye decreased.

Observed losses from the surge tank through either wye-branch during the tests of Group (2) when the units were carrying equal loads, were found in each case to be approximately equal. These losses are plotted as the balanced flow curve in Fig. 6 which passes through Test Points 7 to 12, inclusive, for both penstock branches; it also passes near Point 6. With balanced flows there were no eddy losses above the wye and, consequently, the curve represents the sum of penstock friction losses from the surge tank to the wye and the diversion loss in either wye-branch. It can be reproduced by the expression, $Q^{1.90} = 51.0\,H$.

When comparing this curve with that for observed losses in Branch No. 1 during Group (3) of the test runs, with Unit No. 2 shut down and Unit No. 1 carrying increasing loads, it should be remembered that for equal flows in the penstock above the wye-branch the flow through each branch of the wye with balanced loads would be only one-half as much as that through Branch No. 1 when it was carrying all the water with Unit No. 2 shut down. Thus, the diversion losses in each branch would be 28.6% of the total, since they vary as $Q^{1.75}$. The ordinates between the curve of friction and diversion losses from the surge tank through the wye for balanced loads, and the desired curve of friction losses from the surge tank to above the wye, are equal, therefore, to 28.6% of h_{a1}, which is the diversion loss for corresponding flows in Wye Branch No. 1 when no water was flowing in Wye Branch No. 2.

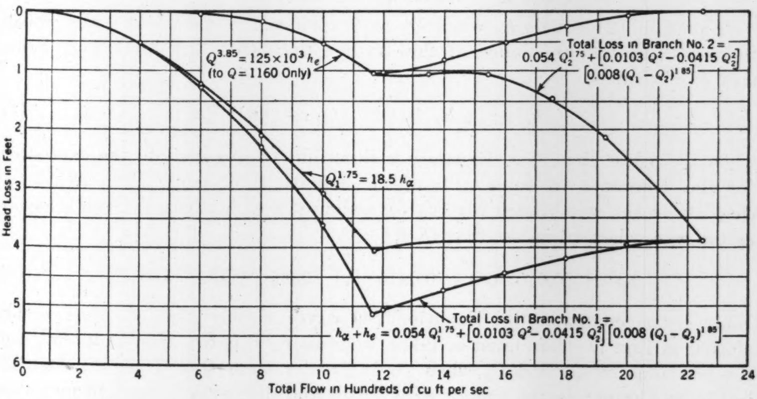

Fig. 8.—Relation of Eddy Losses to the Difference in the Velocity Head in the Wye

It is possible, therefore, to locate a series of points for the curve of friction losses that occur between the surge tank and the wye for flows up to and including a total of 1 167 cu ft per sec, by subtracting the diversion losses from the observed losses for balanced flows. However, from this value to (but not including) a flow of 2 250 cu ft per sec, no points can be located in this manner. At 2 250 cu ft per sec the ordinate between these two curves is equal to the diversion losses that occurred when 1 125 cu ft per sec was flowing through Penstock Branch No. 1 with Unit No. 2 shut down. The curve of friction losses between the surge tank and the wye has been drawn through the points located in this manner. The equation is $Q^{1.75} = 69.7\,H$.

Eddy losses above the wye-branch tie-plate varied with, but not in proportion to, the unbalance of flows in the two branches of the wye. To study this relationship further, curves of velocity heads in each wye-branch and in the penstock above the wye and the differences between each under the test conditions have been plotted in Fig. 8. A curve of eddy losses was likewise plotted on this sheet which shows at once, that the eddy losses are closely related to the difference between the velocity head in the penstock above the wye and in the wye-branch carrying the smaller quantity of water, which, in the case of this group of tests, was Branch No. 2. As shown in Fig. 7 the eddy losses with one unit running were found to vary as $Q^{3.85} = 12.5 \times 10^{3}\,h_e$.

The difference between the velocity head in the main penstock above the wye and the velocity head in Wye Branch No. 2 is:

$$\Delta\, h_v = h_v - h_{v2} = 0.0103\, Q^2 - 0.0415\, Q^2_2 \ldots\ldots\ldots\ldots (1)$$

Dividing h_e by $\Delta\, h_v$, a factor is obtained by which $\Delta\, h_v$ may be multiplied to obtain h_e; thus:

$$\frac{\Delta\; h_v \left(\dfrac{Q^{3.85}}{12.5 \times 10^3}\right)}{0.0103\, Q^2 - 0.0415\, Q^2_2} = \Delta\, h_v \times 0.008\, Q^{1.85} \ldots\ldots\ldots\ldots (2)$$

Equation (2) equals h_e when $Q_2 = 0$. Since the eddy losses were found to vary with the unbalance of flow rather than with the total flow, Equation (2) becomes,

$$h_e = \Delta\, h_v \;[0.008\; (Q_1 - Q_2)^{1.85}] \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

when Q_2 is less than Q_1. Expanding Equation (3) to include the expression for the difference in velocity head, the equation for eddy losses above the tie-plate in the wye-branch for any diversion of flow between the two branches in the wye, when Q_2 is less that Q_1 is:

$$h_e = [0.0103\, Q^2 - 0.0415\, Q^2_2]\; [0.008\; (Q_1 - Q_2)^{1.85}] \ldots\ldots\ldots (4)$$

Eddy losses computed by Equation (4) agree closely with the test results plotted in Fig. 7. Care must be taken when using this equation to interchange the positions of Q_1 and Q_2 when Q_2 is greater than Q_1. The total loss, H, in the wye-branch is the sum of eddy losses and diversion losses and may thus be expressed for Branch No. 1 when Q_2 is less than Q_1:

$$H = h_e + h_a = [0.0103\, Q^2 - 0.0415\, Q^2_2]\; [0.008\; (Q_1 - Q_2)^{1.85}] + 0.0540\, Q_1^{1.75} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The expression for Branch No. 2, when Q_2 is less than Q_1, is:

$$H = [0.0103\,Q^2 - 0.0415\,Q^2_2]\;[0.008\;(Q_1 - Q_2)^{1.85}] + 0.0540\,Q_2^{1.75}\;..(6)$$

When Q_1 is less than Q_2 the expression for Branch No. 2 is:

$$H = [0.0103\,Q^2 - 0.0415\,Q^2_1]\;[0.008\;(Q_2 - Q_1)^{1.85}] + 0.054\,Q_2^{1.75}\;...(7)$$

Equations (5), (6), and (7), may be used to compute the total losses in Branch No. 1 and Branch No. 2 of the wye with any division of flow between the two units. The total losses that were observed in the two branches of the wye during Groups (1) and (3) of the test runs, are plotted in Fig. 7. Equations (5) and (6) apply to these curves.

TOTAL FLOW-LINE LOSSES

With the losses in each part of the flow line and the laws governing them known, it was next desired to combine their values to determine the total flow-line losses for different divisions of flow through the two penstocks. This has been done in Table 1 for the two conditions of loading: (1) Equal flows through both turbines; and (2) unequal flows through the turbines (maximum condition of unbalance).

From the data in Table 1, Fig. 9 is plotted as a working curve to be used for determining flow-line losses and net heads on the turbines. Knowing the net head it is easy to compute the turbine-water consumption. This information is much used for storage and general hydrological computations.

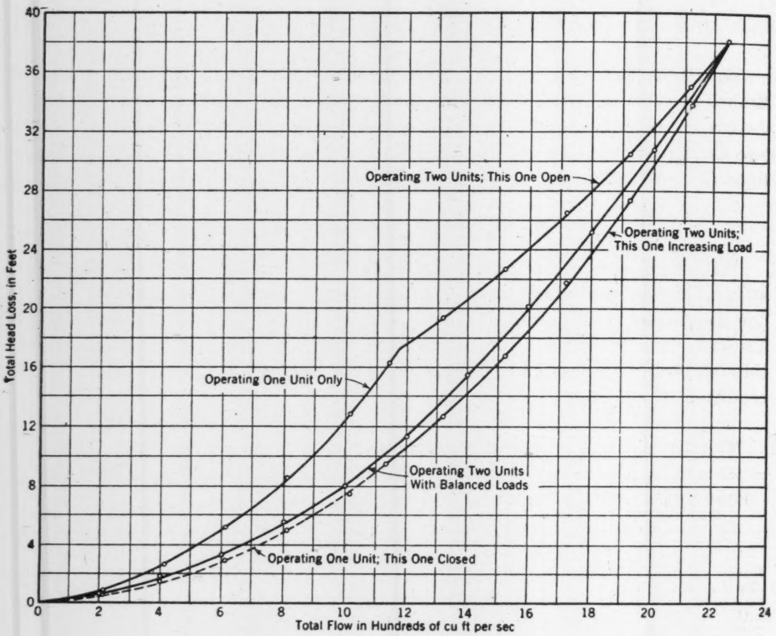

FIG. 9.—TOTAL FLOW LINE LOSS FROM FOREBAY TO SCROLL-CASE.

Williams-Hazen and Chezy Coefficients of Roughness

The final step in this part of the research was first to reconcile Kutter's formula and the Williams-Hazen formula for friction losses in concrete and steel-lined tunnels to the losses actually observed in these tests, and, then, to ascertain how well the coefficients commonly recommended for use in the formula fitted this particular flow-line installation.

To do this it was first necessary to compute the coefficients of roughness which were applicable to the converging steel-lined penstock between the surge tank and the wye in which section the losses had been determined. The coefficients of roughness that were obtained in this manner were used in computing the losses which must have occurred in the steel-lined penstock from the end of the concrete-lined tunnel to the surge tank. They were also used in computing the losses in the steel-lined section of the tunnel just below the vent. The sum of these two losses was removed from the total observed losses between the vent and the surge tank, leaving those losses which occurred in that part of the tunnel with a concrete lining. The coefficient of roughness applicable to the concrete-lined tunnel was computed from these losses by using the Williams-Hazen formula:

$$H = \frac{V^{1.852}}{1.668\, C_w{}^{1.852}\, R^{1.167}} \quad \dots\dots\dots\dots\dots\dots\dots\dots (8)$$

For the purpose of a comparison between the observed and the computed losses in a pipe, Equation (8) may be written:

$$H = \frac{V^{1.852}}{K} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots (9)$$

The coefficients of roughness which were obtained for the steel-lined penstock were found to vary from about 82 for very low velocities of flow to 96.5 for high velocities, as shown in Fig. 10, instead of remaining practically constant for all velocities. This variation is the result of the difference between the Williams-Hazen exponent of 1.852 which is applied to the mean velocity of flow and the exponent of 1.75 which was computed from the observed friction losses between the surge tank and the wye, the equation for these observed losses being:

$$H = \frac{V^{1.75}}{K} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots (10)$$

The coefficients of roughness which were computed for the concrete-lined tunnel were found to remain nearly constant for all velocities, averaging

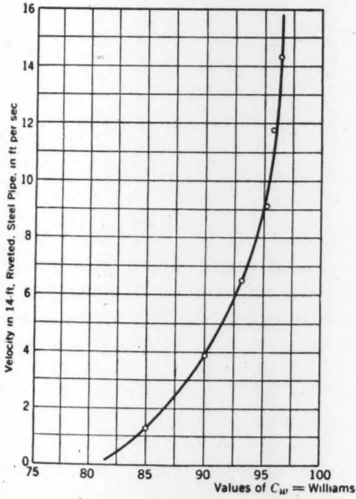

FIG. 10.—VARIATION IN WILLIAMS-HAZEN COEFFICIENT OF ROUGHNESS, C_w, WITH VELOCITY FOR PENSTOCK BETWEEN SURGE TANK AND WYE.

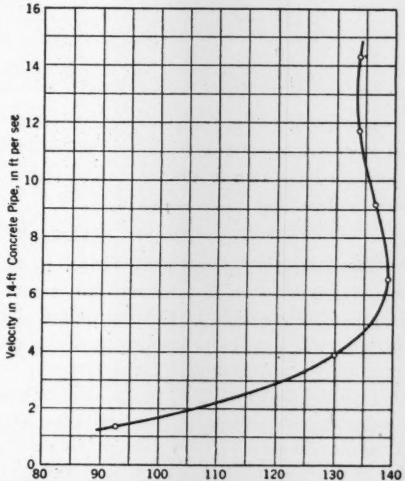

FIG. 11.—VARIATION IN THE WILLIAMS-HAZEN COEFFICIENT OF ROUGHNESS, C_w, WITH VELOCITY IN CONCRETE PRESSURE TUNNEL.

about 134, which is the value most commonly used. The computed values of these coefficients are shown in Fig. 11 where it is seen that, except for the lower velocities of flow, they varied within comparatively narrow limits.

In a similar manner the value of the Chezy coefficient, C, that was applicable to the concrete tunnel and steel penstock for different velocities of flow, was computed from the observed losses. The coefficient of roughness, n, that would be used to compute these values of C was determined from Kutter's formula. These data are plotted in Fig. 12.

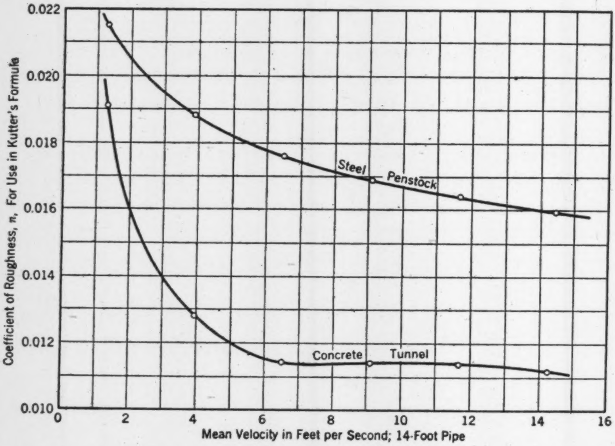

FIG. 12.—VARIATION OF KUTTER'S COEFFICIENT OF ROUGHNESS WITH VELOCITY, FOR CONCRETE TUNNEL AND STEEL PENSTOCK.

The values of n for the steel penstock were found to vary from about 0.022 for very low velocities of flow to 0.016 for high velocities. Likewise, the values of n for the concrete tunnel varied from about 0.020 for very low velocities of flow to 0.011 for high velocities.

CONCLUSIONS

The entrance losses were found to be small and varied almost exactly in proportion to Q^2. The losses that occurred in the concrete-lined tunnel were found to be the same as those which would be computed by the Williams-Hazen formula when using a coefficient of roughness equal to 134, which is the value commonly recommended for concrete-lined tunnels, thus proving the correctness of the formula for use on this particular part of the installation. When computing the losses in the concrete tunnel by means of the Chezy formula, it was necessary to vary Kutter's coefficient of roughness from 0.016 to 0.011 for different velocities, as compared to a value of 0.011 that is commonly used for designing.

The observed losses in the steel-lined penstock were found to vary with $Q^{1.75}$ instead of with $Q^{1.852}$ as would be the case when using the Williams-Hazen formula. As a consequence, in order to compute the true losses for this particular part of the installation when using the formula, it was necessary to vary the coefficient of roughness from a value of about 82 for the lower velocities to a value of approximately 96 for the higher ones. Thus, the formula was not applicable to the steel-lined tunnel of this installation when using a constant value for the coefficient of roughness. When using the Chezy formula for computing the losses in the steel penstock, it was necessary to vary Kutter's coefficient of roughness, *n*, between 0.020 and 0.016 for different velocities, as compared to a value of 0.016 that is commonly used for designing.

The losses in the wye-branch, which were found to be relatively high, were composed of eddy losses occurring above the tie-plate, and diversion losses which were created as a result of the curvature in the flow line at this point. These losses varied according to definite laws which were determined as a result of these tests.

Losses in the penstock branches were found to be composed of friction losses and diversion losses in the lower penstock bends. They were of a greater magnitude than would normally be the case, due to the presence of the diversion losses.

The diversion losses in the lower penstock bends were found to vary with the 2.20 power of the flow, while those in the wye-branch were found to vary with the 1.75 power. A comparison between the diversion losses at these points is of little significance, however, because the shape of the wye-branch was determined mainly by the requirements for mechanical strength rather than by the hydraulic efficiency that could be attained. Consequently, the cross-sectional shape and curvature of each branch in the wye are not comparable to the bend in each penstock branch.

The total flow-line losses from the forebay to either turbine scroll-case were found to increase when the loads on the two units were unbalanced. This was due chiefly to the eddy losses that occurred in the wye-branch. The losses in the flow line were found to be less when operating the two units with balanced, rather than with unbalanced, flows. However, this should not be done to the exclusion of allowances for turbine and generator efficiency under conditions of loading where their effect dominated the over-all efficiency of the plant.

The unsymmetrical arrangement of the spirals in the turbine scroll-case was found to produce unequal diversion losses in the two lower penstock bends. This inequality was relatively small and unimportant with regard to flow-line efficiency, but served to demonstrate the far-reaching effect of the eddies that resulted from the diversion losses.

ACKNOWLEDGMENT

The field work for this investigation was conducted under the supervision of Mr. W. A. Hill, of the Washington Water Power Company, in Spokane, Wash.

DISCUSSION

W. A. Hill,[3] Esq. (by letter).—An important addition to the data available concerning the hydraulic behavior of large pressure conduits in actual operation, is contained in this paper. Although it is to be regretted that no piezometer connection existed immediately above the wye branch, for the purpose of checking the wye-branch losses and, at the same time, affording a direct means of determining the friction losses in the steel-lined section of the tunnel, the conformity of the test points to the theory of the nature and location of the wye-branch losses is such that the validity of the analysis can scarcely be questioned.

The values of the coefficient, C_w, as derived, furnish an important confirmation of those already in use for the concrete section of the pressure tunnel; but the apparent exponential discrepancy, with respect to the steel-lined section, is unexplained. The additional point of observation, previously mentioned, would have aided materially in substantiating these results.

The most illuminating part of the analysis is that which deals with the losses occurring in the vicinity of the wye branch. Little work has been done with this special type of structure in the past, with a view to determining its behavior under varying conditions of flow and the magnitude of the losses involved. Mr. Fosdick segregates these losses into two classes, "eddy" losses and "diversion" losses; the former take place above the point of bifurcation and affect both penstock branches alike, whereas the latter occur beyond this point and reflect the energy losses in the individual branches only. Due to the destruction of directional velocity head, both are essentially impact losses, but their respective values are widely disproportional to the velocity heads involved. A comparison of velocity-head changes produced (see Table 2)—with corresponding losses observed, throughout the range of one unit shut down and the other increasing load—will illustrate this point clearly. For the range selected, $\Delta h_v = h_v$ (since $h_{v2} = 0$), and $\Delta h_{v1} = h_{v1} \sin^2 \alpha$ ($\alpha = 22° 30'$).

TABLE 2.—Comparison of Velocity-Head Changes and Corresponding Losses.

Q	Δh_v	h_e	Factor	Δh_{v1}	h_α	Factor
200	0.04	0.01	0.03	0.02	0.10	5 0
400	0.16	0.02	0.10	0.10	0.50	5.0
600	0.37	0.08	0.22	0.21	1.20	5.7
800	0.66	0.26	0.39	0.38	2.10	5.5
1 000	1.03	0.59	0.57	0.60	3.10	5.2
1 160	1.38	1.03	0.74	0.80	3.90	4.9

A glance at the respective factors for eddy and diversion losses in Table 2 reveals that the former never equal unity, indicating a partial recovery of velocity head; in the case of the diversion losses, however, the approximate factor of five indicates a loss far in excess of the total theoretical impact values.

---

[3] Hydr. Engr., The Washington Water Power Co., Spokane, Wash.

The obvious disparity in the relationship of these losses may lie, conceivably, wholly in the fact that all values of velocity heads used in the computations are based on average conduit velocities, whereas the observed effects result from the actual velocities at the points of varying influence. The velocity changes which produce the "eddy" losses may occur largely near the wall of the conduit, the higher interior velocities being gradually diverted toward the branch carrying the larger flow. That an opposite condition exists with respect to the "diversion" losses is a certainty, for inspection of the design shows that the greatest and most abrupt diversion of flow occurs on the produced axis of the pressure tunnel, where the velocity is at its maximum value. The conclusion to be drawn from these facts is that attempted computation of losses in structures of this character should be made only after giving careful consideration to the matter of velocity distribution.

The magnitude of the losses evident in this particular installation arrests the attention indeed. When a total head loss of 5 ft for one unit wide open, or of almost 4 ft for full plant load, occurs in such a short length of flow line, it is certainly time to give some attention to the matter of design. A quick computation of the horse-power equivalent of this loss will give some idea of its economic importance. However, as long as the problem is left solely in the hands of the structural designer, little, if any, improvement may be expected.

The "eddy" losses, characteristic of unbalanced flow, can never be eliminated entirely although their maximum effect can probably be considerably reduced; the "diversion" losses, which are by far the more serious, can be minimized by adequate care in design. The structural problem involved can be solved in several ways, the method to be used depending on such physical characteristics as internal pressure, size of conduit, and location of structure.

One method of combining hydraulic efficiency with structural adequacy, which is seldom, if ever, used in the United States, is that developed by the French engineer, M. Ferrand; for simplicity and effectiveness it is unexcelled. The device consists, essentially, of a manifold, of proper hydraulic design, which is entirely inclosed in a steel jacket of appropriate structural capacity. This jacket may be of spherical form, of combined cylindrical and hemi-spherical form, or of combined conical and hemi-spherical form, depending upon the dimensions of the inner structure to be housed. By means of open ports in the main penstock, the conduit pressure at any instant is immediately communicated to the otherwise closed chamber lying between the outer shell and the manifold proper. In this manner a uniform, and always balanced, support is furnished for the interior or water-conducting shape. It will be evident that the duplication of metal involved is of little moment, for the interior structure need be only of sufficient weight to withstand unbalanced kinetic pressures.

In view of the fact that the science of hydraulics is, and ever must be, in a large measure dependent upon empiricism, it is to be hoped that a keener appreciation of the certain benefit to be derived from the equipping and testing of future installations, will lead those responsible for the design and construction of hydraulic projects to incorporate in their plans provision for further work of this character. As a general rule, the expense involved in adapting a hydraulic structure to the rôle of laboratory model is so trifling, as compared with the value of the data that may be secured in this manner, that failure to do so can be construed only as a mark of professional indifference.

S. P. WING,[4] M. AM. SOC. C. E., AND J. N. BRADLEY,[4] AND H. P. EVANS,[4] JR., JUNIORS, AM. SOC. C. E. (by letter).—Most hydraulic formulas are essentially empirical and can only be used with confidence within the range for which their coefficients have been determined experimentally. The author's tests of a 14-ft penstock, with velocities as high as 14 ft per sec, give very welcome information at the extreme limit of existing experimental data.

It is to be regretted that the author failed to give his field observations. This has tended to confuse observational with derived results which, combined with a somewhat unusual method of analysis, has made it difficult to compare these tests with the work of others. Since the results of this test, together with those from a very few others, form the basic data from which coefficients for larger installations must be extrapolated, it is thought that a few notes concerning the accuracy of the tests and a brief analysis of the results in a form more readily comparable with the work of others will be of value.

The experiments and analyses consist essentially in the determination of the hydraulic losses in a long pressure conduit with various fittings. Piezometric measurements were made on five sections as follows, lengths being given in pipe diameters: (1) Intake to vent, 18 diameters; (2) vent to Adit 1, 385 diameters; (3) Adit 1 to Adit 2, 274 diameters; (4) Adit 2 to surge tank, 98 diameters; (5) and surge tank to scroll-case.

Section (1) consists of the trash rack, 10.8 diameters of concrete-gathering tube, 4.1 diameters of 14-ft steel pipe to the center line of a horizontal butterfly valve, and 1.1 diameters of steel pipe from the valve to the vent. High-speed water-level recorders measured the hydraulic grade at the lake and the vent.

Section (2) consists of 1.7 diameters of steel pipe, and 383.3 diameters of 14-ft straight concrete-lined tunnel.

Section (3), from Adit 1 to Adit 2, consists of 274 diameters of 14-ft straight concrete-lined tunnel. The hydraulic grades at both adits were measured by mercury manometers connected to single taps in the conduit.

Section (4), from Adit 2 to the surge tank, consists of 98 diameters of 14-ft concrete-lined tunnel, followed by 28.5 diameters of 14-ft single-butt, strap-riveted, steel pipe which contains a 30° bend with a radius of 4.20 diameters. The surge-tank riser, 25 diameters down stream from the bend, is 14 ft in diameter and makes a vertical angle of approximately 19° with the penstock. Water elevations were read by a single piezometer connecting into the riser.

Section (5), from the surge tank to the scroll-case, consists, first, of 712 ft of steel pipe, varying in diameter from 14 ft at the surge tank to 12 ft 6 in. at the wye connection (average, 54 diameters of 13.25-ft pipe). Part of the pipe is single-butt and the remainder is double-butt, strap-riveted. At the symmetrical wye, which has a central angle of 45°, the pipe is reduced from 12 ft 6-in. to two 8 ft 10-in. branches. From the center line of the wye to the center line of a 29° bend with a radius of 7.5 diameters, is a distance of about 6.2 diameters, and from the bend to the center line of the balanced valve is 7.6 diameters, the total length from the wye to the center line of the valve being 13.8 diameters of 8 ft 10-in. pipe. A ring piezometer is connected to a dampened mercury manometer, 15 ft (1.7 diameters) from the center line of the valve. The piezometer connections are 18 in. up stream from the 6 ft 6-in. opening to the turbine scroll-case in the wall of the reducer which follows the valve.

---

[4] Engrs., U. S. Bureau of Reclamation, Denver, Colo.

Prior to the hydraulic tests reported in the paper, efficiency tests were made on the turbines using the Gibson method to determine the discharge. For this purpose a differential manometer was connected to a single tap at a point about 2 diameters down stream from the end of the wye and 1.0 diameter up stream from the bend, and to a single tap at a point about 4.5 diameters down stream from the end of the bend and 0.5 diameter ahead of the valve, the length of included pipe being 8.8 diameters. Simultaneously with the differential pressure readings, turbine head readings were made at the ring piezometer as well as such electrical measurements as were necessary to compute the generator efficiency. Each unit was tested with the other unit closed down, variations in load being obtained by controlling the wicket-gate openings of the unit being tested. From data thus obtained discharge curves were plotted for varying generator outputs, heads, and gate-openings. These curves were then used in the later tests to determine the mean velocities.

Since the author does not give the details of the efficiency tests, it is difficult to estimate their accuracy. As previously described the locations of the pressure taps were near fittings which caused abnormal pressure and velocity distributions in the flowing water, thus making high precision difficult.

The total energy passing a given cross-section of a conduit per second is expressed by: $w \int \left(z + \frac{p}{w} + \frac{v^2}{2\,g} \right) v \, da$. Where unusual conditions exist, such as near fittings, the law expressing the variation of each of these quantities throughout the cross-section is unknown; for example, the ring piezometer, from which the head on the turbine was obtained, is only about 7 diameters below a combined vertical and horizontal bend, 1 diameter below the balanced valve, and only 0.22 diameter up stream from the scroll-case. At this section. the stream lines would not be parallel to the pipe walls.[5] If actual velocity and pressure traverses were to be made across the section the following might represent the magnitude of the corrections required in the nominal values to obtain the true energy grade: ± 1.0 ft $+ 0.1\, h_v + 0.2\, h_v = 0.3\, h_v \pm 1.0$ ft.

For the maximum h_v measured (5.3 ft), this correction equals 0.6 ft to 2.6 ft, and is from 0.16% to 0.70% of the head on the turbine. Although this correction is nothing but an estimate, certain of the tests discussed later give confirmatory evidence. It should be noted that such a percentage correction if necessary also applies directly to the efficiency determination.

---

[5] "Strömung in Spiral Gehausen", by Kranz, V. D. I., *Forschungs*, Heft 370.

Considering the difficulties under which the discharge measurements were obtained originally and the errors involved later in transferring electrical measurements at various gate-openings to velocities, it is believed that for the hydraulic tests an error of at least 3% in the velocities can be expected.

The difficulties which have just been discussed in determining the true energy grade at a point where the stream lines are not parallel and where the velocity and pressure distribution throughout the flowing stream are unknown, apply to three other of the piezometric locations. The effect of this condition will be discussed in connection with the tests.

Section (1).—Intake to Vent.—This section contains trash rack, gathering tube, and friction losses plus an apparent drop in pressure across a butterfly valve. The vent at which the hydraulic grade was measured is only 0.5 diameter down stream from the leaf of the open gate. From Italian tests[6], in which the differential drops in hydraulic grade across butterfly valves were measured, the drop across the valve may be estimated as 0.45 h_v for the author's test, the velocity head being that for the 14-ft pipe. The friction losses in the intake section may also be estimated as 0.1 h_v. Subtraction of the sum of the friction loss and valve drop from the nominal energy loss indicates that the net trash rack and gathering tube entrance losses certainly do not exceed 0.05 h_v and are probably less. The losses given in Fig. 3, which approximate 0.60 h_v, are, therefore, not net intake losses, but consist largely in the drop across the butterfly valve.

Sections (2) and (3).—Vent to Adit 2.—The writers consider that the tests made on Sections (2) and (3), which include 659 diameters of a straight 14-ft concrete conduit, are by far the most accurate and valuable of the author's data and are deserving of more discussion than he has given them. There are few tests of large pipe at high velocities, as free from errors due to the effects of bends and fittings as these tests. Two methods of treating the data are possible: Either Section (3) alone can be analyzed, the difference between the readings of Adit 1 and Adit 2 giving the energy loss directly, as at these sections the velocity distributions are the same; or Section (2) can be combined with Section (3), and the loss over a much greater length of pipe can be used. In this latter case a correction must be applied to the drop in the hydraulic grade as measured to allow for the influence of the butterfly valve. Either of the foregoing two methods yields substantially the same results. However, since errors in piezometer readings affect the accuracy inversely proportional to the length of section in which the friction loss is determined, Sections (2) and (3) combined appear to give the more reliable results, even when the additional error involved in estimating the valve correction is considered. The method of making this estimate is as follows:

If to the reading at the vent (1.0 h_v + 0.45 h_v) is added, the energy grade up stream from the valve is obtained. The energy loss due to the valve, which, of course, is less than the piezometer drop across it, occurs in Section (2) and may be estimated as 0.25 h_v. At Adit 2 the velocity profile is fully developed, so that the true energy head may be approximated by adding 1.05 h_v to the piezometer reading. The net energy head loss in Sections (2) and (3) thus equals the difference in readings between the vent and Adit 2, plus 0.15 h_v. This valve correction may only be within $\pm$ 0.15 h_v of the correct value, but since the measured loss approximates 7.0 h_v, the percentage error would only be of the order of 2 per cent. The probable error of the mean of sixteen field determinations of the friction drop is computed to be about 1 per cent. Combining all errors it is believed that the determinations of the friction factor have a probable error of not more than 4 per cent.

---

[6] *Energia Electtrica*, November, 1933, p. 922.

The best method for estimating and comparing hydraulic losses in pipes, which the writers have found, consists in plotting experimental results on logarithmic paper, using friction factors, f, equal to $\frac{2\,g\,D\,H}{L\,V^2}$, as ordinates and Reynolds' numbers, $\frac{V\,D}{\nu}$, as abscissas. Good discussions of the theoretical basis for using these non-dimensional parameters have appeared elsewhere.[7] A very practical reason for using such plots, however, is that they provide an excellent means of assembling and comparing visually the entire range of experimental data. From them the errors probable in extrapolation, or in using formulas, may be easily estimated.

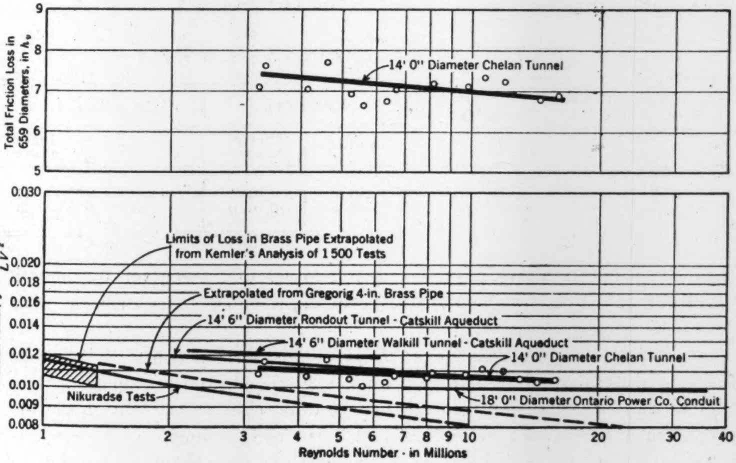

FIG. 13.—FRICTION LOSS IN CHELAN TUNNEL.

---

[7] "Modern Conceptions of the Mechanics of Fluid Turbulence", by Hunter Rouse, Assoc. M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., January, 1936, p. 21; also, "A Study of the Data on the Flow of Fluids in Pipes", by E. Kemler, *Transactions* A. S. M. E., Hyd. 55-2.

Fig. 13 is the plot of the experimentally measured losses between the vent and Adit 2 of the Chelan Tunnel, both the total measured loss and the friction factor, *f*, being plotted against the Reynolds' number. For comparison with this test the results of equally reliable experiments made on two of the tunnels of the Catskill Aqueduct and on the 18-ft tunnel of the Niagara Power Company, as given by Kemler, have been added. These data, obtained from straight concrete conduits, for which the concrete was poured against steel forms, approximating a mortar finish the surface of which was free from form marks, show a consistent trend of losses over a considerable range of Reynolds' numbers. They become of great value, therefore, for the purpose of extrapolating to Reynolds' numbers of from 30 000 000 to 80 000 000, a range which covers flow in pipe from 20 to 50 ft in diameter.

To aid in extrapolation, tests on smooth brass pipe at high Reynolds' numbers have also been plotted. As concrete pipe becomes larger and larger, its surface relatively tends to approach in smoothness that of the smaller brass pipe. The lower limit for losses in large pipe, therefore, may be expected to approach the losses found for brass pipe at similar Reynolds' numbers.

In his analysis of the losses in the concrete pipe, the author apparently used the measured loss between the vent and the surge tank and, from this, subtracted the estimated loss in the steel pipe, making no other correction. Table 3 indicates the differences in the two methods of treatment.

TABLE 3.—COMPARISON OF LOSSES IN PIPES

4	4 360 000	0.0128	0.0120	131	133

Although the author's values are within 2 to 9% of those given by the writers, the differences are large enough to be of significance in connection with the design of large pipe lines.

Section (4).—Adit 2 to Surge Tank.—This section contains losses due to friction in both concrete and steel pipe, a 30° bend, and an apparent pressure change due to expansion into the surge-tank riser. At Adit 2 the energy grade may be obtained by adding 1.05 h_v to the piezometer reading. At the surge-tank riser neither the average pressure nor the velocity head of the flowing water is known, therefore, the energy grade at this point cannot be computed directly. As an estimate the author assumed that, due to the acute angle between the riser and the penstock, the water level in the riser would be lowered about 0.1 h_v. Therefore, he obtained the nominal energy grade by adding 1.1 h_v to the surge-tank reading. The correctness of this assumption may be checked roughly by estimating the friction and bend losses in the steel pipe, adding the friction losses, as obtained from the experiment of the concrete pipe, and subtracting the sum from the energy grade at Adit 2. The following is the computation using the data from the author's Test No. 4:

At Adit 2:

Elevation of hydraulic grade, in feet = 1 069.73

Mean velocity, 12.16 ft per sec; 1.05 h_v, in feet = 2.42

Energy grade, in feet = 1 072.15

Loss Between Adit 2 and Surge-Tank Riser:

Experimentally determined friction loss in concrete pipe, $98D \times 0.0106\ h_v$ = $1.04\ h_v$

Estimated friction loss in steel pipe, $28.5D \times 0.0147\ h_v$ = $0.42\ h_v$

Estimated friction loss in bend = $0.06\ h_v$

Total energy loss, in feet = $1.52\ h_v$ = 3.50

At Surge Tank:

Energy grade at Adit 2 less loss, in feet = 1 068.65

Velocity head, in feet $1.05\ h_v$ = 2.42

Computed hydraulic grade, in feet = 1 066.23

Measured hydraulic grade, in feet = 1 067.04

Re-gain of head, in feet $0.34\ h_v$ = 0.81

The average re-gain of velocity head at the surge tank, as determined by similar computations for all tests having a velocity of 1 ft, or more, was $0.15\ h_v$. Instead of a re-gain, the author assumed there would be a drop due to suction. The result is that in all his computations of the losses in Section (5) he used a surge-tank energy grade $0.2\ h_v$ above that which the writers consider applicable.

Section (5).—Surge Tank to Scroll-Case Piezometer Ring.—This section contains the following losses: (1) Sudden contraction loss from surge-tank riser; (2) friction loss in 54 diameters of 13.25-ft. steel pipe; (3) wye loss; (4) friction loss in 13.8 diameters of 8.83-ft. pipe; (5) 30° bend loss; and (6) balanced valve drop. Since the velocity and pressure distributions at the surge tank and the piezometer ring are both different and unknown, correction factors must be applied to the hydraulic grade drop in order to obtain the total true energy loss in this section. According to previous estimates the true energy grade at the surge tank is about $0.2\ h_v$ less than, and that at the scroll-case, $0.3\ h_v$ higher than, the grades assumed by the author, the combined corrections reducing the total loss as given by the author by about 25 per cent. These figures are applicable to the condition of equal discharge in each of the penstock branches.

Turning next to the author's methods of distributing the total energy loss from the surge tank to the scroll-case into its six component parts, and from these data deriving laws for the losses in a wye, in a bend, and in a steel pipe, the writers consider that in spite of the ingenious methods which were used to make the most of the meager information available, the conclusions must be considered to apply only to the particular installation tested with, moreover, the reservation that piezometric drops are involved and not true energy losses. Even to obtain experimentally the true losses for this single installation, six additional measurements would have been required. For example, to evaluate the losses due to the bends in the wye branch the author made use of the differential pressures measured in the turbine efficiency tests. As already indicated, in this case the absolute magnitude of the pressure drop obtained depended both on the particular location of the piezometers on the pipe sections and on the conditions of flow both up stream and down stream from the piezometer locations. The pressure drop actually measured approximated 0.15 h_v for the higher range of velocities tested. This is three times the energy loss estimated from various bend experiments which have been made on small pipes[8]. Although the results from the latter cannot be extrapolated with any confidence to a bend of the size tested by the author, on the other hand, results obtained under such unfavorable field conditions as existed in these tests can only be regarded with extreme caution.

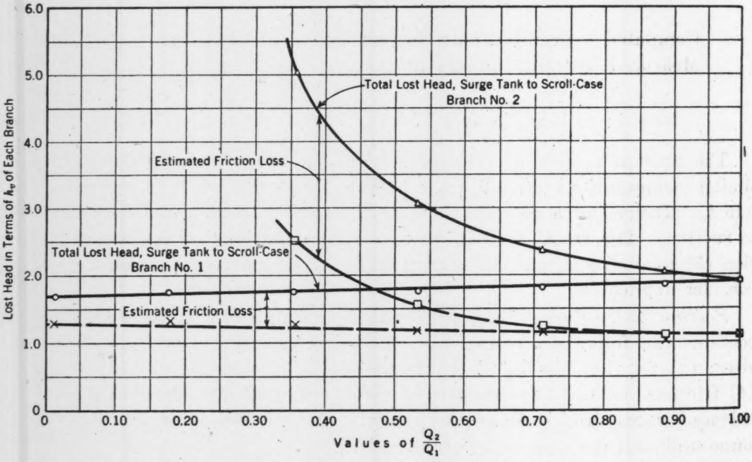

Fig. 14.—Lost Head from Surge Tank to Scroll-Case for Flow of 17 to 1 125 Cubic Feet per Second, in Branch No. 2, and Flow in Branch No. 1 Uniform at 1 125 Cubic Feet per Second.

It is believed the author's treatment of "eddy losses in the wye branch above the tie-plate" and of the losses through the balanced valve is inadequate. Perhaps a piezometric drop up stream from the tie-plate may be expected, but the major part of any energy loss must occur down stream from any obstruction. The author estimated the energy loss through the valve on the basis of the computed friction loss. An additional loss would be expected due to the curvature of the stream lines. On the whole, the writers consider that the best use which can be made of the author's field measurements in Section (5) is for the purpose of comparing the measured nominal total loss in energy due to a wye, 30° bend, and valve with that of a usual estimate.

---

[8] *Transactions*, Munich Hydr. Inst., *Bulletin 3*.

On Fig. 14 the nominal total lost energy head from the surge tank to the piezometer ring, as obtained from Table 3, in terms of the velocity head existing in each of the 8.83-ft branches, has been plotted for various values of the ratio of the discharges in the two wye branches. Subtracting from these total losses, the friction loss in the steel penstocks, as estimated by the writers, two curves are obtained which give the sum of the contraction loss at the surge-tank riser, the wye loss, the 30° bend loss, and the balanced valve loss.

It will be noted, from these curves, that for increasing values of $\frac{Q_2}{Q_1}$, the losses in Branch 2 decrease on account of the great reduction in the deceleration losses through the wye. When $\frac{Q_2}{Q_1} = 1$, the nominal loss is $1.1 \frac{V^2}{2g}$. The following is the writers' distribution of the energy losses for this case, expressed in terms of the velocity head of the branch:

Entrance loss at surge-tank riser	$0.05\ h_v$
Wye loss	$0.20\ h_v$
Bend loss	$0.05\ h_v$
Apparent loss in valve	$0.25\ h_v$
Total	$0.55\ h_v$
Errors in estimates of losses and differences between true and nominal energy gradients at ends of section	$0.55\ h_v$
Total	$1.10\ h_v$

In conclusion, the writers feel that although the author's experiments did not provide adequate data from which true energy losses in bends, wyes, or steel pipe could be determined, they did give required operating data, and information on the friction losses in large concrete pipe which long will be of great value to other engineers.

The courtesy of the author in supplying the writers with information additional to that in the original paper has been much appreciated. To him and to the Washington Water Power Company are due the thanks of all hydraulic engineers for the expenditure of the time and money required in making and analyzing field tests on a large conduit and presenting the results to the profession.

W. S. MERRILL,[9] M. AM. SOC. C. E. (by letter).—Hydraulic engineers are indebted to Mr. Fosdick for the data on friction losses given in his paper describing the Chelan Tunnel and Penstock tests. Data on friction losses in steel penstocks of various sizes and with different types of joints are quite abundant, but similar data for large, concrete-lined tunnels are comparatively rare. The quite complete data given in this paper are, therefore, all the more valuable.

The value of $n = 0.0114$ in Kutter's formula is relatively low and indicates an excellent lining job, probably considerably better than the average to be found in concrete-lined tunnels. Engineers using this or a slightly higher, value in the design of concrete tunnels, must be sure that the figure they adopt is consistent with the kind of concrete surface that may reasonably be expected.

Figs. 10, 11, and 12, showing how the roughness coefficient varies with the velocity of the water in the conduit, are of interest. The relatively constant coefficient for velocities greater than 6 ft per sec in the tunnel should be noted for both the Kutter and the Hazen and Williams formulas. Hydraulic engineers, including Kutter himself, have realized that n is not an exact, unvarying constant. In spite of this, most textbooks, diagrams, and tables make no mention of this fact, and it probably is unknown to many engineers. Corresponding friction loss data for another long, concrete-lined tunnel probably will be of interest. The Waterville Tunnel[10], of Carolina Power & Light Company, is approximately 32 000 ft long, with three long-radius bends in plan. The upper 21 000 ft of the tunnel is on an unbroken grade of 0.285 per cent. At the lower end of this section, the tunnel drops vertically about 500 ft in a shaft 14 ft in diameter, and then extends the remainder of the distance to the wye on grades of 0.20 and 1.5 per cent. In section, the tunnel is horseshoe-shaped with an area of approximately 158 sq ft. The lining, with the exception of the invert, was placed monolithically around movable steel forms and is considered to be an example of excellent work, both as regards alignment and smoothness of the surface. The invert was screeded to shape and is not quite as smooth as the remainder of the lining.

Measurements of head loss in the tunnel were made in 1930, in connection with the efficiency tests of the units, which were conducted by the Gibson method[11]. To determine the exact loss of head in the tunnel for the various flows, it was necessary to make allowance for entrance head losses and for the losses of head at the two 90° bends. Based on the measured water flow and the head lost, the value of n in Kutter's formula was found to be approximately 0.014 for the velocities measured. This was the value used in the design.

ELLERY R. FOSDICK,[12] ESQ. (by letter).—The loss tests that were made in the long flow line at Chelan Station seem to have supplied a welcome addition to this kind of engineering information, judging by the excellent discussions presented. The scarcity of information on this subject is not altogether due to a lack of existing installations upon which suitable tests might be run, but from a lack of research activity. Adequate facilities enabling such tests to be made are not usually found on the older installations and are frequently not included in the newer ones in spite of the negligible cost involved. It would seem expedient and advisable, therefore, that, in the future, engineers recommend strongly that hydraulic installations be equipped with properly designed connections for use in conducting hydraulic loss tests, even if they are not contemplated at the time of construction.

The method of combining improved hydraulic efficiency with structural adequacy by means of the manifold and shell type of construction that is mentioned by Mr. Hill is one that has long been known to hydraulic engineers but has been seldom used. It is particularly suitable for use in reducing the fluid losses that result from conduit bends and branches, and with the present knowledge that is available regarding these losses it is likely that in some future installations designers will incorporate this type of construction in a manner that will materially improve the operating characteristics of flow lines and penstocks.

Great progress has been made in other fields of mechanics but, until recently, the science of hydraulics has been largely based upon empiricism. The use of a dimensionless parameter as a means for comparing the hydraulic performance of various conduits was first made by Osborne Reynolds in the last part of the Nineteenth Century. For many years little or no attention was given to this discovery but, more recently, considerable progress has been made in the use of this basis, which is commonly referred to in terms of the Reynolds number.

The value of the Reynolds number as a basis for comparing the losses in conduits having a smooth concrete lining is well demonstrated in Fig. 13 by Messrs. Wing, Bradley, and Evans. As a result of being able to correlate these data it is possible to extrapolate the results with a considerable degree of accuracy for a range of Reynolds' numbers covering the flow in pipes much larger than any yet tested. The losses occurring in conduit bends and branches may likewise be compared by this method.

The hydraulic properties of the various types of conduits and equipment have long been, and still are, the subject of much investigation and study. As a result of this work the efficiency of flow lines and hydraulic equipment has been improved. However, no material changes have been made in the design of conduit bends and branches so as to decrease the losses that result from them, and these appear to be among the few remaining types of hydraulic structures that have sufficient losses in some instances to justify material changes in design.

Several investigators, both in the United States and in Europe, have made extensive studies of the losses in conduit bends. Sufficient information is now available to permit the construction of bends that will materially decrease the losses resulting from this type of structure.

The laws governing the losses in conduit branches are closely related to those governing losses in bends, but studies of these losses have received comparatively little attention by investigators. Some additional work along this line could very well be done to advantage.

A comparison of the loss factors as determined for the 22° 30′ wye in the Chelan penstock, with the loss factors that were found by Franz Peterman[7] in laboratory tests of a 45° wye when extrapolated for the same ratio of branch area to main-line area as the Chelan wye, are shown in Fig. 15. It will be observed that the shape of the curves for the relation of the loss factors to the ratio of the flow in the branch as compared to the flow in the main line is similar and that the loss factor for the 22° 30′ wye when $\frac{Q_1}{Q} = 1$, or with all the flow passing through one branch, is approximately 23% of the loss factor for the 45° wye. This is about the same relationship that is normally found between the loss factors in single-branch miter bends of 22° 30′ and 45°, respectively.

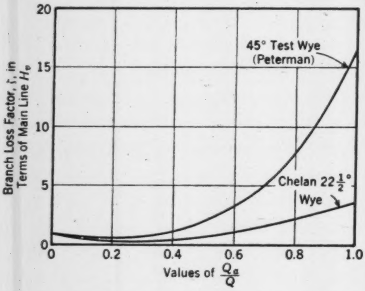

FIG. 15.—RELATION BETWEEN LOSS FACTORS AND DIVISION OF FLOW FOR 45-DEGREE AND 22.5-DEGREE SHARP-EDGED WYE BRANCHES.

In Fig. 16, has been plotted the loss factors for a 30° miter bend for Reynolds numbers from 70 000 to 250 000 as determined by Werner Schubart[8].

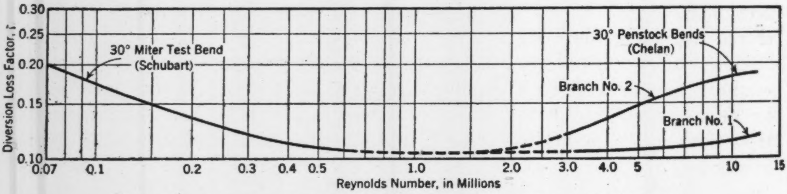

FIG. 16.—COMPARISON OF LOSS FACTORS FOR CHELAN PENSTOCK BENDS WITH RESULTS OF LABORATORY TESTS.

The loss factors for the lower 30° bend in the Chelan penstocks for Reynolds' numbers from about 3 000 000 to 13 000 000 have also been plotted on this diagram.

The loss factors for miter bends have been found by investigators to remain practically constant for values of Reynolds' numbers greater than 250 000, and it will be seen from Fig. 16 that the curve of loss factors for Chelan Penstock Branch No. 1 falls approximately on the extension of the curve of loss factors for the 30° miter bends that were tested in the laboratory. The curve of loss factors for Penstock Branch No. 2 has an upward slope which appears to be in error and for which no satisfactory explanation can be given. The loss factors in each of the penstock bends are undoubtedly influenced to some extent by the disturbance to linear flow originating in the wye-branch which is located about six diameters above, and these factors, therefore, should be used only as approximate values for the purpose of extrapolating the more precise laboratory factors for use with the larger Reynolds' numbers.

The fairly close agreement that exists between the results of laboratory tests and the losses that were observed in the Chelan wye-branch and the penstock bends, that have been previously cited, indicates that these data are fairly reliable and have an accuracy that falls within the limits normally obtainable by field tests of this kind when subject to the various disturbances encountered. The losses that were estimated for certain parts of the Chelan flow line by Messrs. Wing, Bradley, and Evans may be subject to considerable error when applied to this particular installation and should be so regarded when noting differences between their estimates and the observed data.

Paper No. 1953

PROPOSED IMPROVEMENT OF THE CAPE COD CANAL

BY E. C. HARWOOD,[1] ESQ.

WITH DISCUSSION BY MESSRS. C. S. JARVIS, GEORGE R. RICH, AND E. C. HARWOOD.

SYNOPSIS

The Cape Cod Canal has been open to navigation for twenty-one years, but could accommodate only 20% of the North Atlantic coastwise shipping in 1934 because of limited depth and width. Improvement is economically justified. For several years following the purchase of the canal by the Federal Government, plans for improvement have been under consideration. The most important question involved has been whether there should be locks, or a wider, open canal. The engineering and other difficulties involved in each case are discussed, together with the reasons for selecting the open canal. The new bridges which have been constructed are of unusual interest, one having the longest vertical lift span in the world. Construction methods include excavation by land methods as well as by dipper and by hydraulic dredging. The tide and current conditions are important because of their effect on navigation. The writer has attempted to predict the maximum current to be expected.

INTRODUCTION

The Cape Cod Canal is situated in Southeastern New England at the narrow neck where Cape Cod joins the mainland of Massachusetts. It is approximately 50 miles south of Boston and connects Cape Cod Bay on the east with Buzzards Bay on the west. The general location of the canal and the ocean routes from which the shipping through the canal is drawn, are shown in Fig. 1.

NOTE.—Presented at the meeting of the Waterways Division, New York, N. Y., on January 16, 1935, and published in October, 1935, *Proceedings*.

FIG. 2.—GENERAL MAP OF CAPE COD CANAL.

Including its approach channels in Buzzards Bay, the canal has a total length of 13 miles. Beginning at the Cape Cod end, the approximate widths at various sections of the canal (see Fig. 2) are stated in Table 1. The project depth of the canal is 25 ft but this depth has not actually been maintained for several years. At present (1935), the controlling depth is approximately 22 ft.

TABLE 1.—Approximate Channel Widths

Location	Bottom Width, in Feet		Length of section, in feet
	East end of section	West end of section	
Cape Cod approach	300	300	2 500
Land cut	300	300	2 000
Land cut	300	205	1 000
Land cut to a point west of railway bridge	205	205	35 800
To Buzzards Bay	205	250	200
Through Buzzards Bay	250*	250*	29 000

* At turns, the width is 450 ft.

Until June, 1935, the canal was crossed by three drawbridges, each having a horizontal clearance of 140 ft. Necessarily, these structures limited the effective width of the canal, and it was generally regarded as safe for one-way traffic only—at least as far as the larger vessels were concerned. The new bridges (which are discussed in greater detail elsewhere in this paper) have a horizontal clearance of approximately 500 ft and a vertical clearance of 135 ft.

Historical Summary

The first agitation for a canal across Cape Cod followed the establishment of the old Dutch trading post, shortly after the Pilgrims settled at Plymouth, Mass. It is reported that Miles Standish ascended the Scusset River and then crossed the intervening land to the head-waters of the Monument River, there meeting the Dutch traders from New Amsterdam. The commercial use of this narrow neck of the peninsula dates from that historic time.

As early as 1697, the General Court of Massachusetts adopted a resolution providing for a survey to determine whether or not a canal would be practicable. There is no record of the report, which undoubtedly followed, and it was nearly eighty years later that the Colony of Massachusetts again authorized a study of the problem. The Revolutionary War interfered with the completion of the survey, and, in 1791, another committee was appointed to examine and report on the project.

In 1824, Congress passed an Act directing that surveys be made and the report of Maj. P. H. Perault, U. S. Topographical Engineer, was printed in 1830, after being approved by the State of Massachusetts. The project considered at that time was for a canal having a bottom width of 36 ft and a depth of 8 ft, with locks. It is interesting to note that the general public expected the canal to be built immediately thereafter, and that it was even described abroad as one of the great public works projects about to be undertaken.

In 1860 the canal project was reviewed once more, this time by the Governor of Massachusetts. The Legislature ordered a committee of engineers to report on it, and the resulting document is the first comprehensive report of the entire project.

This committee suggested a canal with a bottom width of 120 ft and a depth of 18 ft. Although locks were contemplated, it is interesting to note that apparently the members of the committee were among the first to realize that it might be possible to construct a canal without locks. This suggestion was stated more definitely in 1870 by Brevet Maj. Gen. J. G. Foster, of the Corps of Engineers, U. S. Army, who pointed out at that time, that in spite of the difference in head between the water levels at the two ends of the canal, the resulting currents would not be sufficiently great to require locks.

Subsequently, various charters were granted to individuals or companies that hoped to construct the long discussed canal. It was not until 1883, however, that any earth was actually excavated at the site. Mr. Frederic A. Lockwood, who was something of a mechanical genius, had invented a crude hydraulic dredge. Through his efforts, a company was formed and a channel nearly 1 mile long, 15 ft deep, and about 100 ft wide, was actually dug.

Fortunately, the land for the right of way was obtained at that time, and through the foresight of Col. Thomas L. Livermore it was held until the work was begun in earnest. Had it been permitted to revert to the original owners, there is no question but that the subsequent efforts to obtain a Cape Cod Canal would have found progress hampered by excessive costs for the land involved.

At successive intervals, the Massachusetts Legislature granted other charters to companies which proposed to build the Cape Cod Canal, but it was not until 1904 that financial interests of sufficient strength to carry the project through took an active interest in the work. At that time, Mr. DeWitt C. Flanagan presented the project to the late August Belmont, of New York, N. Y., and obtained a promise of action when the general financial outlook improved.

In 1909, Mr. Belmont decided to begin construction and a construction company was organized for that purpose. The details of the organization, the charter, and the procedure followed, have been well described by the late William Barclay Parsons, Hon. M. Am. Soc. C. E.[3]

OPERATION EXPERIENCE

The canal was opened to traffic in 1914, at which time the depth was approximately 15 ft and the bottom width about 100 ft. Traffic never reached the anticipated tonnage, due in part to the fact that the depth was insufficient and in part to the currents existing in the canal, which made navigation hazardous in its narrow width.

During the World War, the operation of the canal was taken over by the Federal Government. Of course, traffic increased greatly during that period because of the fear of German submarines on the outer route. After the World War, the private interests that had built, and formerly operated, the canal refused to accept its return by the United States Government, and efforts were made to persuade Congress that it should be purchased with Federal funds. After protracted negotiations and condemnation proceedings, Congress finally authorized its purchase by the United States for the sum of $11 500 000 in January, 1927.

---

[3] "The Cape Cod Canal", by William Barclay Parsons, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1.

Prior to acceptance by the United States, dredging to the full project dimensions was required so that a bottom width of 100 ft and a depth of nearly 25 ft were available throughout.

From 1928, when the Government assumed ownership, to the present time (1935) more than $1 000 000 has been spent in maintenance dredging, but the material removed is believed to have come primarily from the banks of the canal. Apparently, there has never been any tendency for sand to enter the canal at either end.

Modern Widening Operations

Since 1933, funds have been available for further widening at the bends and a 70-ft cut was completed early in December, 1934. Subsequently, two large dredges made an additional 35-ft cut into the south bank. The canal now (1935) has a bottom width of 205 ft throughout and a controlling depth of approximately 22 ft. (At the old bridge locations it has been impossible to obtain the full 205-ft bottom width for the time being. That work will be done when the old bridges have been removed.)

The canal is used by a large volume of shipping, both passenger and freight, as well as the slow-moving tows of barges. Some conception of the volume of shipping can be obtained from the record for 1934, which totaled 2 792 000 cargo tons and 11 500 vessels.

Why Improve the Canal?

There are two principal reasons for considering further improvement of the Cape Cod Canal. In the first place, the hazards of the outside route around Cape Cod are well known and by many are considered more serious than those of Cape Hatteras. These dangers may be classified under a number of different headings, as follows: Exposure, lack of refuge, shoals, zigzag courses, currents, storms, ice, and fogs.

In attempting to round Cape Cod a vessel is necessarily exposed to the elements from the time it leaves the vicinity of Martha's Vineyard to Provincetown, a distance of nearly 100 miles, and there is little or no shelter provided by the low-lying land of the Cape itself. Practically all the seriously dangerous storms in the vicinity come from either the northeast or the southwest, and the course followed is especially exposed to northeast storms. In contrast with the route through the Cape Cod Canal, which is sheltered for approximately 60% of the distance between New York and Boston, the outside route involves an equal percentage of the journey without any shelter.

There are absolutely no harbors of refuge along the outside route. Provincetown might be so regarded, but the harbor is open to the southwest storms and, therefore, is not an adequate harbor of refuge. Other minor harbors offer only 15-ft depths so that they cannot be used by the modern larger sea-going barges, motor ships, and steamers.

The shoals on the outer route have long been known to be particularly dangerous because of their shifting character and the impossibility of maintaining a straight channel through them. Although there is some shoaling in the canal itself, maintenance dredging has been sufficient to preserve a reasonable project depth, and there is every reason to believe that, when the banks have been properly riprapped, the constant shoaling that now occurs will greatly decrease.

Much has been heard of the currents in the Cape Cod Canal itself, and it is sometimes forgotten that the tidal currents over the shoals east of Cape Cod although comparatively weak, often change in direction and make the following of a given course, under some conditions, difficult indeed. At certain places on the outside route a rotary current, with a velocity of approximately 2 knots, has been observed. In the vicinity of Chatham, where it is necessary for the ships rounding the Cape to follow a zigzag course, the tidal currents are especially strong and hazardous to navigation.

In view of the foregoing difficulties, it should be obvious that fog offers a far greater hazard to vessels on the route around Cape Cod than to ships well away from land on the open sea. Furthermore, careful study extending over a long period of years has shown that the fogs on the outside route in the vicinity of the Atlantic Ocean are more frequent and of longer duration than those in the vicinity of Buzzards Bay and the Cape Cod Canal.

In navigating the shoals in Nantucket Sound it is necessary to follow a zigzag course, the angles of which at times exceed 90 degrees. During recent years a straighter channel has been dredged by the Corps of Engineers from Stonehorse Lightship northeast to the slue between Pollock Rip Shoal and Bears Shoal. Although this route is somewhat shorter and less tortuous than the outer one, it still involves several changes in direction which, in time of thick fog, means hazardous navigating.

Ice conditions are not usually such as to offer an obstacle to easy navigation, but there are occasionally very severe winters when the ice floes reach large proportions. At such times the shoal areas in the narrow channels are likely to be covered with large ice floes which introduce added hazards to the outside route. It is true that the very shallow, northern part of Buzzards Bay is even more likely to freeze, with resulting dangers to navigation. However, the proposed new straight channel will obviate much of this difficulty, and it is certain that if ice must be encountered, it is far better to grapple with it in the protected waters of Buzzards Bay than in the broader stretches of the outside route.

The outside route, furthermore, is exposed to the full fury of the northeast storms that sweep across the Northern Atlantic. These storms are widely known as among the most severe to occur on any of the oceans of the world, and the loss of property and lives that has resulted during many years past testifies to their destructive power. For example, the records of wrecks for many years past is mute evidence of the dangers of the outside route. Although the data available do not include full information as to cargo actually lost, or even as to the number of lives, the evidence is sufficiently complete to indicate that the annual cost has been approximately $500 000, and that the number of lives lost has averaged at least 15 annually.

COMMERCIAL REASONS

In addition to the desirability of saving lives and avoiding the losses due to wrecks, there are other more definitely commercial aspects of the problem. At present (1935), the value of the shipping that passes through the canal is only a little more than one-fifth of that which might do so if ships were provided with a reasonable depth and freedom from the present hazards of canal navigation.

The traffic available, which might use the canal, can best be shown by reference to the record of coastwise cargoes entering and leaving the Port of Boston. In 1933, this amounted to 12 300 000 tons, whereas the cargo tonnage through the canal was only 2 804 000 tons. Fig. 3, with Table 2, presents the record[3] of passages through the canal from the date of its opening to, and including 1934.

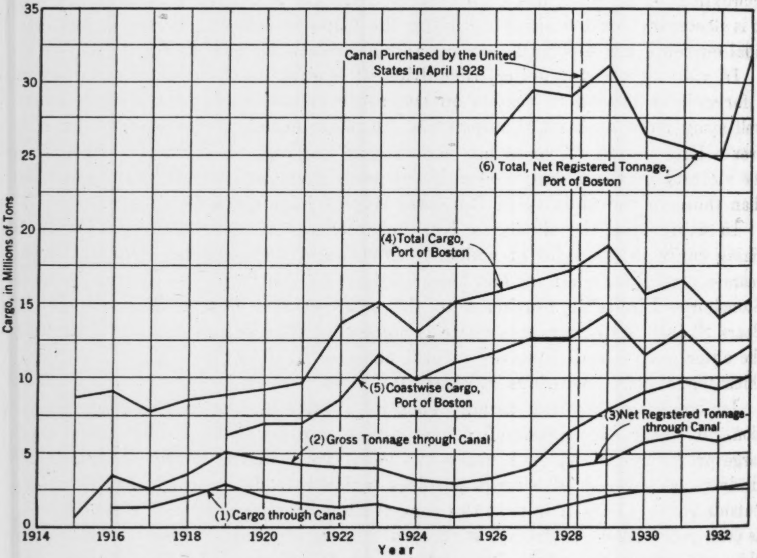

FIG. 3.—COMMERCE THROUGH AND AROUND THE CAPE COD CANAL.

The canal was in operation only two years before the World War. When it first opened, late in 1914, it was not completed to full project dimensions and attracted only a small volume of traffic (see Curve 1, Fig. 3). During the war, many ships used the canal to avoid the submarine dangers of the outside route. The increase continued until 1920, after which traffic dropped until

---

[3] H. R. Doc. No. 795, 71st Congress, 3d Session.

1928. In April, 1928, the canal was taken over by the Federal Government. The volume of traffic then rose rapidly, reaching a peak in 1930, so far as the number of ships are concerned (see Table 2). However, both gross and net registered tonnage have increased steadily in recent years, except for the one year, 1932 (see Fig. 3, Curves 2 and 3). There appear to be several reasons for this increase: First, the elimination of tolls undoubtedly attracted many ships; second, the prejudice of mariners against the canal has been overcome to a large extent; third, the canal is being maintained to a depth of more than 21 ft at mean low water; and, fourth, the widening to 205 ft facilitates passage through the canal. That ships of deeper draft have been using the canal in recent years is shown in Table 3.

TABLE 2.—TRAFFIC THROUGH THE CAPE COD CANAL

Year	NUMBER OF:		Year	NUMBER OF:		Year	NUMBER OF:		Year	NUMBER OF:

TABLE 3.—ANALYSIS OF TRAFFIC

Year	VESSELS DRAWING 18 AND 20 FEET			AVERAGE NET REGISTERED TONNAGE		
	Steamships	All others	Total	Steamships	Barges	Total
1929........	0	1	1	580	543	1 123
1930........	143	47	190	1 039	552	1 591
1931........	193	55	248	1 080	561	1 641
1932........	260	26	286	1 025	558	1 583
1933........	492	21	513	1 083	550	1 633

It is evident that, to a large extent, mariners have ceased to fear the canal. Furthermore, the widening to 205 ft has attracted shipping, and it is logical to assume that any further improvement would attract still more traffic.

More than 80% of the total coastwise trade in and out of the Port of Boston passes around or through the Cape Cod Canal. Furthermore, most of the coastwise traffic passing Cape Cod is with the Port of Boston. Curves 4, 5, and 6, Fig. 3, show commerce in the Port of Boston for the years indicated.[4] The general trend during the years 1929 to 1933 is similar to that found in the case of the Cape Cod Canal.

A large volume of traffic which might use the canal still passes around Cape Cod. Some of it could use the canal at present. Other traffic is unable to use it because of its limiting depths. Table 4 shows the draft and number of trips for vessels entering and leaving Boston Harbor during the calendar years, 1927 to 1933, inclusive. Fig. 4 illustrates the relation between drafts and the capacities of vessels entering and leaving Boston Harbor in the years 1929 and 1933.

(*e*) VESSELS OF A DRAFT TOO GREAT FOR SAFETY WITH A 40-FOOT DEPTH, EXCEPT WITH FAVORABLE TIDES							
More than 35 ft.......	6	2	7	4	2	1	0

The increase in canal passages for 1933 was 605 vessels (see Table 2), whereas the increase in shipping around Cape Cod during the same period was 350 vessels. Of the total increase, 955 vessels (63%) went through the canal and 37% went around Cape Cod. Reference to Table 5 will show that commerce is using larger vessels. A table for Boston Harbor similar to Table 5 gives approximately equivalent results. With the increase in size and draft of ships, a demand for an increase in the depth of the canal may be expected.

It is apparent from the foregoing that the popularity of the Cape Cod Canal is increasing rapidly and that the commerce which now uses the canal, as well as that which may use it in the future, is growing in volume. It is unquestionably significant that in 1933 supposedly one of the worst years of the depression, net registered tonnage passing through the Cape Cod Canal was the greatest in its entire history, except for a short period during the World War when the fear of submarines forced all ships that could do so to use the canal. When it is remembered that the net registered tonnage entering and leaving the Port of Boston was likewise at an all-time high in 1933, and that much of this commerce will use the canal as soon as it is improved, the future usefulness of that waterway is seen to be unquestionable.

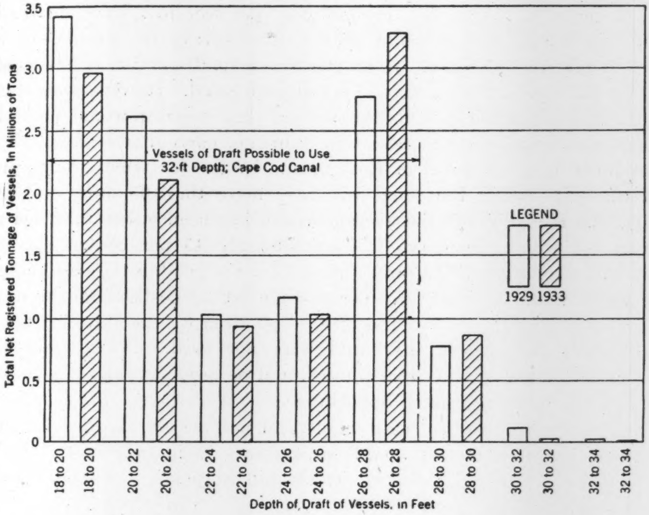

FIG. 4.—DRAFTS AND CAPACITIES OF VESSELS ENTERING AND LEAVING BOSTON HARBOR.

TABLE 5.—AVERAGE NET REGISTERED TONNAGE OF VESSELS PASSING THROUGH CAPE COD CANAL

Type of vessel	1929	1930	1931	1932	1933
Steamships . . .	900	1 190	1 350	1 138	1 365
Motorships . . .	90	100	121	137	148
Barges	720	770	810	790	752

On account of the great diversity of freight and of kinds of ships involved, it would be difficult to make an accurate estimate of the savings to shippers using the canal. However, it is known that the total coastwise cargo in and out of Boston during 1933 was 12 250 000 tons. Approximately 80% of this total will probably use the canal when adequate improvements have been made.

Only 2 805 000 cargo tons were passed through the canal in 1933, leaving 6 995 000 tons which might have gone through. The total costs of all improvements contemplated, including the new bridges, is estimated at about \$31 075 000. At 3%, the annual interest charges would be \$932 000, and this is only 13 cents per cargo ton, or 0.20 cent per ton-mile, even on the basis of commerce during a depression year. (The saving in distance by using the canal is taken as 65 miles. It is true that a small portion of the coastwise tonnage in and out of Boston may never use the canal. However, any decrease in the possible economic benefits derived on that account would probably be more than counterbalanced by coastwise tonnage, particularly coal and petroleum products, to ports north of Boston, and by the fact that a large proportion of the ships using the canal will save more than 65 miles in distance traveled). In recent years, the average vessel has been about 1 200 net registered tons, of which the cargo is approximately 45 per cent. This would mean an average cargo of 540 tons, and at 13 cents per ton the cost chargeable to each vessel would be about \$70 per passage. Fuel costs alone for steamers would probably be between \$50 and \$200, depending on the ship, for the additional distance involved if the canal were not used. For large tows the saving in fuel by use of the canal route would be less, but for them the safety of that route is of even greater importance.

In considering the project as a whole and not merely the justification for the proposed improvement, it would be necessary to include in the total economic benefits the annual losses by wrecks on the passage around Cape Cod. This has averaged more than \$500 000 over a period of several years.

The Problem of Improving the Canal

Hearings held in 1934 and earlier, as well as repeated contacts with masters of ships and pilots by officers and civilian employees on duty in Boston and at the canal, make it possible to state the nature of the improvement desired by interests using the canal. Briefly, it is that the channel should be deepened and widened to permit two-way traffic and that the width should be sufficient to remove the risk of being caught during a falling tide with the bow of the ship on one bank and the stern on the other; or, that the canal should be widened somewhat so as to permit two-way traffic and that locks should be installed in order to still the currents, thereby removing the risk of stranding a vessel cross-wise in the channel.

In considering this aspect of the problem, it is necessary to keep in mind the fact that there are two quite different classes of shipping which use the canal. They are the motor and steam ships on the one hand and the tows of barges on the other. In recent years, the importance of the latter has considerably diminished due to the utilization of powerful motor barges for a large part of the traffic. The shipping that operates under its own power may be further subdivided into the fast passenger-carrying vessels and the slower freight carriers, including motor barges.

The passenger carriers are naturally interested in making the passage as rapidly as possible since they operate on a schedule which gives them little or no allowance for delays. The interests involved desire the improvement to be along the lines first mentioned (that is, without locks) in order that these ships may lose a minimum of time. The slower freight ships, including the motor barges, are not so concerned about maintaining time schedules and, therefore, would not be so strongly opposed to a lock canal, provided there was sufficient width throughout for two-way traffic. The barge proportion of the traffic, which is steadily declining in importance and now constitutes less than one-third the registered tonnage, travels at an even slower rate. It is possible that, on the average, a lock canal might somewhat reduce their time of passage. However, time is of less importance to them than to the other classes mentioned and, although the somewhat faster current in a 500-ft canal might make it necessary for tows to wait for a favoring tide, or else be taken through one barge at a time, it is certain that those tows which had the power could move on through regardless of currents. (At present (1935), even these tows must break up and go through one barge at a time because of the narrow width and the difficulty of keeping tows in line.) Furthermore, favorable currents would be encountered at least 50% of the time, and tows could proceed through without breaking up if the canal were wide enough to permit maneuvering when necessary. It has been reported that no new barges have been constructed for several years and that the trend is emphatically toward the use of motor ships. Obviously, too much consideration must not be given to a class of shipping that is becoming obsolete, which is a decreasing fraction of the whole, and which should benefit substantially under either type of improvement in any case.

The project dimensions on which the estimates are based are a depth of 32 ft and widths of 250 ft and 540 ft for the lock and open canal, respectively. This particular depth was selected because it will accommodate practically all the vessels now entering and leaving the Port of Boston which may be expected to use an improved canal. Taking into consideration the number of ships of the different drafts and their cargo capacity, it is found that this is the economic depth. That such is the case is readily seen by reference to Fig. 4, where the cargo-carrying capacity of vessels entering and leaving Boston Harbor is shown for each of several drafts. (There should be at least 4 ft of over-depth to allow for minus tides, for "squat" in a restricted channel, and for the fact that the channel bottom will not be soft material, but will be thickly strewn with boulders.) It is apparent that a depth of 30 ft would not be sufficient for the relatively large volume of cargo carried in vessels having a draft of from 26 to 28 ft, whereas 32 ft would be deep enough for these ships. The additional 2 ft of depth gives a great increase in cargo-passage capacity. On the other hand, it is equally apparent that a further increase in depth—say, to 35 ft—would result in only a small increase in cargo-passage capacity and that it would not be economically justified at this time. A width of 540 ft is considered desirable for the open canal for reasons already mentioned, and in order that the further deepening to 40 ft at some future time may be made, giving a bottom width of 500 ft, without disturbing the side slopes and bank protection.

THE LOCK *Versus* AN OPEN CANAL

Since the publication of H. R. Document No. 795, important new information has been obtained and experience has been gained which necessitates a revision of earlier ideas. New factors to be considered are: (1) Ice; (2) pile-driving; (3) excavation costs; (4) storms; (5) currents; (6) shoaling; (7) delays in passing through locks; and (8) dredging difficulties.

(1).—*Ice.*—The most important new development was the experience with ice conditions during the winter of 1933–34. The conditions of that period proved definitely that great difficulty would be experienced from time to time in a still-water canal. There appears to be no practicable means of avoiding ice under those conditions, and it would be most undesirable to have the canal closed for an extended period during the winter months when presumably it would be most needed because of storm hazards on the outside route.

(2).—*Pile-Driving.*—Another development of primary importance is the experience with the foundations for the new bridges. Great difficulty was encountered in driving the steel sheet-piling to grade because of boulders. Presumably, cut-off walls of sheet-piling would be required under the lock walls and miter-sills in order that the locks might be unwatered when necessary to make repairs. It is now believed probable that the difficulties encountered in driving such walls of sheet-piling would be extremely expensive to overcome and that the cost of locks would be increased materially for this reason.

(3).—*Excavation Costs.*—Apparently, the possibility of making a 500-ft canal was not previously given much consideration because of the high costs for earth removal which were formerly used as a basis for estimates. In view of the contract dredging completed in 1934, and because of the acquisition of new equipment, including very large dipper dredges (one with a capacity of 26 cu yd began working at the canal in December, 1934), it appears that costs will be lower than was considered possible a few years ago. Furthermore, there is the possibility of still further lowering excavation costs by doing a substantial portion of the work in the dry.

(4).—*Storms.*—Recent experience has shown conclusively that the difficulties of navigation and the hazards peculiar to the canal have been primarily due to the narrow width. Considered solely from the viewpoint of navigability, it is believed that the 500-ft open canal will be definitely superior to a 250-ft or a 300-ft lock canal. One of the hazards which will exist in either case is the fog that is frequently found in that vicinity (although not so frequently as on the route around Cape Cod). The 500-ft open canal will allow ample room for passing ships even under the worst conditions, permitting the movement of vessels. Likewise, the strong northeast gales that accompany the severe storms in this region, should be considered. In a lock canal, some difficulty would probably be experienced, especially in the case of the larger ships when loaded lightly. Because it is necessary to approach a lock very slowly, a ship would be less responsive to its rudder, and the force of the wind would be more effective. On the other hand, the most severe gales would introduce no hazard to navigation in a 500-ft open canal.

(5).—*Currents.*—Although it has been assumed, to be on the safe side, that currents in the 500-ft canal will be increased in accordance with accepted hydraulic formulas, the actual currents found when the improvement is made will probably be somewhat less. It appears that the volume of water passing through the 100-ft canal has somewhat affected the level of the water in Buzzards Bay, with consequent reduction of the difference between the water levels at the ends of the canal. It is only reasonable to suppose that the volume of water passing through a 500-ft canal, about five times as much, will affect the water level in Buzzards Bay to an even greater extent. The result will be to reduce the head, or the difference in level at the two ends of the canal, thereby diminishing the currents.

(6).—*Shoaling.*—Further study of the erosion that has occurred in the 100-ft channel, and the consequent shoaling which requires maintenance dredging, leads to the belief that most of the shoaling has been due to wave wash on the banks and the resulting caving in of large quantitites of sand. It follows that adequate bank protection in the form of rip-rap can be expected to remedy this situation. In any event, the wave wash in a 500-ft canal will be less than in the old 100-ft width. Any hazards to navigation due to shoaling and the maintenance dredging made necessary thereby will probably be of no importance in a 500-ft canal.

(7).—*Delays in Passing Through the Locks.*—In addition to the foregoing, there are several factors which make the lock canal less desirable. The delays incident to passage of the locks would be most objectionable to the fast passenger-carrying ships. The only shipping that would be delayed at all in the case of an open canal would be that portion of the tug-and-barges combinations, or tows, which lacked power to move against the current. However, this traffic moves slowly at best, and saves twelve or thirteen hours by using the canal. Inasmuch as the average delay involved would be less than two hours, and since the currents would expedite passages when favorable, it is clear that what the tows gained by a lock canal would be more than offset by delay to more important shipping which constitutes the largest and a growing portion of the whole. Still another consideration is that locks are vulnerable to attack in the event of war, whereas an open 500-ft canal could scarcely be blocked for any long period.

(8).—*Dredging Difficulties.*—A few years ago it was feared that it would be impossible to dredge in the 100-ft open canal, but this can now be forgotten, inasmuch as the canal has been widened to 170 ft throughout its length, and dredging has started on a further widening to 205 ft minimum width. Apparently, the prevention of shoaling is largely a question of proper bank protection against wave wash and that would be necessary in either type of canal.

The alternate plans of improvement which it was finally decided to consider in detail are the project recommended in H. R. Document No. 795, but with twin locks, *versus* an open canal of adequate width to eliminate the hazard of grounding across the channel during a falling tide. Estimates of cost are given in Table 6. As a result of the studies made, it is believed that

TABLE 6.—COST ESTIMATES, CAPE COD CANAL, 1934

Crushed rock, or quarry spalls	58 000	....	($5)	290 000
Total	....	....	....	$1 516 000

a large part of this excavation, approximately 8 785 000 cu yd, can be done in the dry at a great saving in cost. If funds were made available only in small sums over a long period, it would probably be best to widen by dredging alone, but if the project is adopted and funds are made available so that the work can be done in the most efficient manner, a saving of approximately $2 703 000 may be expected. On this basis, the open canal would be $4 327 000 less expensive than the lock canal.

Other Features of the Improvement

In addition to the deepening and widening, other minor betterments should be provided. The additional volume of shipping anticipated will require enlargement of existing facilities and other work which is discussed briefly herein.

At times, during northerly or northeasterly gales, Cape Cod Bay becomes so rough that tows and smaller craft are unable to continue the voyage out of the canal. Therefore, it will be necessary to provide a mooring basin where vessels thus delayed may tie up until such time as they can proceed with safety. Such a mooring basin should be about 2 000 ft long and extend inshore about 300 ft from the edge of the channel (see Fig. 5). Each end of the mooring basin should be tapered so that the width required (200 ft) is reached in a distance of from 300 to 500 ft. It is planned that additional model experiments will be undertaken, and that one object of the investigation will be to ascertain what size, shape, and location of mooring basin will result in the least interference with navigation through its effects on currents and shoaling.

There are no special difficulties due to weather at the Buzzards Bay end of the canal. The waters are protected and are safe for all but the smaller craft. However, at times, it is necessary to tie up tows at that end while the tug traverses the canal with part load. A mooring basin will be needed to accommodate this traffic, and would occasionally be useful to other vessels in foggy weather. Such a basin should preferably be located northeast of Hog Island and southeast of the new straight channel. It should be about 1 000 ft long and 300 ft wide, with ends tapered. Mooring facilities should be provided.

A harbor of refuge should be provided at the Buzzards Bay end of the canal for smaller craft. For this purpose, a 15-ft channel into Onset Bay would be suitable. The estimated cost of this improvement is listed in Table 6(*c*).

Lighting.—The present lighting system in the canal consists of a series of 60-cp electric lights on piles, spaced 500 ft apart. The alignment is very poor due to erosion of the banks. This system does not meet requirements during adverse weather, because of low visibility. A system of lights should be installed which may be increased in intensity during foggy weather, or while there is vapor in the canal. The lights should be about 25 ft above the water level on poles spaced 300 ft apart. Colored lights placed at critical places in the canal may be used to indicate curves and bridges. The estimated cost of such an installation is $100 000.

Bank Protection.—It will be necessary to protect the canal banks against erosion due to wave wash and currents. This protection should extend for 5 ft (measured vertically) below mean low water and to 5 ft above mean high water. Experience with various forms of rip-rap has shown that a blanket of one-man stone, 1.5 ft thick, on a covering of spalls about 6 in. thick, is the best form. The spalls preferably should be of two sizes, the smaller on the bottom. In this connection, mention should be made of the fact that at one or two points along the banks of the present canal, peculiar difficulties have been encountered in attempting to protect the banks. The sand at these points is extremely fine and either washes out because of eddy currents and boils, or is displaced by a ground-water flow.

The estimated cost of such protection—based on a slope of 1 on 2.5 below, and 1 on 2 above, mean low water, the protection to extend from 5 ft above mean high water to 5 ft below mean low water, and assuming a mean tide range of 6.5 ft—is listed in Table 6(*d*).

Land Takings.—Either the lock or open canal will require additional land, but the total area involved is only a small part of the whole. On the basis of appraisals made and negotiations in progress, it is estimated that the total cost of additional land will not exceed $592 000.

Railway and Highway Relocation.—The widening of the canal to 500 ft will necessitate relocating about 2 miles of highway on the north bank, about 3 miles of railway on the south bank, and short stretches of highway relocation which must be co-ordinated with the railway work. The estimated cost of the work to be done by the Federal Government is $208 000.

Regulating Works in Buzzards Bay.—Consideration has been given to the possibility of constructing regulating works in Buzzards Bay. Such works would be in the form of dikes that would lengthen the channel, thereby reducing the slopes and currents in the open canal. Certain theoretical studies have been made, but it is clear that insufficient data are available on which to base sound conclusions. Although the open 500-ft canal will be an excellent and satisfactorily navigable waterway, the project might be modified later to include regulating works, if experience with the enlarged waterway should indicate their desirability. The project as a whole should not be delayed pending a solution of this relatively minor technical question.

TECHNICAL ASPECTS OF THE PROBLEM

The technical aspects of the problem naturally divide into the two major items of excavation and hydraulics of the proposed canal. Three bridges span the present canal. There are two highway bridges of the rolling lift type which are practically identical. Their substructures consist of isolated piers under each load, stiffened laterally with reinforced concrete girders. These piers were sunk by pneumatic caissons and, in the case of the bridge at Sagamore, piling was used.

The superstructure of these bridges consists of two movable spans of the double-leaf rolling lift type. The elevation of the roadways was about 40 ft above mean sea level and the spans were about 160 ft. Originally, each of these bridges carried a single-track electric railway, but those railways were

abandoned long ago and the tracks have been removed. The clearance between the fenders protecting the main piers is about 140 ft and this is the present limiting width of the channel. The existing railway bridge consists of a double-track, trunnion, bascule superstructure. The piers are of conventional solid concrete on piles with granite facing. The length of this bridge is 160 ft and the clearance between fenders is approximately 140 ft.

When the major improvements contemplated for the Cape Cod Canal were first under consideration, plans were prepared involving a single combination of highway and railway bridge. This was to have a 550-ft span and a vertical clearance above high water of 150 ft; a 6-lane highway for traffic was provided. Since those plans were prepared, however, the substantial growth in summer automobile traffic and the obligation of the United States to protect the interests of the towns near-by, have made it desirable to construct two bridges instead of one for the highways, and a separate railroad bridge.

The highway bridges are similar although the one near Bourne has four approach spans, in addition to the continuous truss extending over three spans which is found in each of the highway bridges. The three-span trusses used are of the Warren continuous type with an arched center span. The floor is supported on the upper chord of the outside spans and is suspended below the arched center spans. Each of the highway bridges has a 40-ft roadway and a sidewalk in addition. Fig. 6 is an excellent view of the Bourne Bridge. The Sagamore Bridge is of similar design, except for the absence of approach spans. The substructures for these bridges consist of piers having massive

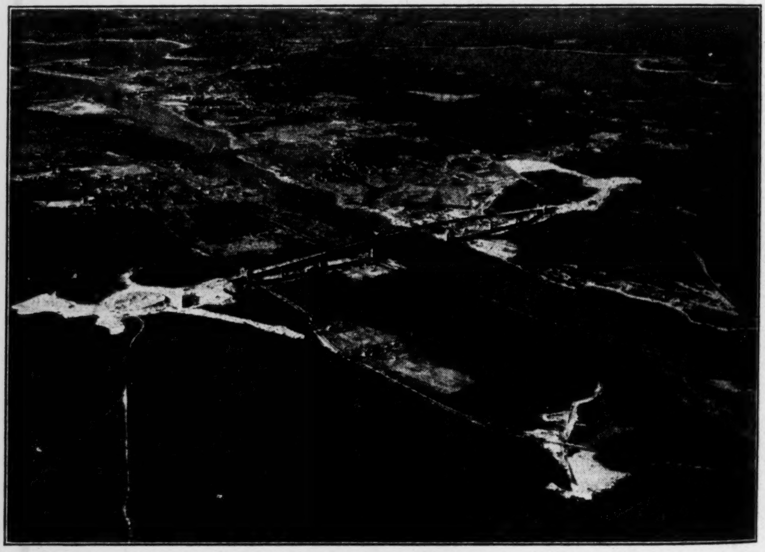

FIG. 6.—NEW BOURNE HIGHWAY BRIDGE AND APPROACHES.

concrete bases with two concrete shafts connected at the top by a concrete diaphragm. The concrete shafts are heavily reinforced and the end abutments are hollow reinforced concrete, with massive pylons.

In the case of the channel piers, coffer-dams were constructed, and, at first, it was expected that the piers would rest on the natural soil. However, due to the fact that there was difficulty with boulders and that it was almost impossible, therefore, to drive the steel sheet-piling as deep as originally intended, and because of the action of the saturated sand under the unequal pressures existing during construction, piles were used in the case of three of the four highway channel piers. They were driven in the wet, but even under those circumstances considerable difficulty was encountered with the blowing in of sand, because the foundation material lacks any substantial quantity of binder, such as clay.

The approaches to these highway bridges are by way of traffic circles at each end, except at the south end of the Sagamore Bridge. A special underpass has been constructed in the approach to the north end of the Bourne Bridge. The railway bridge (see Fig. 2) is the longest vertical lift bridge in the world, with a 544-ft span between end bearings. The towers are 265 ft high, and the vertical clearance of the bridge in the raised position, of course, is the same as in the case of the highway bridges, namely, 135 ft. The truss itself is of the Warren type with vertical members, the trusses being 27 ft, center to center.

This bridge is raised and lowered by four 150-hp induction motors, two of which are used to drive, and two to synchronize, the movement of the two ends of the truss. In addition, emergency motors are provided and emergency gasoline generator sets furnish energy if the commercial power facilities fail.

This structure is the first of this type in the United States to be equipped with roller bearings. Under ordinary operating conditions, it is raised or lowered through 130 ft in approximately 2 min. The bridge is normally in the raised position in contrast with the older bridge, which is normally down and has to be raised as ships approach. Parenthetically, it may be mentioned that this feature will greatly lessen the possibility of a ship striking the bridge. Ship captains will expect to find it up and when they to not find it in the raised position it is to be expected that they will take the necessary precautions to insure that the current will not sweep them into the bridge before it can be raised. Under present conditions, it is normally expected by the ship's captain that the bridge will be raised as he approaches. Consequently, when there have been difficulties with the operating mechanism, this fact has not been realized by the master of an approaching ship until too late to prevent the bridge being struck if the current made it impossible to stop within a short distance.

A few of the difficulties encountered in constructing the new bridges are of special interest. In the first place, the number of boulders which are found in the Cape Cod soil near the canal made it extremely difficult to sink the steel sheet-piling. The foundation material in some cases proved to be very loose and, although it was not compressible if held in position, it flowed easily due to the fineness of the sand and the extremely high water content. Although piles were not contemplated originally, it was believed desirable to use them, and the coffer-dam sheeting was left in place in order to confine the sand. The wooden piles were driven under water in the case of the highway bridges, whereas the coffer-dams were unwatered before driving in the case of the railroad bridge piers. Divers cut the wooden piles used for the highway bridges, and the concrete was placed under water by bottom dump buckets. Another interesting feature of the coffer-dam work at the railroad bridge was the unwatering by the well-point method. Well-points were driven around the coffer-dam and the ground-water flow was discharged into the canal.

The north coffer-dam for the railroad bridge offered many difficulties. The material on that side of the canal seemed to be especially fluid with the result that "blow-ins" of minor proportions were frequent occurrences. Furthermore, the shifting of the earth in the immediate vicinity tended to distort the coffer-dam sheeting and place severe strains on some of the wooden brace members. At one time, it was thought that it might be necessary to place additional bracing to such an extent that driving piles in the quantity desired would have been impossible (see Fig. 7). Finally, a sufficient number of piles were driven so that the first few feet of concrete could be placed, and it was with a feeling of relief that the contractors, as well as the Government engineers, saw the first 3 ft of concrete sluiced into place. Of course, as soon as it had set, the danger of the complete destruction of the coffer-dam was reduced to minor proportions.

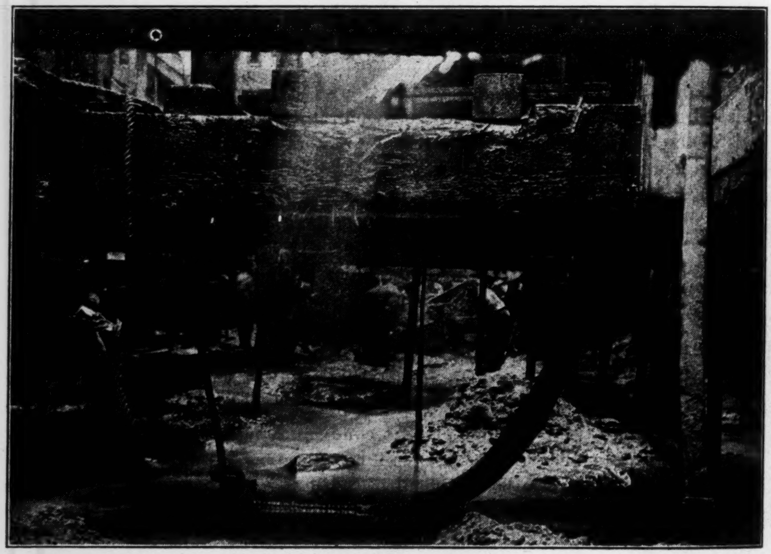

Fig. 7.—Coffer-Dam Unwatered, North Main Pier of New Railroad Bridge.

EXCAVATION

When the canal was first constructed, it was expected that practically all the excavation could be done by hydraulic methods. Actually, however, it was found that although somewhat more than a mile of the channel from the Cape Cod end could be dredged hydraulically, the larger part of the work could not be handled by that type of equipment.

General Parsons has described[3] at great length, the attempts to operate hydraulic dredges in the land cut. When the original contractors found that they could not make further progress by hydraulic methods, they purchased second-hand dipper machines which happened to be available. Unfortunately, these machines lacked sufficient power to handle the large boulders encountered in dredging the canal channel, and, finally, it became necessary to have two 10-yd dipper dredges. The dredges were assembled at the canal and proved to be entirely satisfactory.

General Parsons had previously urged the contractors to consider the use of steam shovels and industrial railway equipment. This was done with very satisfactory results. It was found possible to excavate in the dry to a depth of 20 ft below the ground-water level. Handling the boulders with such equipment where they could easily be broken up by blasting proved to be far more practicable than the use of even the better type of dipper dredge finally obtained. Under modern conditions, with superior shovel equipment and the mobile and highly adaptable truck for hauling away material, it seems certain that excavation in the dry where practicable will be even more advantageous than it was at the time of the original construction of the canal.

Fortunately, recent contracts let in connection with the highway relocation for the new bridges make it possible to estimate closely the cost of dry excavation. Prices of 24 cents per cu yd have been obtained, even where the haul was in excess of 1 000 ft. It seems certain that on such a large volume as will be involved in the proposed widening it will pay to make use of the modern drag-line equipment, or the large steam shovels and 8 to 10-yd trucks. The material is such that no difficulty will be encountered in making roads for the truck transportation, and there are some places where heavy drag-line equipment with a sufficiently long boom can remove the dirt to be excavated in the dry without any need for haulage. With this in mind, further studies have been made in order to ascertain what depth might be reached by excavation in the dry. Tests were made of the permeability of the soil based on samples taken at various points along the length of the canal. It is believed that the seepage from the present canal can easily be cared for by pumping, even if the excavation in the dry is carried to about 18 ft below mean high water. It will be necessary to leave a substantial dam between the present canal and the new excavation, and one having a top width of 30 ft at mean high water will be used.

In addition to the advantage of handling the boulders in the dry and the fact that earth removal will be somewhat cheaper by this means, there is also a great advantage in being able to place the rip-rap in the dry. As every one who has had such experience knows, placing rip-rap under water is a somewhat uncertain process and is likely to be wasteful of material. On the other hand, by placing the rip-rap blanket in the dry, it will be possible to have it exactly as desired with the least cost.

With a large part of the excavation in the dry, the problem of providing disposal areas is introduced. After a careful study of the territory in the immediate vicinity of the canal certain sites have been selected as indicated in Fig. 5. These sites provide more than sufficient disposal areas for the nearly 9 000 000 cu yd which can be excavated in the dry.

The excavation at the east end of the canal, with the exception of sufficient excavation in the dry for the purpose of placing the rip-rap, can be done by hydraulic methods. West of Station 70 (see Fig. 5), however, it will be necessary to make use of the most modern high-powered dipper-dredge equipment. The analysis of borings that have been taken along the site of the proposed straight channel in Buzzards Bay indicate that it may be possible to excavate a major portion of the material there by hydraulic methods.

Program of Construction

Dredging operations on the new straight channel through Hog Island can be started at the earliest practicable date. This can continue to completion without interruption if funds are provided. The approximate maximum rate at which funds can be used efficiently for this part of the work is $3 000 000 the first year, and $3 113 000 the second year. At this rate, the work would be completed in two years.

In the land cut, excavation in the dry will be the most economical. It is estimated that approximately 8 785 000 cu yd of material can be removed by means of drag-line, shovels, trucks, and other land equipment. Much of the necessary equipment would be available in this region and carrying on the work in this manner would provide jobs for the unemployed of near-by cities. The cost of such excavation will probably be little more than one-half the estimated cost of dredging through the major portion of the land cut. Furthermore, by excavating in the dry it will be possible to place the rip-rap for bank protection on dry land instead of under water. This will be more economical and in the long run will give better results. Several contracts for excavation in the dry can be projected simultaneously, and each should include placing the required rip-rap in the section excavated. Areas for the disposal of the material excavated have been selected tentatively. It is estimated that funds for this part of the work can be used efficiently at the maximum rate of $2 000 000 the first year and $1 712 000 the second. Two years will be required to complete this part of the work, including the placing of rip-rap. It is desirable that this part of the improvement be started at the earliest practicable date.

If the excavation in the dry is begun promptly, it will be possible to begin the dredging in the land cut at those sections where the excavation in the dry and the placing of rip-rap shall have been completed. Approximately 21 232 000 cu yd will have to be removed from the land cut by dredging. It is estimated that funds can be used efficiently at the rate indicated in Table 7.

By utilizing dry excavation as far as practicable, the foregoing program would probably effect a saving of about $2 703 000 as compared to the all-dredging method. However, if the enlargement is to be spread over a long period of years, the more costly dredging method will probably be advisable, because each expenditure would provide a more immediate benefit to navigation.

TABLE 7.—MAXIMUM RATES AT WHICH FUNDS CAN BE USED

Description of work	First year	Second year	Third year	Fourth year	Fifth year
Hog Island channel	$3 000 000	$3 113 000	....	....	....

HYDRAULICS

As a very distinguished engineer has expressed it,[4] the problem presented by the flow of water in the Cape Cod Canal is "an extremely complex one in hydrodynamics, being the analysis of the motion of water in a canal of considerable magnitude connecting two seas, the tides in which differ to a great extent, both as to phase and amplitude." In comparative length and cross-section, as well as in the tidal conditions at the ends, the Cape Cod Canal differs to such an extent from the few other similar artificial waterways that methods of analysis which have been applied to some of them cannot be readily applied to it. For example, the "Reflected Wave Theory" developed by Earl I. Brown, M. Am. Soc. C. E.,[5] and applied by him to the Chesapeake and Delaware Canal is difficult to apply to the Cape Cod Canal.

Observations of tides and currents in the 100-ft canal yielded data by which the maximum velocity during a tide and the time of its occurrence could be predicted with considerable accuracy. The United States Coast and Geodetic Survey publishes tables of such values in the yearly "Current Tables." The prediction of the velocities to be anticipated in the proposed enlarged canal presents a difficult problem for which only an approximate analytical solution may be expected, since the flow in the canal is not only non-uniform (surface slope not parallel to bottom), but it is variable (continually changing with time).

The tide in Buzzards Bay (west end of the canal) precedes the tide in Cape Cod Bay (east end of the canal) by approximately 3 hr, one-half the tidal interval. The rise at the Buzzards Bay end is thus well under way while the water is still falling at the other end, and Buzzards Bay begins to fall some hours before Cape Cod Bay has reached its peak (see Fig. 8). The mean range of tide in Buzzards Bay is approximately 4 ft; in Cape Cod Bay, it is approximately 9 ft. The phase relationship is such that the "tide head" (defined as the maximum simultaneous difference in elevation of the water surfaces occurring during any one tide at the recording gauges near the ends of the canal) occurs on the average within 1 hr after high water and within 1 hr after low water in Cape Cod Bay and averages nearly 5 ft (over-all slope, 0.000146). The greatest tide head ever recorded was 9.5 ft (over-all slope, 0.000275), but such a head is most unusual, since less than 1% of the tide heads exceed 7.5 ft.

---

[5] "Flow of Water in Tidal Canals", by Earl I. Brown, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 749.

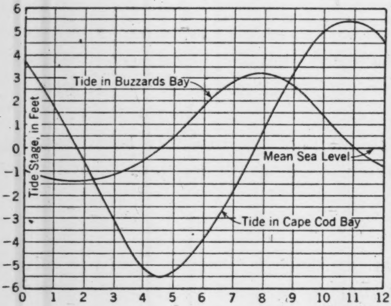

FIG. 8.—TYPICAL TIDE CURVES, FROM OBSERVATIONS, SEPTEMBER AND OCTOBER, 1932.

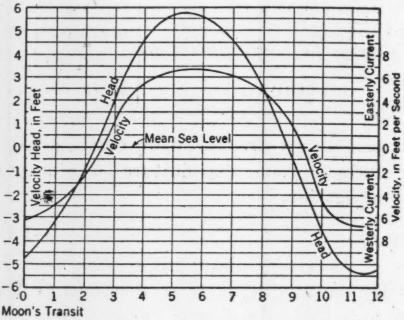

FIG. 9.—TYPICAL CURRENT CURVES, FROM OBSERVATIONS, SEPTEMBER AND OCTOBER, 1932.

Because of inertia effect, maximum velocity and maximum head during any tide do not occur simultaneously; nor do slack-water and zero head (see Fig. 9). The interval of time by which maximum velocity follows maximum head varies widely with individual tides (and is difficult to determine closely because the velocity changes are negligible for a considerable period near the time of the maximum), but it is generally less than 30 min. The interval of time by which slack-water follows zero head also varies with individual tides, and is also generally less than 30 min. For all practical purposes, slack-water may be considered to occur at virtually the same time throughout the length of the canal.

As a result of the tidal conditions at the ends, the water in the canal flows in one direction for approximately 6 hr, reverses, and flows in the opposite direction for approximately 6 hr. The current, therefore, changes direction four times a day. The maximum velocity in each direction is of approximately the same magnitude. The head between the ends of the canal and the velocity of the current in the canal are constantly changing, increasing from zero to a maximum and decreasing to zero in 6 hr. In the following comments the maximum head (tide head) and maximum velocity for any tide will be the quantities most frequently discussed. It should be understood, however, that this maximum velocity persists for a relatively short time. The general relationship between tides, head, and velocity are shown in Fig. 10.

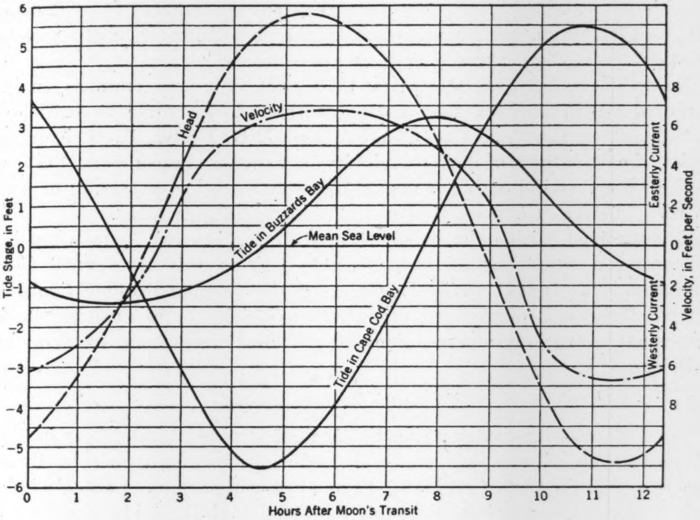

FIG. 10.—TYPICAL TIDE AND CURRENT CURVES, FROM OBSERVATIONS, SEPTEMBER AND OCTOBER, 1932.

EARLY STUDIES

Prior to the beginning of construction in 1909, a number of investigations, surveys, and reports were made. From the time Thomas Machin was commissioned, in 1776, to make surveys and plans, until 1862, all proposals for the canal involved locks. The report of the Massachusetts Joint Committee on the proposed Cape Cod Canal in 1862 contained the first recorded official discussion of the possibility of constructing a canal without locks, as has been mentioned. The Committee was advised concerning technical matters by an Advisory Council (the late Joseph G. Totten, Brigadier-General, U. S. Topographical Engineers, Hon. M. Am. Soc. C. E., the late A. D. Bache, Hon. M. Am. Soc. C. E., and Captain C. H. Davis, U. S. Navy) for which the late Henry Mitchell, M. Am. Soc. C. E., then an Assistant in the Coast and Geodetic Survey, investigated the tidal phenomena involved. The reports of the Advisory Council and of Mr. Mitchell were widely quoted in subsequent reports, and practically all investigators from that time until General Parsons began his tidal observations in 1907, based their computations and discussions of currents on Mr. Mitchell's observations of tides during one month in 1860. Unfortunately, Mr. Mitchell assumed mean tide level in Buzzards Bay to be the same as mean tide level in Cape Cod Bay, and the error was not discovered until nearly fifty years later, when it was pointed out by General Parsons. Mr. Mitchell's observations indicated that the tide head producing flow in one direction would be far from equal to that producing flow in the opposite direction, a result which would tend to make velocities computed from his data higher, in one direction, than those computed from the correct data (a fact which may partly explain the opposition of many prominent investigators to the construction of an open canal).

Nevertheless, between the years 1870 and 1880, two eminent engineers sponsored the proposition that a canal without locks would be feasible. In his "Report on the Cape Cod Canal",[6] Gen. J. G. Foster, U. S. Army, gave results of calculations of current velocity in a proposed open canal 198 ft wide by 23 ft deep, as indicating a maximum probable velocity therein of 4 miles per hr. The late Clemens Herschel, Past-President and Hon. M. Am. Soc. C. E., supported, with independent computations, General Foster's conclusion that an open canal was entirely feasible. From this time until General Parsons was appointed Chief Engineer of the Company which finally constructed the canal, predictions of current velocities to be anticipated in an open canal of various cross-sectional dimensions were made by many other engineers.

PARSONS' INVESTIGATIONS

Tidal observations were begun by General Parsons in October, 1907, with the setting up of two, automatic, recording tide-gauges, one in Buzzards Bay, the other in Cape Cod Bay. From these observations (which continued until 1915) he found that, although the Cape Cod Bay tide is symmetrical above and below mean sea level, the Buzzards Bay tide is unsymmetrical with reference to that plane, mean high water being 2.1 ft above mean sea level, and mean low water being only 1.4 ft below it. Mean tide level, therefore, was above mean sea level and, consequently, the average values of the heads producing velocities in opposite directions do not differ appreciably, as would be the case if the Buzzards Bay mean tide level coincided with mean sea level as assumed in the 1860 tidal observations.

After the canal was completed, observation posts were selected at ten interior points in the land cut, and a series of tide and current observations were made under the direction of General Parsons[3] by observers and assistants at each post. Current velocities were measured by means of surface floats. In addition, current meter observations were made at Station 225 (nearly half way between the ends of the canal, see Fig. 2) to determine the relation between the mean velocity of the cross-section and the observed center-surface velocity. This factor was desired for the purpose of checking the results obtained from the application of various hydraulic formulas with the observed results. It was determined from these observations that: (1) The mean velocity of the entire section = 0.78 times the maximum surface velocity; (2) the maximum velocity in the section = 1.066 times the maximum surface velocity; and (3) the mean velocity of the entire section = 0.73 times the maximum velocity in the section.

Velocities computed by various methods were compared with those actually observed, and a method of solution by harmonic analysis was developed by General Parsons.[3] This method, based on the theory of tides in canals derived by Sir George Biddell Airy, as interpreted by Professor Maurice Lévy, yielded results which checked those observed closely. The method is rather complicated, however, and this consideration, together with the fact that all analytical results must be based on important basic assumptions which may or may not be true, led General Parsons to investigate various approximate methods of solving the problem. The methods included in this study were the formulas of Bazin, Eytelwein, Ganguillet-Kutter, the French Academy of Sciences, and the method of solving the formula for permanent non-uniform flow developed by Professor Bubendey. From this investigation he concluded that the Ganguillet-Kutter formula could be used for the evaluation of velocities in the Cape Cod Canal with sufficient accuracy for all practical purposes.

---

[6] Senate Misc. Doc. No. 145, 41st Cong., 2d Session (1870).

OBSERVATIONS OF TIDES AND CURRENTS BY THE UNITED STATES CORPS OF ENGINEERS

Shortly after the United States purchased the canal in 1928, two automatic recording tide gauges were established in the same locations as those used from 1907 to 1915. These gauges have been maintained in continuous operation since August, 1928, for the purpose of collecting basic tidal data.

TIDE AND CURRENT OBSERVATIONS, 1932

A comprehensive series of tide and current observations was made in 1932 when the project dimensions were 100 by 25 ft, shortly before the beginning of the dredging for widening to 170 ft. The Survey Section of the 1st New York District, Engineers, U. S. Army, supplied the equipment and technical assistance to the Boston District for this series of observations. The field work was conducted by personnel of the Boston District U. S. Army Engineers, and the records were compiled and tabulated by the 1st New York District. The purpose of the observations was to determine the laws governing the flow in the canal as well as to secure a basis for comparison with conditions after future widening.

Observation posts were selected at intervals of approximately 5 000 ft throughout the canal, the locations being made to coincide as nearly as possible with those used by General Parsons in 1915. Two parties were employed in making the velocity observations, one party remaining at the master current station, at Station 225, making continuous observations for the full period of the survey (September 28 to October 6, 1932), the other party observing at each of the other posts for a period of approximately one day. The continuous record at Station 225 served as a basis for comparisons between the shorter records at the other points. A similar arrangement for observing tides was used, three master recording gauges being maintained for the full period of the survey while the intermediate tide staffs—one at each observation post—were read by the current observer during the period his party was in position at that post.

Current observations were made from launches anchored in the center of the canal, the measurement at each observation post being confined to a single vertical located at the axis of the deep-water channel, which was also close to the point of maximum velocity. Observations were made with two current meters simultaneously, one at three-tenths the depth, the other at seven-tenths the depth. The meters used were of the standard, large, Price type, mounted in an open rectangular iron frame. A sealed chamber of special design on the meter frame was used to protect the electrical connections against the effects of long-continued immersion in salt water. An automatic graphic recorder with pen arm was actuated by a magnet controlled by a magnetic accumulator relay connected in series with the electrical circuit of the meter. Each meter had its individual circuit with separate relay and recorder.

In order to eliminate minor fluctuations in the current velocities measured, average values over 15-min periods were taken from the records. After all these observed velocities were tabulated and platted, the observations of tides and current velocities at the subsidiary stations were reduced to mean values for the full period of the survey by reference to the master tide and current stations. For convenience, time was reduced to equivalent hours after the time of the moon's transit. From these reduced values, water-surface elevations and velocity were platted against time, as shown in Figs. 8, 9, and 10.

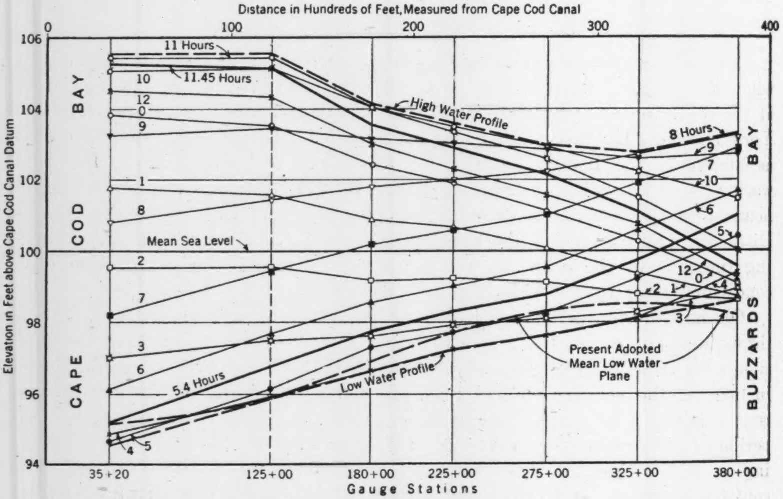

FIG. 11.—PROFILES OF WATER SURFACES: AVERAGE OF OBSERVATIONS, SEPTEMBER 28 TO OCTOBER 6, 1932.

The hourly profiles were also platted, as demonstrated by Fig. 11. The high-water and the low-water profiles were obtained by drawing lines osculatory to the hourly profiles.

As noted previously, the lag of the Cape Cod Bay tide behind the Buzzards Bay tide averages 3 hr. Therefore, high and low waters at one end of the canal occur nearly simultaneously with mean sea-level elevation at the other end. A noticeable feature, shown in Fig. 11, is the flattening of the water surface for a distance of more than two miles from the eastern end of the canal. The profiles near the time of high water especially reflect this effect which is probably due primarily to the propagation of the Cap Cod Bay tidal wave into the canal.

Analysis of Relation Between Head and Velocity

The data obtained from the 1932 observations were used as a basis for an investigation of the relation between head and velocity by Charles K. Panish, Assistant Engineer, 1st New York District, Engineers, U. S. Army.[7] In order to establish this relationship in simple form it was found desirable to distinguish between the observed head and the ideal, or effective, head producing velocity. The effective head is defined as that existing in a canal of equivalent uniform section under conditions of steady flow, and was determined by means of the following equations:

For decreasing heads:

$$H = H' + \Delta h + \Delta H \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and, for increasing heads:

$$H = H' + \Delta h - \Delta H \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which $H =$ the effective head; H', the observed head; Δh is a correction due to the fact that the actual canal was not of uniform section; and, ΔH is a correction due to the acceleration in the current brought about by changes in the tide. The numerical values of these corrections were determined by Mr. Panish, thus: Values of ΔH vary from 0.0 to 0.5 ft, being 0 when the head is at a maximum during any tide; values of Δh vary from 0.0 to 1.1 ft, having, for the most common heads, the values listed in Table 8.

TABLE 8.—Values of Δh

Head, in feet	Values of Δh, in Feet	
	Current from west to east	Current from east to west
4.0	0.50	0.68
5.0	0.63	0.82
6.0	0.78	1.00
7.0	0.92	1.05

The study made by Mr. Panish of the observed velocities and the corresponding effective heads indicated that for all values of the velocity important to this paper (that is, when turbulent flow occurs), the dominating forces are hydraulic, and that the velocities in the canal as it existed at the time of the observations, could be computed approximately from:

$$V = C \sqrt{H} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

---

[7] "Hydraulics of the Cape Cod Canal", April 11, 1933. (Unpublished Departmental report.)

in which V is the velocity, in feet per second; H is the effective head corrected as described previously; and C has values as follows:

Definition of velocity, V	Value of C
Average over entire section	1.75
Average in the center vertical	2.24
Maximum in the section	2.40

These coefficients were determined for the canal as it was in 1932 (with project dimensions of 100 by 25 ft), and the proper values for a different cross-section can scarcely be determined analytically in advance of construction to that size of cross-section.

For predicting velocities in an enlarged canal, the method employed by Maj. Willis E. Teale, Corps of Engineers, U. S. Army, as developed from his analysis of both the Parsons' and the 1932 observations,[8] may be used. He concluded from this analysis that (with slope defined as the over-all slope determined from the head, corrected for acceleration only, between the recording gauges near the ends of the canal; and with R defined as the mean of the hydraulic radii of the interior sections of the canal) the Ganguillet-Kutter formula gives the then existing (1932) velocities in the canal with any required degree of accuracy when a value of $n = 0.0336$ is adopted. The correction for acceleration applied to the head between the recording gauges is $\frac{aL}{g}$, in which a is acceleration, in feet per second per second; L, the length of the section; and g, the acceleration due to gravity. For increasing velocities the acceleration head is subtracted from (for decreasing velocities added to) the over-all head. This correction for acceleration can be disregarded in computing the maximum velocities, inasmuch as the maximum head without acceleration correction is usually identical in value with the maximum corrected head.

Tide and Current Observations, 1934.—Dredging for widening the canal to a bottom width of 170 ft began October 31, 1932, the project depth remaining the same—25 ft. A much less extensive series of tide and current observations than the 1932 observations was made in September, 1934. At the time of the beginning of these observations the canal had a bottom width of at least 170 ft from the east end to Station 260, and a project bottom width of 100 ft from Station 260 to the west end. During the progress of the observations the west end of the dredged cut was advanced from Station 260 to Station 282 (see Fig. 2). With the canal 170 ft wide for about 70% and 100 ft wide for the remaining 30% of its length, it was naturally anticipated that the surface slopes would be steeper, and, in consequence, the current velocities higher, in the narrow part.

The observations were made in order to: (1) Determine the maximum velocity in the, as yet, unwidened part; (2) obtain data on the distribution of velocity within the cross-section with a bottom width of 170 ft; and

---

[8] Cape Cod Canal—Analysis of September–October, 1932, "Velocity Observations", June 7, 1933. (Unpublished Departmental report.)

(3) determine the value of the roughness coefficient for the 170-ft section. Both the work in the field and the office computations were under the immediate direction of Donald F. Horton, Jun. Am. Soc. C. E.

The current observations were made from one launch from which were suspended two current meters of the identical type used in the 1932 observations. The Survey Section of the 1st New York District, U. S. Army Engineers, again supplied the equipment and technical assistance. Tide staffs were set up at the same locations as in 1932 and were observed as required to obtain data for the accomplishment of the specific objects outlined herein.

To determine the maximum velocity in the narrow section, observations were made at the center of the canal with one meter at three-tenths, and the other at seven-tenths, the depth. Two points had been selected as the probable locations at which the highest velocity would occur, and observations during two tides were made at each point. The highest velocities were observed at Station 346 and are as given in Table 9.

TABLE 9.—HIGHEST OBSERVED VELOCITIES AND TIDE HEADS (1934).

Direction of current	Tide head, between ends of canal, in feet	Velocity at 0.3 depth at center of canal, in feet per second
East to west	6.35	10.1
West to east	6.80	8.2

In order to eliminate minor fluctuations the velocities tabulated from the records were taken as averages over 15 min. The master current station of the 1932 observations (Station 225) was selected for the observations to obtain data on the distribution of velocity in the 170-ft cross-section. This location was chosen primarily because the canal alignment is a tangent for a considerable distance in each direction; it is also nearly mid-way between the ends of the canal. Nine measuring verticals were selected; one at the center, the others spaced 20 ft apart across the channel width. Velocity curves were observed at each of these verticals by means of the two current meters, one suspended constantly at three-tenths the depth, while, with the other meter, the velocity at each tenth the depth from surface to bottom was observed for not less than 7.5 min. The results obtained in each vertical, therefore, were a value of the velocity (average record of 7.5 min) at each tenth of the depth, and simultaneous values of the velocity at three-tenths the depth. Since the velocity is continually changing, the observed velocities at each tenth the depth were reduced to a common value of the velocity at three-tenths the depth by means of the simultaneously observed values. A vertical velocity curve was thus obtained for each of the nine verticals.

The determination of the variation in velocity across the channel was made by observations at three-tenths and seven-tenths the depth for not less than 7.5 min, successively, at each vertical. During the meter observations at each vertical the center surface velocity was determined by means of surface floats. The series of observations was made as expeditiously as possible during the period from 1 hr before, to 1 hr after, the time of maximum current, and was repeated the next day in the same manner when the water was flowing in the opposite direction. From these observations the average ratio of mean velocity of the entire cross-section to mean velocity in the center vertical was determined for four different elevations of the water surface and was found to be 0.87.

From these ratios and the relationship between the observed velocities and the mean velocity of the center vertical (which mean was determined from the vertical velocity curves observed at the center vertical), reduction factors for the convenient determination of mean velocity of the cross-section directly from the observed velocities were computed for use in:

$$V_m = F_1 V_{0.3} + F_2 V_{0.7} \dots\dots\dots\dots\dots\dots (4)$$

in which V_m = the mean velocity of the cross-section; $V_{0.3}$ = the observed velocity at 0.3 depth at center; $V_{0.7}$ = observed velocity at 0.7 depth at center; and, F_1 and F_2 are reduction factors, the average values of which, as determined for four different elevations of the water surface, were found to be $F_1 = 0.51$ and $F_2 = 0.31$. The average ratio, $\frac{V_m}{V_{0.3}}$, was determined to be 0.76.

For the determination of the roughness coefficient in the 170-ft canal, the reach from Station 180 to Station 275 (Fig. 2) was selected. Tide staffs were observed at Stations 180, 225, and 275, and current meter observations were made at the center of the canal at Station 225, with one meter at three-tenths, and the other at seven-tenths, the depth. These observations were made during the period from 1.5 hr before, to 1.5 hr after, the time of maximum velocity for both directions of the current. From these observed velocities (each an average of 15-min record), by application of the reduction factors already determined, the corresponding mean velocities of the section were computed. From the tide-staff observations, the average of the hydraulic radii within the reach under consideration, and the water surface slope corresponding to each of these mean velocities were determined. (The water surface slope was determined from the carefully observed difference in elevations between Station 180 and Station 275 corrected for acceleration.) By substitution of these known values in the Ganguillet-Kutter formula, a value of n for each of the twenty mean velocities determined from the observations was computed. The average of these values of n was 0.037. The methods used in analyzing the results of these observations followed, in general, very closely those used by Major Teale in his analysis of the 1932 observations.[8]

PREDICTION OF VELOCITIES IN AN ENLARGED CANAL

The flow of water in the Cape Cod Canal being variable (velocity and water surface continually changing), as well as varied (non-uniform), an exact analytical determination of the velocities to be anticipated in an enlarged cross-section cannot be made by any means known to the writer. Since the maximum velocity during a given tide is of paramount practical importance, the problem may be simplified in some respects by restricting it to the approximate determination of the maximum velocity resulting from a given tide head. Since the general equation[9] for variable-varied flow, namely,

$$S = \frac{V^2}{C^2 R} + \frac{d}{dx}\frac{(V^2)}{2g} + \frac{1}{g}\frac{\delta v}{\delta t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

differs from the general equation for varied flow only in the term, $\frac{1}{g}\frac{\delta v}{\delta t}$, which is zero at the instant of maximum velocity, the problem, as thus restricted, may be considered, for all practical purposes, one of steady varied flow in which the water surface elevations at the ends of the canal are given and the resultant discharge and velocity are desired. In Equation (5), S = slope; R = hydraulic radius; and t = time.

The ultimate size of cross-section which has been proposed is that with a bottom width of 500 ft, depth below mean low water of 40 ft (with 1 ft overdepth) and side slopes of 1 on 2.5. The maximum velocities to be anticipated at a point approximately midway between the ends of the canal (Station 225) with a cross-section of this size were computed by solution of the varied flow equation for a number of combinations of water surface elevations at the ends. The method solving the varied flow equation developed by Boris A. Bakhmeteff,[9] M. Am. Soc. C. E., was used for flow from west to east. In the other direction, flow takes place against an adverse or negative slope. In this case, the method developed by Arthur E. Matzke, Jun. Am. Soc. C. E.[10] (from equations derived by Professor Bakhmeteff), was used.

In the determination of the varied flow factors used in both these methods of solution, the Ganguillet-Kutter formula with coefficient of roughness of 0.035 was used.

The velocities first derived were obtained by dividing the computed discharge by the area of cross-section at Station 225, and, therefore, were mean velocities of the section. Mean velocity, however, is not of direct interest to navigators. The velocity at three-tenths the depth at the center—which roughly approximates in value the maximum velocity in the section—is believed (for most vessels which will use the canal) to be a better criterion of the extent to which a vessel may be affected by the current. The mean velocities first computed, therefore, were reduced to values corresponding to velocity at three-tenths the depth at the center by the application of the factor, 1.31, determined from the 1934 observations. The results are given in Table 10. These results agree closely with those obtained from the application of the method used by Major Teale previously described.[8]

Theoretically, since the surface slope is not parallel to the bottom slope, the highest velocity resulting from a given tide head would not occur at Station 225, but at one end of the canal, depending on the direction of the current. Actually, it is probable that this effect will be somewhat obscured, as it was observed to be in the existing canal, by unavoidable irregularities resulting from dredging operations.

---

[9] "Hydraulics of Open Channels", by Boris A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932.

[10] "Varied Flow in Channels of Adverse Slope", by Arthur E. Matzke, *Proceedings*, Am. Soc. C. E., February, 1936, p. 193.

Assuming the same ratio between mean velocity of the section and velocity at three-tenths the depth at the center, as determined at Station 225, these highest velocities would be as given in Table 10(*b*).

TABLE 10.—PREDICTED VELOCITIES IN THE CENTER OF THE 500 BY 40-FOOT CANAL

Tide head, in feet	MAXIMUM VELOCITY AT 0.3 DEPTH				MAXIMUM VELOCITY AT 0.3 DEPTH			
	From West to East		From East to West		From West to East		From East to West	
	In feet per second	In knots	In feet per second	In knots	In feet per second	In knots	In feet per second	In knots
	(*a*) AT STATION 225				(*b*) HIGHEST VELOCITIES AT ANY SECTION			
6.0	8.8	5.2	9.2	5.4	9.2	5.4	10.2	6.0
6.5	9.2	5.4	9.4	5.6	9.6	5.7	10.7	6.3
7.0	9.4	5.6	9.9	5.8	10.0	5.9	11.1	6.5
7.5	9.8	5.8	10.2	6.0	10.5	6.2	11.5	6.8

Since a comparable velocity of 10.1 ft per sec occurred with a tide head of 6.4 ft in the narrow section of the existing canal during the widening to 170 ft, it appears that the maximum velocities to be anticipated in a 500 by 40-ft canal will not greatly exceed those which have been actually experienced with similar tidal conditions in the short restricted 100-ft section before the completion of the 170-ft widening program. Velocities in the proposed 540 by 32-ft canal should be approximately 7% less than in the 500 by 40-ft canal.

The frequency of tide heads of the magnitudes listed in Table 10 have been approximately as follows: Higher than 6.0 ft, 15% of tides; higher than 6.5 ft, 10% of tides; higher than 7.0 ft, 5% of tides; and higher than 7.5 ft, 1% of tides. The phase relationships of the tides at the ends of the canal are such that the effect of the increased discharge through an enlarged canal will be to decrease the frequency with which heads of a given magnitude occur. It is probable, for example, that with the 500 by 40-ft canal, tide heads higher than 6.5 ft will occur during less than 10% of the tides.

The computations described herein, of velocities to be anticipated in an enlarged canal, were based on the tidal data observed with the 100 by 25-ft canal, because the changes in tidal conditions resulting from the increased discharge through an enlarged canal cannot be determined analytically with certainty. Furthermore, the exact value of the coefficient of roughness (n in the Ganguillet-Kutter formula) is not known definitely. It is thus seen that, for these reasons, if for no others, the predicted velocities can be considered approximate only and are possibly in error by as much as 10 per cent.

MODEL STUDIES

Of practical importance in the control of the dredging operations for the enlargement of the canal is the locus of the plane of mean low water which will obtain after the completion of the enlargement, since the depth is to be determined with reference to that plane. It is anticipated that the increased discharge through an enlarged canal will change the elevation of mean low water in Buzzards Bay and in the canal proper, but no analytical method of determining this change quantitatively is known. Another problem of practical importance is the design of the proposed mooring basins, to eliminate as far as possible undesirable and dangerous eddies, which would not only menace shipping, but also would increase the difficulty and cost of maintenance. Both these problems are considered suitable for analysis by means of model studies. Therefore, it is believed desirable to undertake model studies of the enlarged canal for the purpose of studying these two problems. At the same time, determinations of velocity would be made as a check of the computed velocities, and with little additional cost, the effects of regulating works in Buzzards Bay may also be studied.

The proposed model of the enlarged canal would necessarily include enough of the upper end of Buzzards Bay to insure reaching a point at which the tide will not be affected by the increased discharge through the canal. No difficulty in this respect is anticipated for Cape Cod Bay since its characteristics are such that the increased discharge will not be large enough to affect the tide therein appreciably. Preliminary computations indicate that the area which should be reproduced will necessitate, with the scale tentatively selected, a model approximately 110 ft long.

During the investigation of a lock canal, two model studies were made. The first of these was undertaken by Thomas A. Lane, Jun. Am. Soc. C. E., and Lt. John L. Persons,[11] Corps of Engineers, U. S. Army. The purpose of the study was to determine the amount of depression below sea level of the water surface at the dock. This problem is of practical importance in the determination of the datum plane for dredging and of the design elevation of the lock sill. The study was made with a concrete model, approximately 40 ft long (scales: Horizontal, 1:1 000; vertical, 1:49). The results indicated that the depression of the water surface at the lock would be so small that for all practical purposes it could be neglected. This conclusion confirmed that reached by computations made in the office of the Boston District, U. S. Army Engineers, using the methods developed by Colonel Brown and General Parsons, to which reference has previously been made.

Model tests were also made to determine the most satisfactory design of the filling system for the lock. These tests were made by George R. Rich, M. Am. Soc. C. E.,[12] on a model to a scale of one-fortieth of a lock with a chamber 110 ft wide, 1 000 ft long, and 40 ft deep. Five different conduit designs were tested for filling time and effect on a vessel in lockage. The test ship used was a model of a standard cargo vessel, 600 ft long, with 75-ft beam, loaded to 35 000 tons displacement.

DISCUSSION

C. S. JARVIS,[13] M. AM. SOC. C. E. (by letter).—On a project that required about 260 yr between its serious inception and the first construction work, and another 30 yr, or more, before it was opened to traffic at the outbreak of the World War, it is not surprising that many questions and problems require serious consideration before radical enlargements, revisions of alignment, and structural improvements of the Cape Cod Canal are authorized. The value of this project to navigation, as satisfactorily demonstrated during its first few years of operation, from the standpoint of time and distance saved as well as hazards avoided, led naturally to its being taken over by the Federal Government. To measure up to national standards for maintaining and promoting commerce by navigation, it was found necessary to enlarge the cross-section, revise the curvature and some other features of alignment, and to provide other measures of safety for vessels beset by fog and storm.

The restricted depth and width of the canal as originally constructed, together with the high velocities occasionally attained, due to tidal differences prevailing in Cape Cod and Buzzards Bays, were directly accountable for several mishaps to vessels undertaking to use the new waterway. Although the losses were relatively small as compared with the disasters avoided along the outside route, it became imperative to enlarge the cross-section and to improve the alignment of the canal. During the preparation of plans for this improvement, it developed that some vital differences of opinions existed among those responsible for the design, review, and supervision of the work; for example, it seemed to be regarded as axiomatic among some official circles, that the increase of cross-section would result in a considerable increase of velocity due to tidal action. To others, it was just as evident that there should be no pronounced change of velocity due to doubling or trebling the bottom width, with some increase in depth. In fact, the opinion was even ventured that if the widening were carried to great extremes, say 800 or 1 000 ft, the tides in Cape Cod Bay and Buzzards Bay would occur more nearly in synchronism, with decreased differences in water-surface elevation and velocities of flow. The apparent proof of this assumption is to be found in a consideration of what would be the condition if the two bays were connected by a very wide and unrestricted channel of great depth. Unquestionably, their tidal phases would thereafter be in fairly close agreement.

Investigations by Earl I. Brown, M. Am. Soc. C. E., and the late Harry Franklin Flynn, M. Am. Soc. C. E., in connection with the proposed New Jersey Section of the Intracoastal Waterway, to connect the Delaware and Raritan Rivers through a 31-mile land cut, demonstrated that enlarging the cross-section reduced the velocity of flow. The dimensions of the cross-sections compared were approximately those of the original and the recently authorized enlargement of the Cape Cod Canal, but somewhat greater in each case. If the aforementioned investigations and demonstrations are accepted as conclusive, it appears questionable whether the proposed enlargement to 540 by 32 ft will result in velocities already experienced in the original cross-section, or observed during the process of widening to the present 205-ft bottom width. From analogy, it seems to be fairly well assured that the wider section will accommodate a sufficiently greater volume of water interchanged from the two ends of the canal to reduce the tidal differences and the period of lag by measurable and considerable amounts, with a corresponding reduction in velocity of flow.

---

[13] Hydr. Engr., Soil Conservation Service, Washington, D. C.

In view of the cost estimates published in Table 6, showing that the 540 by 32-ft canal section should cost approximately $4 300 000 less than a 250 by 32-ft canal with twin locks, it would be interesting to trace back among the earlier estimates in which the financial advantage was generally claimed for the lock canal. The project, the Engineering Profession, and the Federal Service are all greatly indebted to the Division Engineer of the North Atlantic Division, Col. G. M. Hoffman, Corps of Engineers, U. S. Army, who was largely responsible for the modification or reversal of prevailing opinion as to the proper procedure. His plea was for progress along lines that have been proved or that are readily susceptible of proof. As a result, the lock construction was delayed during the preliminary widening of the canal; and the intensive study of canal velocities as related to tidal differences in Cape Cod and Buzzards Bays resulted in significant data to prove that, with sufficient widening, the velocities would be found tolerable and the locks unnecessary. On the other hand, if the trend of evidence and opinion had continued to favor the construction of the locks after partial widening, then the structural work could have continued with more assurance, as the result of more mature consideration.

During the hydrologic observations of canal velocities simultaneously at designated stations, both before and after widening during recent years, notable progress was achieved in the art of gauging stream velocities with relation to water-surface elevations. In addition to the excellent controls introduced, as well described in the paper under appropriate headings, special notice should be accorded the practical use and value of the automatic graphic recorder specially devised in the Engineer Office for such work. It was the writer's privilege, after participating in the preliminary studies, to observe the apparatus, some of the records, and the methods of developing and correlating the data. Unusual skill and ingenuity were displayed by those responsible for the operation.

The orderly presentation of historical and technical data relating to the Cape Cod Canal, especially at this time, is of great value to the profession. The author is to be commended for his painstaking effort.

George R. Rich,[14] M. Am. Soc. C. E. (by letter).—The application of the harmonic theory advanced by the late General Parsons[3], or the reflected wave theory defined by Colonel Brown[5], to the determination of velocities and surface elevations at several selected cross-sections of an open waterway, such as the Cape Cod Canal, connecting two seas having substantial differences in tidal phase and amplitude, is both complicated and laborious. Moreover, as stated by Captain Harwood, such involved calculation is unwarranted in many cases because of the paucity of available data upon which to base the selection of the pertinent physical constants.

---

[14] Hydr. Engr., U. S. Engr. Office, Boston, Mass.

However, in computing the action of a navigation lock, located some appreciable distance from the entrance to Cape Cod Bay, in raising the elevation of high tide and depressing the elevation of low tide at the lock site, relative to similar Cape Cod Bay levels, the writer has found that the basic equations of General Parsons may be adapted to give a rational yet comparatively simple means of estimating the hydraulic effect on the canal in advance of conducting confirmatory model tests. For example, the two general equations defining the oscillatory flow are:

$$\xi = e^{p x}\left[C \cos\left(\frac{2 \pi t}{T} + q x\right) + D \sin\left(\frac{2 \pi t}{T} + q x\right)\right] + e^{-p x}\left[C' \cos\left(\frac{2 \pi t}{T} - q x\right) - D' \sin\left(\frac{2 \pi t}{T} - q x\right)\right] \ldots\ldots (6)$$

and,

$$h = - d\, e^{p x}\left[(C p + D q) \cos\left(\frac{2 \pi t}{T} + q x\right) + (D p - C q) \sin\left(\frac{2 \pi t}{T} + q x\right)\right] + d\, e^{-p x}\left[(C' p - D' q) \cos\left(\frac{2 \pi t}{T} - q x\right) - (D' p + C' q) \sin\left(\frac{2 \pi t}{T} - q x\right)\right] \ldots\ldots (7)$$[15]

in which, in addition to the notation of the paper, ξ = the displacement, or distance traveled by a particle of water in time, t, in feet; h = the height of the water surface at any section, x, referred to the elevation of mean tide, in feet; t = the time, in seconds, referred to the time of mean tide preceding high water; and x = the distance of any cross-section from the entrance to Cape Cod Bay, in feet.

The following are physical constants, determined by the conditions of the given particular problem: T = the time, in seconds, between successive high tides; e = the base of the natural system of logarithms; A = the area of the average cross-section of canal, in square feet; w = the unit weight of the liquid, in this case 64 lb per cu ft for sea water; X = the wetted perimeter of the average cross-section of canal, in feet; d = the reduced depth of the canal, in feet; that is, the depth of a rectangular section having the same area and top width as the average actual section, measured from the elevation of mean tide; and f_0 = a coefficient such that the friction force, F, per unit of surface is proportional to the nth power of the velocity so that $F = f_0\, v^n$, or $F = f_0$ for unit velocity.

---

[15] The second minus (—) sign from the end of this equation is erroneously given as plus (+) in *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 113, Equation (12).

Fig. 13.—Schematic Elevation of Locked Canal.

For a locked canal with velocities of the order of 1 ft per sec, or less, $f = 0.00756$ lb per sq ft; or,

$$f = \pm \frac{g f_0 X}{w A} \quad \text{.........................(8}$$

$$p = \frac{\left(\frac{2\pi}{T}\right)}{\sqrt{2 g d}} \sqrt{-1 + \sqrt{1 + \frac{f^2}{\left(\frac{2\pi}{T}\right)^2}}} \quad \text{.............(9}$$

and,

$$q = \frac{\left(\frac{2\pi}{T}\right)}{\sqrt{2 g d}} \sqrt{1 + \sqrt{1 + \frac{f^2}{\left(\frac{2\pi}{T}\right)^2}}} \quad \text{..............(10)}$$

The symbols, C, C', D, and D', are constants of integration to be determined from the terminal conditions of each particular case. For a locked canal they are determined as follows (see Figs. 12 and 13):

When $x = 0$,

$$h = h_0 \sin \frac{2\pi t}{T} \quad \text{........................(11)}$$

and, when $x = 30\,000$,

$$v = \frac{d\xi}{dt} = 0 \quad \text{........................(12)}$$

Differentiating Equation (6) with respect to time, t, to obtain a general equation for velocity:

$$\frac{d\xi}{dt} = e^{p x}\left[-\frac{2\pi}{T} C \sin\left(\frac{2\pi t}{T} + q x\right) + \frac{2\pi}{T} D \cos\left(\frac{2\pi t}{T} + q x\right)\right]$$
$$+ e^{-p x}\left[-\frac{2\pi}{T} C' \sin\left(\frac{2\pi t}{T} - q x\right) - \frac{2\pi}{T} D' \cos\left(\frac{2\pi t}{T} - q x\right)\right] \quad \text{...(13)}$$

The next step is to compute the physical constants (see Fig. 14). Let $X = 444$ ft; $A = 12\,250$ sq ft; $w = 64$ lb per cu ft; $g = 32.2$ ft per sec²; $d = 28.5$ ft; $L = 30\,000$ ft; $\frac{2\pi}{T} = \frac{2\pi}{44\,715} = 0.00014$ radian per sec; $f_0 = 0.00756$ lb per sq ft; $f = 0.000138$; $p = 0.00000208$; and $q = 0.00000507$.

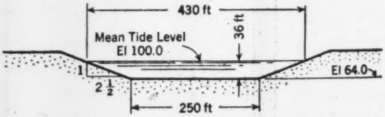

FIG. 14.—ASSUMED AVERAGE CROSS-SECTION LOCKED CANAL.

Substituting the values of the foregoing physical constants and making $x = 30\,000$ and $\frac{d\xi}{dt} = 0$ in Equation (13); then setting $\frac{2\pi t}{T}$ equal, successively, to 0 and $\frac{\pi}{2}$, two simultaneous equations are obtained involving C, C', D, and D'.

Next, substituting the values of the physical constants and making $x = 0$, $h = 6.00 \sin \frac{2\pi t}{T}$ in Equation (7); then setting $\frac{2\pi t}{T}$ equal, successively, to 0 and $\frac{\pi}{2}$, two additional equations are obtained in C, C', D, and D', giving $C = 1.77 \times 10^4$; $C' = -1.77 \times 10^4$; $D = -0.40 \times 10^4$; and $D' = -1.07 \times 10^4$.

With the foregoing constants of integration determined and substituted in Equation (7), the maximum value of h for $x = 30\,000$ is obtained by first placing $\frac{dh}{dt} = 0$, solving for t, and then computing h from Equation (7) for the value of t thus obtained, giving $h = \pm 6.10$ ft for $t = 20$ min after $\frac{T}{4}$ and $\frac{3T}{4}$. In other words, maximum high water and minimum low water at the lock site occur shortly after the time of occurrence of the corresponding levels at the entrance to Cape Cod Bay.

Similarly, with the constants of integration substituted in Equation (13), the maximum value of velocity, $\frac{d\xi}{dt}$, for $x = 0$, is obtained by placing $\frac{d^2\xi}{dt^2} = 0$, solving for t, and then computing $\frac{d\xi}{dt}$ from Equation (13) for the value of t thus obtained, giving $\frac{d\xi}{dt} = \pm 0.94$ ft per sec for $t = 0$ and $t = 22\,358.5$ sec. In other words, the maximum velocity at the entrance to Cape Cod Bay occurs close to the time of mid-tide.

Since the original objective in making the foregoing study was to determine the order of magnitude of the super-elevation and depression of tidal heights at the lock, rather than the refinement in the numerical result, slide-rule computations were used almost exclusively; and hence no claim is made to great accuracy in determining the critical times, which may be in error 10 min, or more. However, the following series of observations, brought to the attention of the writer by Lt. Col. Richard Park, Corps of Engineers, U. S. Army, then District Engineer at Boston, Mass., regarding a similar situation which occurred at the time when the Chesapeake and Delaware Canal was being lowered to sea level, tends to confirm the reliability of the method of analysis. The Delaware end of the Canal was opened to the tide for a distance of about three miles up to the lock at St. Georges. For a period of

TABLE 11.—COMPARISON OF OPEN AND DEAD-END CONDITIONS, CHESAPEAKE AND DELAWARE CANAL

Location	High-water lunitidal interval, in hours	Height, in feet	Low-water lunitidal interval, in hours	Height, in feet	Range, in feet
Reedy Island	10.83	5.96	5.46	0.46	5.50
Reedy Point	11.19	5.90	5.59	0.53	5.37
St. Georges (February, 1927)	11.47	6.01	5.96	0.45	5.56
St. Georges (April, 1927)*	11.44	5.57	5.95	0.67	4.90

* After canal was cut through.

about two weeks this was as far as the tide could be propagated, and advantage was taken of the opportunity to set a gauge in the lock, so as to permit comparison of its readings with those of the Delaware River gauges. As shown in Table 11, the St. Georges ranges were perceptibly higher until the canal was cut through.

E. C. HARWOOD,[16] ESQ. (by letter).—Various interesting aspects of the Cape Cod improvement program have been mentioned by the discussers, and the only phase that seems to require further clarification is the reference by Mr. Jarvis to the change from earlier estimates in which, to use his words, "* * * the financial advantage was generally claimed for the lock canal."

Although no published data are available, various estimates, together with general assertions in reports, certainly justify Mr. Jarvis' statement that earlier estimates had claimed a financial advantage in favor of the lock canal. The writer's estimate for the open canal, 32 ft deep, with a bottom width of 540 ft throughout the land cut, was $23 172 000, whereas the corresponding estimate for a lock canal was $27 499 000. The marked change shown by the estimates presented in the paper is traceable to two major features, each involving approximately the same sums of money.

In the first place, estimates for twin locks complete (110 ft by 1 000 ft), as originally presented by the Engineer Department, allowed a total of $8 940 000 for these features of the work. Subsequent to the publication of those estimates[17], extensive model studies were undertaken and new estimates were prepared. The result was a revision upward of the estimated cost of such locks, especially taking into consideration the difficult foundation conditions as revealed during the construction of the new bridges at the Cape Cod Canal. The increase in this part of the estimate was $2 560 000, making the total estimated cost of the twin locks, $11 500 000. This is the value given in the paper.

The second important feature which resulted in a marked reduction of cost estimates for an open canal was a reconsideration of the possibilities of excavating "in the dry." A careful study of earlier data, including the paper on this subject presented by General Parsons,[3] led the writer to believe that the excavation "in the dry", to the maximum extent possible would result in marked savings. The estimates prepared with that idea in mind show a saving in the amount of $2 703 000.

It will be noted that the sum of the two amounts just mentioned (that is, $5 263 000) is substantially in excess of the saving shown for an open canal according to the estimates in the paper. Although the figures are not precisely the same as would be found in earlier studies, it is plain that in the absence of these changes the lock canal would have been the more economical of the two so far as first cost is concerned, at least.

Of course, it will always be impossible to test the accuracy of the estimates for the cost of constructing twin locks, but readers will be interested to know that the estimated rate of savings for excavation "in the dry" has actually been realized in the work done to date (1936).

Paper No. 1954

THE ENGINEER AND HIS CODE

ADDRESS AT THE ANNUAL CONVENTION, PORTLAND, OREGON, JULY 15, 1936

BY DANIEL W. MEAD,[1] PRESIDENT AND HON. M. AM. SOC. C. E.

> "The President shall * * * deliver an address at the Annual Convention." (Society By-Laws, Article 3, Paragraph 2.)
>
> "The Engineer shall endeavor to assist the public to arrive at a correct general understanding of the technical phases of public questions. He shall discourage and challenge untrue, unfair, and exaggerated statements on technical subjects, especially when such statements may lead to unworthy or uneconomical public enterprise." (Society Code of Practice, Part V, No. 3.)

Great crises frequently bring into play high ideals and are met by great sacrifices, even from those from whom such action would be least expected. In the stir and excitement of such events the spirits of men are exalted to meet, undaunted, almost any contingency. But when the excitement subsides, when the crisis is over, the selfish spirit of personal advantage returns; the love of country again becomes subordinated to the love of self.

The persistent exercise of the higher ideals, as a basis of life and action—which is often of even greater importance than a supreme sacrifice to the continued development of civilization—requires continued and unremittent effort which human nature, in the main, is apparently too weak to sustain. It has been said that it is easier to die for one's country than it is to live for one's country.

War always seems to bring out both the best and the worst in the people of a nation. In the World War in which we engaged "to save the world for democracy", hundreds of thousands willingly took up arms; thousands gave their health and their lives; and millions laid aside their own affairs and eagerly accepted service for the common good. After the Armistice, in many cases these high ideals rapidly faded away; the motive of personal advantage returned almost immediately, often greatly accentuated; action and reaction were equal. In the back-wash of post-war events, the worst frequently came to the fore; sorrow, suffering, and sacrifice had exhausted the patience and forebearance of the people of many nations. Democracies were born and hastily abandoned because they did not immediately entail Utopia. In some nations liberty has been destroyed and dictatorships have been established, throwing additional doubts on an uncertain future.

---

[1] **Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin: Cons. Engr., Madison, Wis.**

In our own country, recovery and re-adjustment seemed at first to be rapid, but it was a false recovery, based on extravagant hopes and resulting speculation. Low moral standards seemed to have gained the ascendency in political, financial, social, business, and, to an extent, in professional life. Such low ideals can by no means be entirely attributed to the war and its consequences for many such ideas antedate that event by many years.

Corporation and financial ethics have been for many decades in a chaotic condition. The history of many corporations, dating back over a long period, brought to light corporate practices in perhaps their worst phases and, while the most reprehensible of the practices on which these organizations were erected, have been eliminated, further restraint seems necessary for the welfare of the nation.

This century, and the closing years of the last century, witnessed the creation of many corporations which at times secured such great financial power and political control that they were able to ride roughshod over the rights of individuals and communities. The impersonality of such corporations has led their officials to disregard human rights and frequently human laws and to exercise their powers, to the great detriment of the nation, in ways which even the members of such corporations would never as individuals have desired or have dared to attempt.

These examples have had a depressing effect on the ethical standards not only of those exercising these powers but of many business and professional men who have been associated with them or who have been affected by them until the "law of the jungle" seemed at the time to have become the rule of business.

During this same period, however, there has been a development of higher ideals in the thoughts of the best professional and business men. The idea of the necessity of "service" as a sound fundamental requirement of professional and business activities has become dominant. Many codes of ethics and rules of conduct have been adopted, and although many who have recognized the desirability and necessity of such codes have not always observed them, when they could be ignored to individual advantage without too severe a reaction, there has been a distinct improvement in ethical ideals Such codes always have been and perhaps always will be objective ideals to be approximated as nearly as practicable. Some of the principles declared in these codes, however, are so important that their observation is essential to common decency and honesty, and the lack of their observance should disbar the offender from his association with honorable men. Such are the principles embodied in the present code of the American Society of Civil Engineers.

During these last decades the Federal and the State Governments have passed regulatory laws and have organized utility, rate, railroad, and trade commissions which have been able to eliminate many objectionable corporation practices, and the way seemed open to a gradual and satisfactory adjustment of professional and trade practice.

The objectionable practices of the past, however, under the immediate excuse of the depression, are the apparent cause of the Federal Government attempting to take over the control of the business of the country, and are the only apparent excuse for the construction of competing power plants built by the Federal Government itself and by the Federal financing of competitive plants constructed by municipalities.

It must be remembered that these private corporations are organized under law. Their securities were issued under the supervision of the States, and such securities have been sold under the laws of the States to millions of innocent purchasers who have had nothing to do with the management of the corporations. While the States have made no guaranty of permanency or of adequate returns on investments, they did to all intents and purposes guarantee a fair deal and honorable treatment to the corporations and to the investors. It cannot be maintained that our Government has met these conditions on any higher ethical plane than that which previously had been used by business.

I hold no brief for those who favor the law of the jungle in finance, in business, or in government, and I am entirely in sympathy with every reasonable effort to control improper individual and corporate initiative for the benefit of our social advancement. I cannot remain neutral when I believe that recovery would respond immediately to the establishment of confidence in a fair and equitable governmental control and that under such condition unemployment would soon be a thing of the past.

Many engineers will find it difficult to square high ideals with conditions that now exist or with the new doctrine that they are now asked to accept. Although the very foundation of the Engineering Profession is based on the belief that improved production, improved facilities, and new inventions and discoveries will add to the happiness and welfare of the people of our nation and that such results brought about by the engineers of the country are worthy of the highest praise, the engineer is now asked to believe that, in the future the road to national advancement, to happiness, and to prosperity should, with the single exception of power supply, be based on a doctrine of scarcity and high prices. Under this doctrine the few will profit at the expense of the many, and the unfortunate will do without. Under this doctrine he who makes "two blades of grass to grow upon a spot of ground where only one grew before", is to be condemned rather than praised. Under this doctrine the days of development are past, and the engineer must confine his attention simply to maintenance and modification of the things that are. The doctrine is not only destructive to engineering ideals, but it is false and vicious. If I know the engineers of the United States, as I believe I do, they will not accept this doctrine of despair, this principle of pessimism.

Much still remains to be done for the further advancement and improvement of our country, for the protection and welfare of our people, for the happiness and contentment of our citizens. The work of the engineer is not completed; we shall go on to greater things in the future than the past has ever known.

The doctrine of plenty needs for its success only an adjustment in exchange and not a cessation of effort, in order that all may benefit. The problem of exchange can and will be solved, and with abundance the needy shall be fed not on the enervating basis of charity, except to the helpless, but on a fair basis of an exchange of effort that shall arouse a feeling of manhood and womanhood instead of apathy and dependence in a free and self-reliant people. There is even hope that the principles of economics and politics may some day be better understood and be placed on a uniform, sound, honest, and intelligent basis. On this doctrine of abundance the engineers of the nation will take their stand.

Since the birth of our nation there has never been a time when intelligence, sound judgment, high ideals, and an unwavering stand for honesty, fair play, and a square deal, have been more needed than at present, and such ideals and ideas should find their firmest support from the professional men of our nation.

The Code of Ethics of the American Society of Civil Engineers, which in effect is a code of laws for the members of our Society, and the codes of most other engineering societies, apply most directly to the small percentage of engineers in general practice, and only remotely to the large majority of the membership. It seems highly desirable that a code of ethics and of conduct, perhaps advisory rather than mandatory, should be adopted which will be applicable to our entire membership.

A code of ethics for the Engineering Profession is somewhat complicated by the fact that the profession contains many men who are not engaged exclusively in independent engineering practice nor employed by those in such practice; it includes also many engineers employed in public works—Federal, State, and municipal—as well as those who are officials of transportation, utility, manufacturing, or contracting corporations, or who are employed by such corporations. There are also engineers engaged in promotional and financial operations.

The American Institute of Architects requires that its members shall not personally be interested in the building trades or be under personal obligation to manufacturers or others whose products enter into work under their supervision. The American Institute of Consulting Engineers requires that its members shall be in independent practice and not be connected with contracting or promotion, except in a purely advisory or supervisory capacity.

The American Society of Civil Engineers cannot limit its membership in any such manner, as many of its most valued members comprise not only those who are engaged in independent engineering work, but also those in all the various activities just mentioned and in various combinations of those activities and who, in the course of time, change from one occupation to another. Therefore, it becomes difficult but even more essential to prepare a Code of Ethics which will be reasonably applicable to the entire fraternity of engineers.

Although high ideals are essential to moral progress in the development of civilization and for the future welfare of the nation and of the professions, it must be recognized that such ideals must be limited by the actual conditions of life. A supreme sacrifice is possible in a crisis, but long-continued service must involve some consideration of the one who serves if such service is to continue. "The laborer is worthy of his hire." Personal consideration of self, family, dependents, and the ordinary duties of life is also of primary importance in a practical world. The nice adjustment between service and self is the real difficulty in the way of the successful application of any ethical code. Such a code of ethics, therefore, should cover as far as possible the best thoughts on the duties of the engineer in all his activities. The profession is equally interested in the consulting engineer and the engineer in general practice, and in the engineer in public works, in the service of corporations, in various combined relations, in business, in expert legal work, and in the subordinate positions of the profession, and also in the student who is intending to enter the profession.

I am greatly interested in the engineering students for they are the men who will take the place of those of us whose professional work will soon be over. They are the men who in the future will make the profession great if they possess great ability and high ideals. The profession owes a duty to these young men to see that they appreciate the necessity of high attainments and that they are informed concerning both the privileges and the duties of our great profession. At the present time many of these young men are leaving their Alma Maters without any information, other than technical, as to their duties as citizens and as engineers, many are morally injured by unfortunate associates or employment, due to their ignorance of professional ideals.

The Educational Committee of the American Institute of Architects is apparently taking great pains to see that the important matters of professional relations are discussed in all architectural schools. While a knowledge of professional ideals is of great importance to all professional students, it seems to be doubly important to the student of engineering who is to enter a profession so complicated in its manifold relationships. The profession owes to these young students, to the public, and to the profession itself, a clear statement of the best thoughts and the highest practical ideals concerning the duties of the engineer in all his relations in life.

It is my greatest hope that by the careful preparation of such a code the opportunity will be available for all engineers to review frequently the ideals of their profession and improve their relationships with the public and with their fellow engineers and associates; that through the pressure of this Society and its other co-ordinate societies, an understanding of these ideals shall be brought to every student of engineering; and that ultimately the ideals of honor, integrity, and dependability shall predominate in all the relations of our great profession.

MEMOIRS OF DECEASED MEMBERS

CHARLES FREDERICK LOWETH, Past-President, Am. Soc. C. E.[1]

Died May 15, 1935

Charles Frederick Loweth was born on March 3, 1857, in Cleveland Ohio, the first son of Daniel and Mary Ann Pennington (Brown) Loweth. His education included attendance at the Bellevue High School and one year, 1876–77, at Oberlin College, Oberlin, Ohio, where he took courses in the natural sciences and mathematics. He began his engineering work in 1875, the year before he entered Oberlin, as a Chainman on surveys.

After his year in Oberlin, Mr. Loweth was employed as Rodman in 1877 and, later, became Assistant Engineer on the construction of the Wheeling Extension of the Cleveland, Tuscarawas Valley, and Wheeling Railway, later part of the Baltimore and Ohio Lines. In this work as Assistant to the Chief Engineer, the late William Warren Card, M. Am. Soc. C. E., he gained his first experience in tunnel work. During the year 1878, he was employed as a Draftsman by the American Bridge Company, of Chicago, Ill., under E. Hemberle, Engineer. Following that engagement Mr. Loweth was employed in making surveys for the entrance of the Wabash Railroad into Chicago, by the Chief Engineer, C. S. Masten. Then followed in 1879 and 1880 ten months as a Draftsman, "designing iron bridge and roof work", with the Edge Moor Iron Company, at Wilmington, Del.

From March, 1880, until May, 1881, he was with the Atchison, Topeka and Santa Fé Railroad Company, first as Draftsman, at Topeka, Kans., in the Department of Construction, and, later, in the Department of Track, Bridges, and Buildings. Mr. Loweth arrived at Topeka the day after Mr. George S. Davison, and both young men started as Draftsmen in the office of the late Howard Vernon Hinckley. The late Charles Le Roy Annan was also in the same office, and these four formed a congenial quartette. Later, they all became Members of the Society. Of this group George S. Davison, Past-President, Am. Soc. C. E., alone survives.

The following year, 1881–82, when he was only twenty-four years of age, Mr. Loweth was Principal Assistant Engineer, under the late Edward Cornelius Kinney, M. Am. Soc. C. E., Chief Engineer, of the St. Louis, Des Moines, and Northern Railway. In this position, he was in charge of the construction of High Bridge over the Des Moines River on the line of that railway. This structure was 2 020 ft long, and 101 ft above the water.

In May, 1882, he became Engineer for Raymond and Campbell, Bridge Builders, at Council Bluffs, Iowa, and, in 1883, Manager of the Branch Office of that firm at St. Paul, Minn. This engagement permitted him to enter into private practice, and Mr. Loweth became Consultant to cities and towns, including Mt. Pleasant and Fairfield, Iowa, and Eau Claire, Wis., making investigations, plans, and reports for water supply and sewerage. It was about this time that he made application for admission to the Society and was elected a Junior on January 3, 1883. He was then twenty-five years of age, but showed an early realization of the obligations of young engineers to their profession as well as the benefits they may gain by identifying themselves with the national organization connected with it.

---

[1] Memoir prepared by Theodore L. Condron, M. Am. Soc. C. E., George S. Davison, Past-President Am. Soc. C. E., and Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E.

Mr. Loweth continued, from 1883, to practice as a Consulting Engineer and maintained his office in St. Paul from that year until 1901, designing and supervising the construction of bridges, water-works, and sewerage systems for about one hundred municipalities, and for several railroad companies with lines extending from Michigan to the Pacific Coast. It was during this period that he acted, successively, as Chief Engineer of the South St. Paul Belt Railway Company and the Davenport, Rock Island and Northwestern Railway Company, and as Consulting Engineer for the Northern Pacific Railway Company, the Minneapolis, St. Paul and Sault Ste. Marie Railway Company, and others.

In going over some of Mr. Loweth's personal files, a specification for the superstructure of a bridge across the Rum River at Anoka, Minn., for the St. Paul Northern Pacific Railroad Company, was found, written in long hand in that fine penmanship with which all his friends and correspondents became familiar. Although this bridge was not a major structure, it was no inconsiderable undertaking in 1883 for a young man, twenty-six years of age. It was a span of 160 ft. The specifications provided that the design be based on the actual "static weight" and a moving load consisting of two consolidation engines weighing 81 tons each, coupled, and followed by a train weighing 3 000 lb per lin ft, the engine wheel loads being applied as shown by a diagram introduced into the manuscript, the lettering and drawing of which look like copper-plate work. This document is an example of the careful and painstaking manner which characterized Mr. Loweth's work from his youth to the time of his retirement, two weeks before his death. No more perfect examples of careful and beautiful draftsmanship can be found than the drawings of some of these earlier structures which were very elegantly made by him personally. It is worth recording that Mr. Loweth earned the money to purchase his first book on an engineering subject by chopping wood.

It is difficult to follow the number of engagements that Mr. Loweth fulfilled, or even to list the most important of these engagements. He was not given to indulging in publicity. However, from such records as are available, the following examples of his work have been selected.

In 1885, he designed the double-track railroad bridge over the Mississippi River, at Minneapolis, Minn., for the Northern Pacific Railway Company. This bridge had two deck spans of 245 ft each over the river, and an approach viaduct, 750 ft long, built on a curve, the total length of the structure being 1 240 ft, with the tracks 101 ft above the water. The Lafayette Avenue Bridge, at St. Paul, was built in 1887, with a roadway 40 ft wide, the total width being 60 ft, and the span, 90 ft. The St. Paul Union Station Train-

Shed was built on Mr. Loweth's design in 1889. This shed was 190 ft wide and 640 ft long. The steel trusses were carried on two lines of columns with overhanging cantilevers. In 1891, the bridge across the Mississippi River between Lyons, Iowa, and Fulton, Ill., was completed on his design. This bridge included five spans ranging in length from 200 ft to 360 ft, the total length of the structure, including approaches, being 2 617 ft, with the channel span 73 ft above low water. On May 1, 1895, the highway bridge over the Mississippi River, designed by Mr. Loweth and built by the City of Red Wing, Minn., was opened to traffic. The channel span of this bridge was 430 ft long and the total length of the steel structure, 1 725 ft. The channel piers were 69 ft high. In the same year Mr. Loweth designed the Mississippi River Bridge for the South St. Paul Railroad Company. This was a double-deck structure with a railroad track on the upper level and a highway floor on the lower deck. The revolving draw-span was 442 ft long and the total length of the steel structure, 1 633 ft.

All these structures were completed on designs made by Mr. Loweth before he was thirty-eight years of age. This indicates the surprising attainments of so young a man and the great responsibilities which had been entrusted to him.

In 1885, a bridge was proposed across the Mississippi River between Davenport, Iowa, and Rock Island, Ill., for which a charter was granted by Congress in that year. Mr. Loweth was retained early as Engineer for this project. It seems that there were many difficulties, financial and otherwise, which caused the project to drag on until 1895 when several contracts were entered into for the substructure, but work did not actually begin until April, 1896. A later substructure contract was made and work resumed in September, 1896. The contract for the river piers was not made until September, 1897, after which work on the substructure and superstructure proceeded continuously until the final completion in 1899. This bridge is quite a notable structure having a revolving draw-span, 442 ft long, seven spans over the river varying from 200 ft to 365 ft. Approaches on both sides of the river were on 7° and 8° curves, with 0.6% grade. The curvature caused the bridge to be known as the "Crescent" Bridge. This bridge is still in service and is used by both the Burlington Route and the Chicago, Milwaukee, St. Paul and Pacific Railroad Company. It has a total length of 2 639 ft.

Mr. Loweth made the design and supervised the construction of the bridge over the Mississippi River at Brainerd, Minn., erected in 1898. This steel highway bridge included three long span deck trusses and had several unusual and original features, such as cantilever extensions of the main trusses beyond the single tower bent and beyond the rocker bent at the other end of the third span. From a photograph, the spans of this bridge are of ten panels each, and each span is probably about 150 ft long. The expansion and contraction of the three spans are taken care of by tall rocker bents carried on slender masonry piers.

His noteworthy accomplishments led to his being called in 1901 by the Chicago, Milwaukee, and St. Paul Railway Company to fill the position of Engineer and Superintendent of Bridges and Buildings, to succeed Onward

Bates, Past-President, Am. Soc. C. E., who had resigned. Mr. Loweth's long connection with that Railway Company was a brilliant one. He was advanced to the position of Chief Engineer in 1910, upon the retirement of the late Don J. Whittemore, Past-President, Am. Soc. C. E. He held this position until, upon his own request, he was retired and appointed Consulting Engineer, only two weeks before his death.

During Mr. Loweth's services with the "Milwaukee", as Engineer and Superintendent of Bridges and Buildings, and as Chief Engineer, a great variety of important undertakings were designed and executed under his direction, including new lines, grade reductions, relocations, and double-tracking. Some of the grading done in connection with the double-track projects in 1912 involved earth quantities comparable in volume with those handled on the Panama Canal. The masonry construction and bridge erection were largely done by the Company's own forces under Mr. Loweth's direction, and during the period of greatest activity these forces numbered more than two thousand men.

Mr. Loweth was keenly interested in the early development of concrete construction for railroad structures and was one of the pioneers in the use of concrete slabs for subways, in the track elevation work at Evanston, Ill., in 1908. He also inaugurated the use of concrete ballast deck floors as early as 1904. Concrete trestle construction and reinforced concrete pipe for culverts were used by him at an early date, and a concrete pipe manufacturing plant was established at the Company's Bridge Shop.

He was called upon to design and replace, for heavier loading, bridges across all important rivers on the older parts of the System as well as new constructions for the Western Extension from Mobridge, S. Dak., to the Pacific Coast. These structures included crossings over the Mississippi, Missouri, Yellowstone, and Columbia Rivers, as well as many of their principal tributaries.

The location of the Pacific Coast Extension also required the construction of a number of trestles, many more than 200 ft in height, most of which have concrete floor ballast decks. These trestles aggregate a total length of three miles and their erection during the building of the new line developed interesting and difficult problems for which special derrick cars had to be designed and built.

The double tracks and relocation of the line through Iowa in 1911 to 1913 called for a great number of permanent structures, including several reinforced concrete arches and a concrete deck, double-track viaduct, 2 425 ft long and 145 ft high, which was probably the longest double-track viaduct in the West when it was built in 1913.

After the completion of the Pacific Coast Extension a number of the tunnels were given a permanent lining of concrete, the most interesting example of which is the St. Paul Pass Tunnel, 2 miles long, which was done by Company forces. Much of the concrete lining of this tunnel was placed by the pneumatic process, all the work being done during steam operation and prior to the electrification of this part of the line.

A striking example of emergency work handled by Mr. Loweth was the restoration of the line to Kansas City, Mo., when the flood of June, 1903, washed ont the west approach of the Missouri River Bridge. He took personal charge of the situation, bridging a gap, 1 300 ft long and 100 ft deep, in ten days.

He was more than an Engineer, frequently being consulted by the Executive Staff, for his wisdom and fine judgment in all matters involving both legal and engineering considerations. Notwithstanding his arduous duties in connection with this railroad, Mr. Loweth took great interest in all kinds of engineering and general improvement efforts, devoting his talents especially to the development of City Planning as a broad topic. He attended the meetings of the National Conference on City Planning, contributing to the discussions. One of his valuable contributions was his paper entitled, "The Place of the Railroad in City Planning", presented at the Eighteenth National Conference on City Planning, in March, 1926. He was a Charter Member of the Chicago Regional Planning Association.

One of Mr. Loweth's last contributions to general engineering and to a great national problem, was a paper by him entitled, "Some Economical Considerations Involved in the Construction and Use of Inland Waterways of the United States". This paper is dated July, 1934, but was revised by him after that date and before he was obliged to give up his active work. The material compiled by Mr. Loweth in this paper is of tremendous importance. Certainly, the statistics included therein show that there is a serious question as to the economic justification supporting the enormous expenditures of money raised by taxation for questionable benefits to the taxpayers at large.

Mr. Loweth's direction of the Society during the year that he was President, and his wise counsel and advice while he was still a member of the Board of Direction, are preserved in the records of the Society. Anything that affected the standing and welfare of this organization was of deep concern to him. His mind was distinctively of a constructive type. He labored unceasingly for the advance of his profession and for the benefit of all members of that profession.

The very traits that made him esteemed as an engineer made him loved and admired by those who came in close personal contact with him. His interest in civic and church activities was as marked as his leadership in the Engineering Profession. His devotion to his family surpassed his devotion to his profession, which seemed to those who knew him only professionally, to be the absorbing interest in his life.

Following his death the Board of Directors of the Chicago, Milwaukee, St. Paul and Pacific Railroad Company, passed a resolution expressing deep regret at his passing, calling attention to his long service with the road and stating further:

> "Mr. Loweth's work was always conducted with great care and skill and his life was one of conspicuous achievement, marked by strict adherence to the highest ideals.
>
> "*Resolved* further that this Board hereby records its deep appreciation of his keen business ability, splendid character and his long and faithful service to this Company and its predecessor."

D. J. Brumley, M. Am. Soc. C. E., Past-President of the American Railway Engineering Association, states that:

"Among the stalwarts who participated in the early history of the A. R. E. A. was Charles Frederick Loweth. He brought to the Association thirty years of accumulated experience on railroad and municipal engineering work in the middle west. This experience was obtained at a time when precedents were few and far between, and when the engineer was placed upon his own ingenuity and resources as to specifications, design, and construction procedure."

Mr. Loweth was a member of the American Railway Engineering Association (Treasurer, 1901–1910, and Director, 1911–1912 and 1913); member of the Western Society of Engineers (President, 1908, and Honorary Member since 1931); Charter Member and Past-President of the Civil Engineers Club, of St. Paul, Minn.; and a member of the Engineers Club, Union League, and University Clubs, of Chicago.

He received the Honorary Degrees of Civil Engineer from the University of Wisconsin, Madison, Wis., in 1915, and Doctor of Engineering from Rose Polytechnic Institute, Terre Haute, Ind., in 1926.

He was married in Wilmington, Del., on February 15, 1881, to Carrie T. Curtis who, with their four children, Mary Grace, Margaret, Frederick Curtis, and Robert Charles, survives him.

Mr. Loweth was elected a Junior of the American Society of Civil Engineers on January 3, 1883, and a Member on February 6, 1884. He served as a Director of the Society from 1910 to 1912; as Vice-President in 1914 and 1915; and as President in 1923.

FRANCIS LEE STUART, Past-President, Am. Soc. C. E.[1]

DIED JANUARY 15, 1935

Francis Lee Stuart was born on December 3, 1866, in Camden, S. C., the son of Barnwell Rhett and Emma Croom (Lee) Stuart. Left an orphan at two years of age, he first lived with his maternal grandmother, who before her marriage had been a Miss Cooper, of Cooperstown, N. J., then with his paternal grandmother, of South Carolina, who died when he was eleven years of age. He then went to live with his uncle, the Reverend Dr. Albert Rhett Stuart, Rector of Christ Church, Georgetown, D. C.

Mr. Stuart was graduated from Emerson Institute, in Washington, D. C., in 1882, and entered the service of the Baltimore and Ohio Railroad Company in 1884. During the next thirteen years, he had active experience on the Baltimore and Ohio and other railroads in the East and South, in their Engineering, Maintenance, and Operating Departments, in coal mining, and in public works. In 1897, he secured a position on the surveys for the Nicaraguan Canal and became Assistant Engineer. Upon the appointment of the Isthmian Canal Commission, he was sent to Nicaragua to complete the organization for further surveys.

---

[1] Memoir prepared by a Committee consisting of George H. Pegram, Past-President and Hon. M. Am. Soc. C. E., *Chairman*, Lincoln Bush, Past-President and Hon. M. Am. Soc. C. E., and George L. Lucas, M. Am. Soc. C. E.

Returning to the United States, Mr. Stuart re-entered the service of the Baltimore and Ohio Railroad Company and became unusually expert on location of lines. He was often called in on other railroads to make reconnaissances, examine locations, and report on the economics of grade reductions. He was largely responsible for establishing grades lower than 0.3% on the Trunk Lines.

In 1905, he was appointed Chief Engineer of the Erie Railroad Company and remained with that Company until 1910, during its greatest period of improvement and expansion, which included the four-track open-cut and tunnel entrance into Jersey City, N. J., and re-vamping of the station, waterfront, and terminal tracks, the completion of the Erie and Jersey Railroad for a low-grade freight line, and the building of the Genesee River Railroad—a low-grade cut-off from Cuba, N. Y., to the Buffalo Division through difficult country. The improvements also included double-tracking and grade reduction on the Chicago Division, and on other Divisions.

In 1910, Mr. Stuart returned to the Baltimore and Ohio Railroad Company as Chief Engineer. As such he was in charge of the Company's large improvement plans, including an unusually heavy construction program of new lines, second-tracking, tunnels, grade reduction, and terminal work, until 1915, when he resigned to devote his time to private practice as a Consulting Engineer in New York, N. Y.

During the period he was Chief Engineer of the Erie and of the Baltimore and Ohio Railroads, he served on many technical and terminal committees in New York and other ports, in Chicago, Ill., and in Cleveland and Cincinnati, Ohio, and had a part in the conception of many improvements since made.

In 1913–14, he designed the Baltimore and Ohio Coal Pier at Curtis Bay, Md., and took out several patents to cover the principal features. It has two car dumpers ashore, and the coal is carried by belt and discharged into ships on either side of a long pier. It has loaded more tons per hour than any other coal pier in the world and handles material at a very cheap rate.

From 1915 to 1917, he was busied with varied consulting work. He was one of the three Technical Advisers to the War Board of the Red Cross in Washington, D. C., in an engineering capacity. He also helped to formulate standards of cantonment houses, barracks, and health methods which were adopted in the Army camps by the War Department.

In 1917, Mr. Stuart became Chairman of the Terminal Port Facilities Committee of the Storage Committee of the Council of National Defense, and assisted in outlining the plans for handling the Government supplies, from point of manufacture in the United States to point of distribution in France. He was also instrumental in the location and layout of the Army Bases at

Port Newark Terminal, in New Jersey, Philadelphia, Pa., Baltimore, Md., Norfolk, Va., Charleston, S. C., and some interior points. During this time, he was also a member of the Depot Board and other Committees in the Service.

As Chairman of the Budget Committee of the United States Railroad Administration, with the assistance of the Chief Engineers of the Baltimore and Ohio, the Pennsylvania, and the New York Central Railroads, he passed on the plans, estimates, and reasons for the proposed improvements by the railroad companies east of Chicago, and north of Norfolk, and recommended the expenditure, through the Regional Directors to the Director of Capital Expenditures, of more than $550 000 000 of the $800 000 000 spent for improvements by the railroad companies during the World War.

In 1920, Mr. Stuart was Consulting Engineer to the Hydro-Electric Power Commission of Ontario, Canada, on the canal from above the rapids of the Niagara River above the Falls to the 600 000-hp power-house below the Whirlpool. Some new construction methods and hydraulic improvements were evolved, and are serving as precedents on large undertakings.

During 1921 he was Engineering Expert for the Port Development Commission of Baltimore, and also a member of the Technical Advisory Board of the Port of New York Authority, in a consideration of the many plans for the development of New York Harbor. About this time, the Cunard Steamship Company proposed a $50 000 000 development south of Weehawken, N. J., and Mr. Stuart was retained as Consulting Engineer. In 1923, he was a member of the Transit Advisory Board of Philadelphia, Pa., and made a report on rapid transit matters in that city.

From January 1, 1923, to December 31, 1926, he was retained by the eleven trunk-line railroads which serve the Port of New York, to report on transportation matters in that Port as they affected the railroads collectively and individually before the New York Port Authority. During that time he made a joint study with the Port Authority and the forces of the railroad companies on lighterage and floatage methods and costs. He also was Chairman of the Committee of Engineers of all the railroads entering New York City, to make a joint study of the co-operative use of facilities. During 1927 he was retained by the eleven trunk-line railroads in New York City as Consultant in Port Authority matters.

During 1924–25 Mr. Stuart was Consulting Engineer to the Greater Harbor Committee of Two Hundred of the Los Angeles, Calif., Chamber of Commerce. The plan made was adopted by the Government, the railroad companies, and the City.

He was a member of the Board of Review of the Sanitary District of Chicago in the Lake Leveling Controversy and Remedial Program, in 1924, and was Chairman of the Committee on the Value of Diverted Water for Transportation from Lake Michigan to the Gulf of Mexico. He was also a member of the Committee on Great Lakes Regulation.

From 1920 to the time of his death, Mr. Stuart was Consulting Engineer of the North River Bridge Company, which proposes a bridge of 3 250-ft span at 57th Street, New York City, across the Hudson River, which, with the approaches, is estimated to cost $180 000 000, and also proposes large terminal projects on both ends of the bridge and changes in the present method of handling rapid transit and freight in New York City. Many plans of improvements in transportation in New York Harbor have been considered. At one time, a Committee of the Chief Engineers of the Trunk-Line Railroads, with the North River Bridge Company, developed a plan for bringing freight cars across the bridge and distributing them through a continuous seven-story warehouse from 57th Street to Chambers Street.

From 1915, to practically the time of his death, except during the World War, he was Consulting Engineer for several railroad companies. As a Consultant, he also gave counsel to many different projects in widely separated fields of endeavor.

Mr. Stuart was married on March 18, 1901, to Anne Morson Rives, when he was in Western Pennsylvania building a railroad over the mountains to get out coal. Their home was, successively, at Cumberland and Baltimore, Md., and Essex Fells, N. J.; then back to Baltimore and, finally, at Essex Fells.

They had four daughters, Anne Morson (Mrs. A. B. Sayre), Lee (Mrs. W. H. Sayre), Elizabeth Scott (Mrs. J. J. Whelan) and Rives (Mrs. James M. Newall) all of whom, with Mrs. Stuart, survive him. Two sons were born to them, who died in infancy—Francis Lee Stuart, Jr., born in 1907, and Barnwell Rhett Stuart, born in 1910.

Mr. Stuart was fond of engineering problems, but when in need of relaxation resorted to golf and the study and practice of horticulture, importing and planting many trees and shrubs. He gave to the Borough of Essex Fells a large collection of trees and shrubs.

He loved people and was rarely heard to speak uncharitably of any one, and then always citing extenuating circumstances if he could think of any.

The quality of Mr. Stuart's achievements speaks more for the character of the man than their number, great as it is. To be entrusted with the execution of great enterprises is an acknowledgment of merit, and where the enterprise has been initiated by such executive, or undertaken largely through his endorsement, the honor is indeed great. It is in this light that they must be viewed. Mr. Stuart was progressive and extended all the fields of activity which he entered. Bereft of both parents at the age of two, and without the advantages of professional education beyond the age of seventeen, he must perforce have been endowed with very superior qualities.

He was analytic, ingenious, and had very unusual clarity of vision, which, combined with his absolute honesty, led to his frequent engagement for investigations and reports on large financial problems. It was these qualities doubtless, which determined his selection as Chairman of the Budget Commission of the Eastern Railroads during the World War.

His inventions in methods of handling coal and freight at terminals simplified that work, and his engagement in the solution of so many great railroad and harbor terminal problems testified to his pre-eminence in that line.

Mr. Stuart's cheerfulness was proverbial. He was an optimist and carried the air of cheerfulness and optimism wherever he went.

One of his contemporaries, John E. Greiner, Hon. M. Am. Soc. C. E., writes of him, as follows:

"I first met the late Francis Lee Stuart when he was an office boy in the Consulting Engineer's Office of the Baltimore & Ohio Railroad, back in 1885.

"He was a very handsome, attractive and ambitious boy with a keen sense of humor and a desire for adventure. His personality at that time caused everybody to like him, and that same personality and liking were retained by him throughout his career. He always had original and big ideas on questions of railroad locations and terminal improvements, and could see further into the future than most of the other railroad officials with whom he worked.

"I followed his career since his boyhood days and have never heard of any man who, after meeting him either in business matters or socially, had retained any feeling except confidence in his ability and fair dealing, and a desire to be his friend.

"He could not help becoming a prominent, nationally known, successful engineer, and it was his lovable personality just as much as his broad-minded engineering ability which contributed to his successful career."

While living in Baltimore Mr. Stuart became President of the Engineers Club, a member of the Maryland Club, and of the Elkridge Kennels. While living in New Jersey, he became President of the Country Club of Essex Fells and a Charter Member of the Fells Brook Club of that place, and of the Engineers Club, at Roslyn, Long Island. During the World War he joined the Chevy Chase Club, of Washington. He was Chairman of the Building Committee for Yeaman's Hall, a club fifteen miles from Charleston, S. C., which was built on a tract of land first owned by Sir Thomas Yeaman—his ancestor. He was a member of the South Carolina Historical Society, the Southern Society of New York, the Engineers Club of Philadelphia, and the Engineers Club of New York.

His connections with professional societies included the following: He was a Past-President of the United Engineering Trustees; a member of Engineering Foundation Board; the John Fritz Medal Board; American Engineering Council; American Railway Engineering Association; a Past-President of the Terminal Engineers of New York; a member of the Institution of Civil Engineers of Great Britain, and of the Engineering Institute of Canada.

Mr. Stuart was elected a Member of the American Society of Civil Engineers on May 3, 1899. He also served as Director of the Society, from 1909 to 1911; as Vice-President, in 1920 and 1921; and as President, in 1931.

PALMER CHAMBERLAINE RICKETTS, Hon. M. Am. Soc. C. E.[1]

DIED DECEMBER 10, 1934

Palmer Chamberlaine Ricketts was born in Elkton, Md., on January 17, 1856, the son of Palmer C. and Elizabeth (Getty) Ricketts. When he was a young boy, his parents moved to Princeton, N. J., and there he prepared for college, studying with a tutor from Princeton University.

---

[1] Memoir prepared by J. A. L. Waddell, M. Am. Soc. C. E.

In his course at Rensselaer Polytechnic Institute, at Troy, N. Y., Mr. Ricketts was truly a plodder and a most successful one, as his official records there testify. He was absolutely faithful in his attendance, never wilfully "cutting" a recitation, and always on time and ready to recite. He was well liked by his classmates; but being so constantly occupied with his studies, he failed to make many acquaintances outside his Class. He did not play "Institute politics"; but in Class matters he always did his part. It was not until after graduation that his great popularity began to develop and eventually to attain what a large number of his friends deem to be absolute uniqueness.

Mr. Ricketts was graduated from Rensselaer Polytechnic Institute in June, 1875, and the following September he returned as an Instructor of Mathematics and Astronomy. In 1882, he was made Assistant Professor of Mathematics and Astronomy, and, two years later, became the William Howard Hart Professor of Rational and Technical Mechanics, taking the place of the late William Hubert Burr, Hon. M. Am. Soc. C. E., who passed to the beyond only two or three days after the death of Professor Ricketts.

Recognizing the necessity for practical experience in the engineering field, Mr. Ricketts sought and obtained it soon after his graduation, quickly becoming widely known as an efficient and successful engineer in charge of the design and construction of both bridges and hydraulic works.

In 1876, he was named Assistant Engineer with the Troy and Boston Railroad Company; and, in 1887, he became Consulting Bridge Engineer of the Rome, Watertown, and Ogdensburg Railroad Company, besides handling numerous small constructions of various kinds in the vicinity of Troy. His outside duties did not take him far from there, because he would not let them interfere with his pedagogical work.

In 1892, Professor Ricketts, at the age of 36, became Director of the Institute; and, in 1901, upon the death of President Peck, the two offices were combined, Professor Ricketts becoming both President and Director, a position which he held until his death.

Up to 1904, the Institute consisted of only a few scattered buildings, with the main building on the site of the present approach steps; and the number of students was quite limited. The present stately campus with its ten splendid main buildings, its dormitories, and club houses, the magnificent approach from Broadway, its many hundreds of students from the United States and from numerous distant lands, and its imposing list of Faculty members, was not even dreamed of. The great changes that have taken place in the last three decades are almost entirely due to the boundless energy and the indomitable perseverance of Director Ricketts.

In 1904, there fell upon Rensselaer what appeared to be a terrible catastrophe, but which proved to be a blessing in disguise. The Main Building at the head of Broadway burned to the ground, leaving a few small structures, which had outlived their usefulness, as all that remained of the

Institute. There were rumors to the effect that it would have to be moved from Troy to merge with some other school. Director Ricketts held a long conference with the late Robert Woolston Hunt, M. Am. Soc. C. E., a man of great prominence in the world of steel, and then went to interview Andrew Carnegie, whom he persuaded into giving $125 000 for a building; and soon thereafter he induced Mrs. Russell Sage to donate $1 000 000 as a memorial to her deceased husband. There was also considerable insurance money from the burned building.

A fitting appreciation of his character and succeeding accomplishments at the Institute was presented in the January, 1935, *Rensselaer Alumni News.* Quoting from this splendid tribute:

"When in June, 1904, the old Institute was practically wiped out by the destruction of its main building at the head of Broadway, only the personality of Director Ricketts stood between its historic past and dissolution. With an enthusiasm and zeal, born of whole-hearted devotion, he took up the Herculean task of rebuilding a truly great institution upon its ashes. Enlisting the hearty co-operation of an interested Alumni and tapping the sources of wealth which had devoted themselves to the development of higher education, he visioned anew the dreams of the earlier promoters, the hopes his predecessor, Dr. B. Franklin Greene, had for a true polytechnic, and enlarged that vision with new and higher impulses that welled within himself. Step by step through three decades he brought project after project to fruition, erected and equipped one modern laboratory and campus structure after another, until the Institute is complete in all its ramifications and departments encompassed by the field of modern science and engineering. Living to the ripe age of almost 79 years, he has seen brought to reality the full measure of his vision of a greater Rensselaer Polytechnic Institute, with a physical property of more than $10 000 000 valuation, a complete re-organization of homogeneous departments, and a faculty and student body more than five times what they were thirty years ago—his own pride, and himself a recognized peer in the scientific-education world.

"The Director made Rensselaer Polytechnic Institute his life work, with a singleness of purpose and devotion such as has seldom been exemplified. * * * it stands to-day as a personal monument to his wisdom, his scholarship, and his executive ability.

"Personally he disliked the term 'genius'; and yet his life experience demonstrated all the qualifications of a genius in his chosen field. The motto which he set for himself and for the thousands of students from all parts of the world who came under his direction and all-embracing personal interest, was 'work.' He demonstrated this with an energy that was tireless and unflagging, even with the passing years, with a capacity that indicated a quick grasp of the essential, with a broad-minded appreciation of the range of the human mind, and with an incisiveness and insistence that never brooked failure. He won the esteem, the confidence, and the friendly appreciation of all with whom he came into contact, and with none more devotedly than the Alumni who, during many decades, came under his direct and impelling influence.

"Although the Director counted honors lightly in comparison with concrete accomplishment, he was accorded several honorary degrees, was a prominent figure in many distinguished engineering societies, was often sought as a consultant in notable bridge and other engineering projects, and had conferred upon him the titles of Commander of the Order of the Crown of Italy and Commander of the Legion of Honor of France. He took a deep interest in both civic and educational affairs in his adopted city, in which he enjoyed a devoted home life, and served as Trustee or Director of educational, charitable, and financial institutions.

"Dr. Palmer Chamberlaine Ricketts left the impress of an unusually able and unique character upon the institution which he made so fully his own, and in the community in which he cast his lot and performed a truly great life work, the influence of which will remain permanently.

"As Director Ricketts' position in the world of science and engineering grew in importance, he was honored in many fields. In 1905, Stevens Institute of Technology conferred on him the honorary degree of Doctor of Engineering, and, in 1911, he was given the degree of Doctor of Laws by New York University.

"Although he confined his activities almost exclusively to the Institute, he was accorded national and international distinction because of his educational achievements. Upon him was conferred the rare tribute of Honorary Membership in both the American Society of Mechanical Engineers and the American Society of Civil Engineers. * * * He was also a member of the American Institute of Mining and Metallurgical Engineers, the Institution of Civil Engineers of Great Britain, and the American Philosophical Society.

"His 'History of Rensselaer Polytechnic Institute' and his contributions to technical journals won him wide recognition as an engineer and an author.

"Always intensely interested in civic affairs and business life, Dr. Ricketts was a Director of the National City Bank of Troy, a Director and a member of the Executive Committee of the Samaritan Hospital; Trustee of the Albany Academy; Trustee of the Dudley Observatory, at Albany; and Trustee and Vice-President of the Troy Public Library.

"He was a member of the Troy Club, the Union Club of New York, and the Schuyler Meadows Country Club of Albany. * * * In politics, he was an independent, never becoming affiliated with any party.

"On November 12, 1902, he married Vjera Renshaw, of Baltimore, Md. Mrs. Ricketts, a brother, and a sister are the only immediate family survivors."

The funeral services of Director Ricketts, held on the Institute grounds on December 13, 1934, were of a character befitting a man of his world prominence. Educational leaders from most of the principal institutions of learning in the East, engineers whose names are universally famous, business men, graduates, students, and former friends, came to pay their last respects and to do homage to the memory of one of America's truly great men.

Director Ricketts will be greatly missed by all the Alumni, and this will be true for many years to come—but why mourn him? He had lived a full life and had almost reached the Biblical extreme age limit of four score years, without in any manner losing his splendid mental faculties. He passed on quickly at the zenith of his career, instead of slowly failing in health and gradually losing his mental grip. It is far better to remember the gloriously fine fellow, the eminently useful citizen, the noted and honored scientist, the outstanding technical teacher, the kindly and courteous gentleman, and the brilliant man of affairs that he was, instead of thinking of him as a "has been." In his passing, the Engineering Profession has lost one of its most prominent and respected members; for he was, in every sense of the words, a great man, a true gentleman, and a famous engineer—than which there could be no higher praise.

As Director of the Institute, Dr. Ricketts was certainly a strict disciplinarian—he had to be such in order to compel obstreperous students to obey the rules of the campus, to maintain the high standard of scholarship which Rensselaer has enjoyed throughout its long career, and to keep peace between "town and gown." Although at times he had to be severe, nevertheless, he was universally conceded to be strictly just and reasonable, as well as the students' best friend—always ready to devote time and attention to their needs, to steer the wanderers back to the path of rectitude, and to help materially all who were worthy of his assistance. The indubitable proof of the correctness of this statement was his universal popularity among the students, the Alumni, and the Faculty of the Institute, as well as the citizens of Troy.

His outstanding generosity in the spending of his income both for needy students and in aiding the Institute to carry on during the long existing depression is a matter that, by his desire, has been kept in confidence. It has been talked of, especially among the Alumni, but it has not been mentioned in print.

In spite of having earned at the Institute the reputation of being of a rather retiring disposition, eventually Professor Ricketts developed, in a socio-scientific sense, into one of America's most prominent men of affairs in the field of engineering education.

In conclusion, the writer desires to say a few words about his old friend and classmate. Not only did he hold him in the highest esteem for more than half a century, but he truly loved him—and the affection was reciprocated. When it comes the writer's turn to pass on, he will be quite content if he can count even one-tenth as many true, loyal, and devoted friends as did Palmer Chamberlaine Ricketts.

Director Ricketts was elected an Affiliate of the American Society of Civil Engineers on February 3, 1886; a Member on October 5, 1887; and an Honorary Member on October 5, 1931. He served as a Director of the Society from 1899 to 1901, and as Vice-President in 1916 and 1917.

JONAS WALDO SMITH, Hon. M. Am. Soc. C. E.[1]

Died October 14, 1933

Jonas Waldo Smith died of a sudden heart attack at his home in New York City on October 14, 1933. He had not been in good health for several months yet, characteristically, at the moment of his death he was preparing to go to the golden wedding celebration of a life-time friend and associate of his early days at Holyoke, Mass. His remains were interred in the family plot at Lincoln, Mass., on a cloudless day amid the gorgeous foliage of autumn and, as one stood beside the grave, it seemed as though Nature had bedecked herself for the ceremony of taking back that which she had given.

J. Waldo Smith, as he always subscribed himself, was born at Lincoln, Mass., on March 9, 1861. He was the youngest son of Francis and Abigail Prescott (Baker) Smith. On his father's side his ancestry goes to John Smith, who came to Watertown, Mass., from England as a freeman in 1636. On his mother's side the line goes to John and Elizabeth Baker who came to America about 1720. From these roots he inherited those inherent qualities of intellect, of courage, of honesty, and of sincerity which shaped his life and made of him not only a man among men, but a leader and counselor of them.

At the age of 15, Waldo Smith helped on the construction of the water supply system of his home town and, at 17, had charge of its Pumping Station as Fireman, Engineer, and Superintendent. He attended the public schools and, when 18 years old, entered Phillips Academy, at Andover, Mass., from which he was graduated in the Scientific Course in 1881. Thereafter, he went to Lawrence, Mass., and was employed in the Engineering Department of the Essex Company. Here, he came into contact with those masters of hydraulics—Hamilton Smith, Jr., Mills, Boyden, Davis, Francis, Storrow, Herschel, and Freeman—and was inspired to further study at the Massachusetts Institute of Technology, from which he was graduated in 1887. During his summer vacations, he worked for the Holyoke Water Power Company and, for three years after graduation, he continued under the same ægis and under the influence of the men previously mentioned. These were the formative years of his life. From the living examples before him he learned the necessity for care and precision and the importance of research and experiment but, even more significantly, he also came to understand that human relations ranked at least equally with those of a technical nature. So it was that the traits of his ancestry came to bloom in the environment of his younger days and out of them grew the man of scientific vision and human understanding.

In 1890, a great water development was projected in the rapidly growing district of Northern New Jersey, and the late Clemens Herschel, Past-President and Hon. M. Am. Soc. C. E., who was in charge of these operations called young Waldo Smith to his aid. Thus began his association with the East Jersey Water Company where he learned the art and business of water supply from the standpoint of construction as well as from that of the maintenance and operation of the works which delivered the water to the ultimate consumer. In the field of construction he was engaged in the building of the Oak Ridge, Canistear, Clinton, Macopin, and Great Notch Reservoirs and on the laying of the main lines of steel pipe, 42 and 48 in. in diameter, for conveying the waters of these reservoirs to the City of Newark, N. J. Then, in 1900, he became Chief Engineer of the East Jersey Water Company and its affiliated companies, on the supplies of Paterson, Passaic, Montclair, and other communities in New Jersey. Soon thereafter it became evident that the raw water delivered by the Little Falls Pumping Plant direct from the Passaic River was rapidly becoming unsuitable for use, and that a remedy for the situation must be found. This condition led to the construction of the Little Falls, N. J., Filtration Plant which was the model and the forerunner of that great host of similar works which have since given to the people of America the best and most potable water supplies on earth. The Little Falls plant was due to the inspiration, the logic, and the insistence of Waldo Smith, and to the aid of George W. Fuller, William B. Fuller, Charles L. Parmelee, and others, to all of whom he would give due credit were this writing his own.

---

[1] Memoir prepared by Thaddeus Merriman, and Frank E. Winsor, Members, Am. Soc. C. E., and Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E.

Early in 1900, the interests which Mr. Smith represented undertook to complete the system that had been proposed for the supply of Jersey City, N. J. This project included the Boonton Dam, a masonry structure, 3 150 ft long and 150 ft high, and an aqueduct of cut-and-cover sections, tunnels and 72-in. steel pipe passing under the tidal waters of the Hackensack and Passaic Rivers and aggregating 22 miles in length. The Boonton Dam was one of the notable structures of its day. It was the first dam built of "cyclopean concrete" all of American-made Portland cement. Here thermo-couples were first installed for measuring the internal temperatures of the masonry and here was constructed the first hydraulic model of which there is record. This model of the spillway was tested, and the design of the final structure was based upon the results obtained from it. The Boonton Dam was also notable in that the water impounded by it was treated with chlorinated lime before being delivered into the aqueduct. Jersey City thus became the first American municipality to enjoy a sterilized water.

During the years 1890 to 1903, Mr. Smith, while occupied on the various undertakings outlined, never lost an opportunity for study, for research, or for investigation. He constantly experimented with his structures and subjected them to frequent operating trials. He tested the materials of construction and observed their behavior. Always had he in mind that improvement was possible, and that each succeeding construction should be better than the last. Indefatigable in his efforts, he shirked neither responsibility nor danger. During the great flood of October, 1903, on the Passaic River, he took personal charge of the Little Falls Pumping Station which the flood threatened to destroy. With a few men inside that structure, while the waters rose high against and around it, he strutted the walls to prevent their collapse. Had those walls failed there would have been no escape, but the station was saved and the pumps ran on.

This period of intense activity and achievement marked the second phase of Mr. Smith's development. The teachings he had learned and the character he had formed during his earlier days in New England grew and ripened and the Man was shaped by his own effort, by his contacts with men of affairs, by his constantly increasing responsibilities, and by his continued study of the human heart. As he was thus growing in stature his reputation was increasing day by day while he constantly made friends of his associates and endeared himself to all with whom he came in contact.

In 1903, the water situation in the rapidly growing City of New York had become most difficult, and the Metropolis, confronted with the gravest of problems, sought the solution by engaging Waldo Smith as Chief Engineer of its Aqueduct Commissioners. From the beginning he showed his quality by infusing new life into a situation which had practically reached an impasse. He quickly decided the questions which were delaying the operations on the New Croton Dam, then the largest masonry dam in the world; he resolved the difficulties which surrounded the Jerome Park Reservoir and the Muscoot Dam, and put the design for the Cross River Reservoir under way. Here, in a new environment and under public auspices totally different from those on the private enterprises with which he had been previously associated, he showed such high technical skill and administrative ability coupled with such indomitable energy that, through his keen grasp of the human factor in life, he was able to accomplish results and to have his decisions accepted and respected by all. Later, in 1905, when the City of New York needed a man to direct the destinies of its Catskill Water Supply System, the choice naturally fell to Waldo Smith, and, on August 1 of that year, he was designated as Chief Engineer of the greatest and the most costly water supply undertaking which, up to that time, had been conceived.

Entering upon that great task he did so with energy and determination, but with the future always in view. Around him he gathered a group of men upon whom he could rely. The work, he knew, was far beyond the capacity of any individual, and his immediate staff was augmented by a number of Consultants so that every detail would be made as nearly perfect as humanly possible. Waldo Smith was always the first to give credit to his associates, as he fondly called his staff, and, therefore, he would not approve this memoir were their names not mentioned. As Deputy Chief Engineer there were, from time to time, Charles L. Harrison, Merritt H. Smith, Alfred D. Flinn, and Thaddeus Merriman. As Department Engineers, there were Carleton E. Davis, George G. Honness, Robert Ridgway, Ralph N. Wheeler, Frank E. Winsor, William W. Brush, Walter E. Spear, and Charles M. Clark. The Senior Designing Engineer was Thomas H. Wiggin. The Consulting Engineers were John R. Freeman, Frederic P. Stearns, William H. Burr, Alfred Noble, Allen Hazen, and George W. Fuller. There was also a group of Consulting Geologists, James F. Kemp, W. O. Crosby, and Charles P. Berkey, whose duty it was to advise as to the geological features of the terrain in which the structures were to be built and through which the tunnels would pass. Waldo Smith was foremost among American engineers who felt and understood the need for close co-ordination between the scientific arts of geology and engineering.

As an important part of his philosophy Waldo Smith held that the relations between the Engineer and the Contractor were those of men associated on a common enterprise. He often said: "The Engineers and the Contractors on this work are partners. We must work together. We must respect each other's opinions and be fair one to another so that when the work is done it will be a credit to everybody as well as to the City." He infused this spirit into his men and into those directly engaged on the construction with the result that both Contractor and Engineer all strove together, each helping the other, to give to the "job" the best they had. The idealism of Waldo Smith was based on truth, on honesty, on fairness, and on his abiding faith in the loyalty of men.

The preliminary plans and estimates for the Catskill System were completed within two months after his appointment as Chief Engineer. Then followed a period of careful planning and sub-surface investigations so that, as Mr. Smith said, "both we and the contractors may know all about the work before it is begun." The first contract was let in the spring of 1907, and water was delivered to the city from the Esopus development in 1915. The second part of the System, comprising the Schoharie development, was completed in 1926. In the meantime, in 1922, Mr. Smith retired as Chief Engineer, but continued in the capacity of Consulting Engineer to his last day. His great love was the Catskill Water System and those who worked with him. He gave to it and to them all he had and was happy to see it to its conclusion.

He felt, however, because of the large growth in population from 1900 to 1930, that this System was not sufficient for a city as great as New York, that it provided too small a margin of safety, and that the only way of putting the water supply of the city on a sound basis was to increase it by developing a new source. The best of the possible supplies available was the Delaware, but, as the waters of this river were interstate between New York, New Jersey, and Pennsylvania, the line of approach presented difficulties of an unusual kind. It was Mr. Smith's firm belief that there was no reason why the situation could not be fairly composed, because the other States, sooner or later, would need Delaware River water for themselves and also because the plan of New York, looking as it did to an equitable apportionment, was fair, just, and reasonable. Beginning in 1921, with the hearty co-operation of the Commissioners of the Board of Water Supply, of which Mr. George J. Gillespie was President, of the late Mayor John F. Hylan, and of Governor Alfred E. Smith, the establishment of compact commissions in each of the three States was consummated. Mr. Smith was designated as Engineer to the New York Commission, and the three Commissions early in 1923 unanimously agreed on a form of compact under which the waters of the Delaware River might be used by each of the three States. This form was approved by New York State; but failed in the legislatures of the other States.

Nothing daunted, the attempt to reach a conclusion was continued and, in January, 1925, the Commissions once more unanimously agreed on a second form of compact, but history repeated itself, and the outcome in the legislatures was the same as in 1923. In the meantime, the situation was growing more acute and it seemed clear that early provision should be made for an additional supply of water. The City then, in 1927, the Hon. James J. Walker being Mayor, formally approved a plan for utilizing these Delaware waters. New Jersey thereupon sought to enjoin the project through an original action in the Supreme Court of the United States, while the Commonwealth of Pennsylvania intervened *pro interesse suo*. The issues were finally joined in 1929. Hearings before a Special Master were held in 1930, and the decision of the Supreme Court was handed down in May, 1931. This momentous decision written by the late Mr. Justice Holmes established a new doctrine relating to the use of interstate waters. Wrote Justice Holmes:

> "A river is more than an amenity, it is a treasure. It offers a necessity of life that must be rationed among those who have power over it. New York has the physical power to cut off all the water within its jurisdiction. But clearly the exercise of such a power to the destruction of the interest of lower States could not be tolerated. And on the other hand equally little could New Jersey be permitted to require New York to give up its power altogether in order that the river might come down to it undiminished. Both States have real and substantial interests in the River that must be reconciled as best they may be. The different traditions and practices in different parts of the country may lead to varying results but the effort always is to secure an equitable apportionment without quibbling over formulas."

Thus was the judgment and foresight of Mr. Smith confirmed, and so, out of the facts, did a new principle of the common law arise.

This memoir cannot attempt to describe the Catskill System, which was part and parcel of Mr. Smith's very life. That has been done in many papers by many authors, but it is essential that a few of the important developments of technical progress which grew out of this work should be stated briefly as a record for posterity to read. In the largest sense they were the work of Waldo Smith, because of the continual support, encouragement, and recognition he gave to his men. While he constantly urged them on to newer and better things, his marvelous insight enabled him to rule out the chaff and few indeed were the innovations he approved that were not successful.

First, should be mentioned the deep pressure tunnels and particularly that which passed 1 100 ft under the Hudson River. No tunnels of such size and operating under so great a head had previously been built. Equally noteworthy was the 18-mile City Distribution Tunnel, far below sea level, passing directly beneath the city and delivering its water through shafts into the distribution mains.

Second, was the use in the Olive Bridge and Kensico Dams of expansion joints with copper cut-offs, drainage wells, and inspection galleries. No previous dam had these features.

Third, was the consolidation by grouting under pressure with Portland cement of the foundations of all the dams as well as the linings of all the shafts and tunnels. It may be said that the modern art of grouting was developed under the direction of Waldo Smith.

Fourth, the use of bronze for all important valves and operating parts in all the dams and along the aqueduct. The pressure-reducing needle-valves at the Ashokan Reservoir and the riser valves and their control mechanisms in the City Tunnel, were all new and novel and involved special developments of design and in the art of bronze manufacture.

Fifth, the compressed lead joints in the flexible jointed pipe under The Narrows from Brooklyn to Staten Island.

Sixth, the beginning in 1912 of a research program looking toward a determination of the reasons for the deterioration of Portland cement concrete. This work is being continued.

Seventh, the adoption of Portland cement mortar as an interior lining for steel pipes of large diameter, together with the correlative outer concrete support for holding the pipes to true form.

Eighth, the use of models for many purposes, including stress determinations, hydraulic behavior, and other related phenomena.

Ninth, the form of contract specifications which divided the work into many definite items so as to present to the contractor as complete a picture of the work as possible—included under this heading was the prescribing of fixed and definite payment lines based on previous actual experience.

Many other items could be mentioned, but these must suffice. Mr. Smith was a man of natural research instinct and, because of his understanding of hydraulics and the behavior of flowing water, the details of the great system as a whole were always in the forefront of his mind.

The Catskill Water System was inaugurated and begun during the administration of Mayor George B. McClellan, whose term of office was from 1904 to 1909. There had been great objection to this project in the New York Legislature and Mayor McClellan led the fight in its favor almost single-handed. It is of interest, therefore, to note what he said at a dinner given on June 27, 1922, to mark the retirement of Mr. Smith from the position of Chief Engineer:

"The task that was mine was to appeal from Pilate to Cæsar. To create a public opinion so strongly in favor of the right to existence of the people of New York as to force a partisan legislature in very shame and self-defense to grant us the legislation we required. I should not have had the courage to carry the fight through had it not been for the constant help and encouragement, the professional knowledge and the technical skill, the friendship and the sympathy of Waldo Smith.

"Immediately after I became Mayor I met the Chief Engineer of the Croton Aqueduct Commission as Smith then was, and found that in developing the new Catskill Water Supply project he was just the man I needed. We soon learned to understand each other and to work together, so that ever since the Catskill project has been for me nothing but the concrete expression of the personality and of the genius of Waldo Smith.

"When a reluctant legislature had given us our needed legislation and when the commission had taken office, as a matter of course Waldo Smith was appointed Chief Engineer. And such he has remained until today, increasing always in the respect of his subordinates, in the affection of his friends and in the confidence of the public."

Following his resignation as Chief Engineer in 1922, Mr. Smith continued as Consulting Engineer to the New York Board of Water Supply. He also served in the same capacity for the Metropolitan Water District of Boston, Mass., on its new development of the Ware and Swift water-sheds and, among others, he gave advice and counsel to the Cities of Philadelphia, Pa., Providence, R. I., San Francisco, Calif., St. Louis, Mo., Hartford, Conn., Baltimore, Md., Kansas City, Mo., Kingston, N. Y., Asheville, N. C., Vancouver, B. C., Canada, and Havana and Santiago, Cuba. He was also Consulting Engineer on the Moffat Tunnel, in Colorado.

On April 17, 1918, the John Fritz Medal was conferred on Mr. Smith, "for achievement as engineer in providing the City of New York with a supply of water." Commenting on this award *Engineering News-Record,* in its issue of April 25, 1918, under the editorial caption of "J. Waldo Smith, Human Engineer", stated:

> "With utter modesty and self-effacement the recipient of the John Fritz medal last week brought out, as the previous speakers had failed to do, the chief reason for rejoicing that he should have been chosen for the highest honor possible for an American engineer. It is found in the fact that J. Waldo Smith never misses an opportunity to share his laurels with his subordinates. He did not forget them on the occasion of his designation as the fourteenth to receive this emblem of high engineering achievement. He asserted that it would be presumptuous for him to assume that the award was based on his individual work; and told of the ability and *esprit de corps* that had characterized his organization throughout. True enough, the spirit of the Catskill organization is far famed; but J. Waldo Smith is responsible for that spirit, and without it the ability of his staff would have counted far less."

At the Annual Meeting of the Western Society of Engineers in 1925 the Washington Award of that organization was bestowed on Mr. Smith in these words:

> "For Preeminent Services in Promoting the Public Welfare and for the Rare Combination of Vision, Technical Skill, Administrative Ability and Courageous Leadership in Engineering."

Columbia University conferred on him in 1918 its honorary degree of Doctor of Science and in that same year there came from Stevens Institute of Technology the honorary degree of Doctor of Engineering.

Mr. Smith was a member of the American Society of Mechanical Engineers, the Institution of Civil Engineers of Great Britain, the American Institute of Consulting Engineers, the American Public Health Association, the New Jersey Sanitary Association, the American Water Works Association, the Boston Society of Civil Engineers, the New England Water Works Association, the Chamber of Commerce of the State of New York, the Municipal Engineers of New York City, and the Franklin Institute of Pennsylvania. He was also a member of The Century Association, the Technology Club, and the Engineers Club, all of New York.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on October 5, 1892, and a Member on April 5, 1899. He served as Director from 1906 to 1908, and as Vice-President in 1913 and 1914

On October 1, 1928, he was elected an Honorary Member of the Society and, at the Annual Meeting in January, 1929, he was presented for the award by the late Clemens Herschel, Past-President and Hon. M. Am. Soc. C. E. Among others, Mr. Herschel used these words:

"But there is another feature in the work of Waldo Smith for New York City, of peculiar gratification to me who contributed to it, by transplanting him into this vicinity. It is the sterling honesty of purpose and of action with which his public work has invariably been conducted. He has left a broad trail of ability, efficiency, and of duty well done in public work, in New York City; an environment which tests its engineers as though by fire, not only in technical integrity, but also in great steadfastness of character and of upright action."

Mr. Smith contributed many discussions to the *Proceedings and Transactions,* and served the Society in many diverse ways on committees and as representative on many occasions.

The following paragraphs are from *Engineering News-Record,* of October 19, 1933:

"Mr. Smith's exceptional abilities and character are reflected more adequately in the following words, written at the request of *Engineering News-Record* by one of his intimate friends, associated with his work for many years past:

"'It is seldom possible from a categorical recital of the accomplishments of an individual to glean anything as to the true inwardness of the man. Every normal person admires success and feels respect for him who has earned it. The winning of distinction is significant of greatness and of quality. But from what roots does greatness spring and wherein lies its essence? I am writing these words because you have asked me out of my long friendship and love for Waldo Smith to analyze, as best I may, the reasons for the fulness of his life and the great measure of distinction he achieved in the hearts and minds of all with whom he came into contact. And this is most fitting because Waldo Smith fully as much as any engineer of the period exemplified the highest ideals of the profession. His mind and heart were a book as open as his office door, which was never closed. Nothing was ever said or done in that office which could not have been shouted from the housetops. His door was always open to those who came and no previous appointment was needed.

"'Sprung from a long New England ancestry, he inherited those qualities of fairness, of economy and of rugged honesty which controlled and characterized his every thought and action. No matter what question came to him, his primary concern was that his decision should be just and that the equities should be balanced. Had he followed the law he would have been a great judge. But Waldo Smith was an engineer by nature. He could determine the value of a plan almost at a glance and his mind at once went forward to the effects which would follow from the plan. To him the details of a structure pictured an operating whole; the plan for a project visioned the social, the economic and the political consequences to which it would give rise. Yet his reports were models of brevity, though full and complete.

"'As an engineer he worked not only with materials, but even more brilliantly with men—both the men who put the materials from the drafting board into the completed structure and the public officials who provided the necessary funds and approved his plans. Waldo Smith worked with men as one of them. As they had ability he recognized it, as they had faults he overlooked them. He was the engineer and director of men because he held the respect and confidence of all.

"'His qualities were brought into outstanding relief by his great personal modesty. Never did he seek publicity or notice for himself. Always did he insist that credit should go to the men who deserved it, and always did he particularly remember those who served with faithful distinction. The organization he built up on the Catskill Aqueduct was one of socialized service, and partly because of this fact its spirit and loyalty were boundless and its influence has gone far and wide. Each man of his staff as well as every one of the many contracting organizations which executed the work saw in him the exemplification of all that was good and noble and true. His friends were legion. They were his strength and his comfort'."

In order that a fitting memorial to the man and the engineer might remain as an outward and visible sign for the future, about 400 friends of Mr. Smith contributed to the erection of a tablet resting on the south face of the triangulation tower on a hilltop overlooking the Olive Bridge Dam and the Ashokan Reservoir, and bearing the following inscription:

IN TRIBUTE TO
J. WALDO SMITH
ENGINEER OF WATER SUPPLY
NEW YORK CITY 1903 TO 1933

1861 1933

MAN OF VISION AND OF COURAGE
LEADER AND COUNSELOR OF MEN
STUDENT OF THE HUMAN HEART
HE INSPIRED HIS ASSOCIATES
AND ADORNED HIS PROFESSION
THE CATSKILL WATER SYSTEM
IS HIS ENDURING MONUMENT

"NONE KNEW THEE BUT TO LOVE THEE
NOR NAMED THEE BUT TO PRAISE."
Halleck.
ERECTED BY HIS FRIENDS IN 1936

At the center of the tablet is a bronze medallion 19 in. in diameter showing a portrait relief of the features of the man in whose memory it stands. The tower is surrounded by a grove of beautiful pines. These trees were planted under Mr. Smith's direction as part of the forestation program around the Ashokan Reservoir. The tower is not far from "Menaltink", his country place on the shore of the reservoir, where he spent many happy hours entertaining his friends and associates both during and after the days of the Catskill operations. It was dedicated on June 25, 1936.

By his will and testament, Mr. Smith bequeathed to the Society the sum of $20 000, the income of which is to be used in the way of promoting and advancing the best interests of Engineering as the Board of Direction may determine. One of the first objectives is to be a memorial volume describing the Catskill Water Supply Project. For effecting this purpose the Board of Direction at its meeting in January, 1936, appointed a committee of Society members.

Such was the man, so was he honored in life, and so did he to the very last strive to discharge his debt to the profession. His whole life was devoted to that end—to help his fellow workers—to make his profession better and broader and of greater service to mankind.

These words are in tribute to his memory. He was a genius of skill and prophetic vision. His leadership was that of fearless honesty. He held his profession as a cause to be kept sacred and to this end he accomplished far more than falls to the lot of most. As his name is written high on the record of accomplishment so also is it inscribed at the top of the scroll of those who labored to promote both the welfare of the engineer as an individual and the ideals of his calling.

And withal, Waldo Smith was a man of exceeding gentleness. The modesty of greatness was his. He shunned publicity. As honors came to him he insisted that they were the due of his associates. He was kind and considerate always, but forceful and direct whenever occasion required. He loved the simple things of life. In his friends, his flowers, his pigeons, his dog, in music, and in poetry he found peace and inspiration and comfort. The autumn of each passing year brought to him rare delight in the delicate blue of the fringed gentian; and now, in another autumn, he sleeps under the sod of Massachusetts where in boyhood he learned to live the truth and where the gentians, as heralds of winter, will bloom in all the years to come.

Waldo Smith, we salute you. Your name and your influence will live through the years both as history records them and as the legion of your friends tells them to its children. *Sic itur ad astra.*

WILLIAM VALORUS ALFORD, M. Am. Soc. C. E.[1]

DIED AUGUST 2, 1935

William Valorus Alford was born in Windham, Ohio, on October 7, 1858. He was the only child of Darius Manley and Cathaline (Brewster) Alford, being, on his mother's side, the tenth generation direct from William Brewster who came to America on the *Mayflower*, and on his father's side, the ninth generation from Patience Brewster, the daughter of William Brewster.

He attended school in Garrettsville, Ohio, and was graduated from High School in 1879. As a boy on a farm, he looked forward to surveying and engineering and worked toward the goal which he determined to attain, and in which he achieved great success. Wherever Mr. Alford went, he continued his studies.

---

[1] Memoir prepared from information supplied by the family and on file at the Headquarters of the Society.

When very young, his first engineering trip took him with a party into the Southwestern United States, where they found it necessary to hide in canyons in order to escape the raids of Apache Indians under Geronimo. In 1887, he was employed on the Nicaragua Canal Survey and was the first white man to go through the wilderness of the Isthmus of Darien. The late Rear-Admiral Robert E. Peary, U. S. Navy, who afterward attained fame as an Arctic explorer, was Chief Engineer at Nicaragua at that time, and his tireless energy and steadfastness of purpose won the sincere admiration of Mr. Alford, who always felt Admiral Peary to have been one of his truest friends.

After the taste of the tropics, Mr. Alford always longed for the southland, and much of his life was spent in Central America and South America, his work taking him into all the South American countries with the exception of Chile and the Guianas, and across the Isthmus of Panama thirty-five times. He especially enjoyed railroad construction work and from 1907 to 1910 was Engineer of Maintenance for the Cerro de Pasco Railway Company in Peru. This work included preliminary surveys, triangulation covering about 40 to 100 miles of surveys for hydro-electric power plants, etc. He made four reconnaissance trips into the Valley of the Amazon, investigating timber resources. He always took great interest in the life of the country through which he passed. He was a keen observer of both plant and animal life, and always made friends with the natives in order to study their primitive ways of living.

In 1911, he was Locating Engineer on about 350 miles of railway in Uruguay. In 1912, he was Government Engineer, on the Island of Santo Domingo, on highway location and construction of about 30 km of water-bound macadem. From 1913 to 1916, he was Chief Engineer for the United States Steel Products Company on railway location, in Salvador. This road was never built because of the World War.

The years 1917 and 1918 found Mr. Alford again in the High Andes as Chief Engineer for the American Vanadium Company in charge of all plans, maps, and estimates, as well as the location of five miles of aerial tram-line for conveying ore. Other trips into the Valley of the Amazon followed until 1921, when he went to the Orient in charge of construction work in Shanghai, China. While in the East, where he remained until 1923, he constructed the foundation for St. Luke's International Hospital in Tokyo, Japan. This site was abandoned after the 1923 earthquake, although the foundation withstood the crash, and was practically the only construction which remained in that part of Tokyo.

His last trip was in 1926 and 1927 when he was Chief Engineer for the Venezuela Gulf Oil Company, at Maracaibo, Venezuela. Ill-health made it necessary for him to return to the United States, and he never was well enough to undertake further extensive work, although he was engaged in land surveying and smaller projects at Garrettsville for several years.

Mr. Alford had a keen appreciation of beauty and the eye of a true artist. He realized the field for photographic work on his trips, and early in his career took time off to perfect himself in this interesting hobby. At one time he conducted a photographic gallery, but soon gave it up to continue his chosen profession. He always carried a complete photographic outfit with him wherever he went and brought back a thorough record of the country through which he had traveled and of the work which was being done. He carried this hobby to such perfection that his pictures have been published in many leading magazines and books. The Fifteenth Edition of the Encyclopædia Britannica carries a full page of illustrations on South America, and the Pan-American Union has in its files many fine pictures from his negatives. The *Nature Magazine* for September, 1935, contained two of his interesting pictures from the Rock Forest of Peru. He was so completely in love with photography that he never disposed of a negative; he did his own printing and sold (or gave away) only prints. His splendid collection of negatives was one of his greatest sources of joy.

Mr. Alford was a great lover of trees, flowers, and birds, and when his health became so poor that he was no longer able to engage in active outdoor duties, he found great pleasure in his own door yard and home. Tulips were his favorite flowers, and he cultivated and enjoyed them to the utmost.

He was a member of the Masonic Order. He was also a Fellow of the Royal Geographic Society of London, England.

He was married in 1919 to Georgia Lee Robinson, of Warren, Ohio, who survives him, and lives at their home in Garrettsville. Three children by a former marriage, Mrs. J. C. Archer, of New Haven, Conn., Mrs. D. D. Kellogg, of Warren, Ohio, and William Brewster Alford, of Cleveland, Ohio, are also left to mourn his passing.

Mr. Alford was elected an Associate Member of the American Society of Civil Engineers on November 1, 1910, and a Member on March 5, 1928.

THOMAS HENRY ALISON, M. Am. Soc. C. E.[1]

Died July 2, 1932

Thomas Henry Alison was born in Toronto, Ont., Canada, on September 25, 1872. His parents, James and Mary (McCord) Alison, came from Belfast, Ireland, and settled in Toronto.

He was prepared for college at the Wellesley School, and at Jarvis Street Collegiate, in Toronto. He was graduated in 1892 from the School of Practical Science in Civil Engineering (the Engineering Department), of the University of Toronto. In 1892 the University established the degree of Bachelor of Applied Science open to graduates of the School; Mr. Alison took the extra year and obtained the degree of Bachelor of Applied Science in 1893. In 1898, the University conferred on him the degree of Civil Engineer. The degree of Civil Engineer is only granted at this University three years or more after graduation.

---

[1] Memoir prepared by T. Kennard Thomson, M. Am. Soc. C. E.

The School of Applied Science of the University of Toronto was founded by Professor John Galbraith, who later became Principal, and, finally, Dean. It is now called the Faculty of Applied Science and Engineering. Professor Galbraith who was fifty years ahead of his time, thought it foolish to call a man a Civil Engineer until he had at least three years practical experience after graduation. He always said that he did not try to turn out full fledged engineers, but only endeavored to teach his students how to study. He realized that if they obtained actual work during the summer vacation, they would better understand what they were studying during the winter, and, therefore, made the college term six months, from October to April, with the vacation (for work) from April to October. Mr. Alison took advantage of this opportunity to obtain work with the Toronto Belt Line Railway Company in the summers of 1890 and 1891.

After finishing his post-graduate course in 1893, Mr. Alison was appointed Assistant Engineer for The Central Bridge and Engineering Company, at Peterboro, Ont., Canada, until October, 1895. From October, 1895, to March, 1896, he was Designing and Assistant Engineer for the New Jersey Steel and Iron Company, at Trenton, N. J., on the designs for cableways in Haiti, bridges and buildings, including theatres, etc., working with the writer much of the time.

From March, 1896, to February, 1897, Mr. Alison was with the firm of Post and McCord, in New York City, on steel work. In February, 1897, he accepted a position as Engineer for Brunner and Tryon, Architects, on steel buildings and foundations, leaving that work in April (at the request of the writer) to become Assistant Engineer for the Dutton Pneumatic Lock Company, which proved to be interesting work.

In July, 1897, Mr. Alison became associated with the late Augustus Smith, M. Am. Soc. C. E., Engineer and Contractor, in New York City, as his Chief Engineer, a connection which lasted until Mr. Smith died in March, 1932, a period of thirty-five years of mutual respect and friendship. Mr. Smith had left the management of The Bergen Point Iron Works largely to Mr. Alison for years, and the day before his sudden death he told the writer with satisfaction that although they were not making money in 1932, owing to the depression, they had not been discharging their men.

On Mr. Smith's death, from a heart attack, Mr. Alison became President as well as Chief Engineer of The Works, but, like Mr. Smith, he had long suffered from heart trouble, and the strain of losing his old friend and Chief of thirty-five years' standing was very severe, although, as usual, he faced the situation bravely.

It would be impossible to mention all the structures designed or built by Thomas H. Alison for Augustus Smith and The Bergen Point Iron Works, but some of these are: The West Bank Light House, 50th Street, in New York City; 129th Street Recreation Piers, New York City; New York Central and Hudson River Railroad Freight Terminal at Barclay and Desbrosses Streets, New York City; the bridge at 135th Street and Mott Haven Canal, for the Department of Bridges, New York City; the design and construction of coal pockets for various companies, and for the United States Navy Department, at Washington Navy Yard, etc.; coaling stations for the U. S. Navy Department, at the New York and Boston (Mass.), Navy Yards, and at Balboa and Cristobal, Canal Zone; the Narragansett Bay Coal Depot, concrete buildings and pockets, steel bridges, etc.; and buildings for sugar factories in Cuba and Puerto Rico.

Mr. Alison was an Engineer in the highest sense of the word, a born student, and fond of research work. He was a quick, accurate, and industrious worker, with the most necessary qualifications for a good Engineer—common sense, a strong sense of justice, and love for his fellow men.

While at college, he had been Captain of the Cricket Team and frequently played the game at the Old Athletic Grounds of the Bergen Point Section, of Bayonne, N. J. An Englishman says that anything dishonorable "is not cricket". Here, we say a good man "played the game". Mr. Alison always "played cricket" and "played the game".

He had a summer home at Orr's Island, Me., and had lived for many years in Bayonne, N. J., where he died.

Mr. Alison was married to Mary Lowery Moorhead, the daughter of the famous Dr. Joseph Moorhead, and their fine children are: James Moorhead Alison, and Janet and Mary Lowery Alison.

In spite of his strenuous engineering work, Mr. Alison found time for many other activities; he was an Elder of the Fifth Street Reformed Church of Bayonne; and Treasurer of the Bayonne Chapter of the American Red Cross. He was connected with the Young Men's Christian Association for about forty years, and was on the Board of Directors of the Central Young Men's Christian Association; a member of the Mutual Culture Club, the University of Toronto Club of New York (26 yr), serving as a Director, Vice-President, and then, for five years, as Secretary-Treasurer; and of the Canadian Club of New York for many years, serving as a Director and on many Committees. No matter how many organizations he belonged to, he gave the best of his ability and time to each.

Thomas Henry Alison was loved and held in the highest esteem by all who knew him. A man of great ability, quick, hard working, accurate, absolutely honest and faithful to his family, friends, and work, his passing at the age of 60 left a great void.

Mr. Alison was elected a Member of the American Society of Civil Engineers on October 7, 1908.

CHARLES KYES ALLEN, M. Am. Soc. C. E.[1]

Died July 14, 1935

Charles Kyes Allen, the son of Hiram Kyes and Martha (Davis) Allen, was born in Massillon, Ohio, on February 20, 1867. Shortly after his birth, his parents moved to Missouri where his father was engaged in railroad contracting and, later, in agricultural interests near Columbia.

---

[1] Memoir prepared by Mrs. Martha (Allen) Hyre, Louisville, Ky.

Charles Allen was educated at the State University of Missouri, at Columbia, from which he was graduated in 1890. In 1892, he entered the State School of Mines at Rolla, Mo., from which he was graduated with the degree of Bachelor of Science in Civil Engineering.

He commenced the practice of engineering as Resident Engineer in charge of the construction of a sewer system for Mexico, Mo. He was appointed City Engineer of Mexico and County Surveyor of Audrain County, holding both positions for several years. During this time he was married to Katye Lee Ringo, of Mexico. After completing his term as County Surveyor, he was employed for a few years in railroad location surveys and in the surveying of large ranches in the (then) Indian Territory. He was also employed on the precision level survey for the Mississippi River Commission.

In 1900, Mr. Allen moved to Kansas City, Mo., and was engaged in the drafting of designs of bridges for J. A. L. Waddell, M. Am. Soc. C. E., working in that capacity for about nine months. He resigned to become Chief Inspector in the Water Department of Kansas City, remaining in that position for about eight years, during the last half of which he was Assistant Engineer in active charge of the design and construction of all plants.

He returned to the office of Mr. Waddell in the latter part of 1908 and was Resident Engineer on the Congress Avenue Bridge, at Austin, Tex., several large lift bridges, in Portland, Ore., the Arroyo Seco Bridge, at Pasadena, Calif., and the Kaw River Bridge and the Blue River Bridge, in Kansas City. Later, he made surveys and borings of the Mississippi River at New Orleans, La., for Mr. Waddell.

In February, 1919, he entered the service of the United Iron Works of Kansas City as Designer for new steel sheds at several of its plants, but, in 1920, he again returned to Mr. Waddell's Office to take charge of the building of a highway bridge over Red River at Author City, Tex., and various other work being constructed by the firm, in the next few years.

In the fall of 1925, Mr. Allen went to Bath, Me., as Resident Engineer on the building of the large bridge over the Kennebec River at that place. On that bridge caissons were sunk 123 ft below high tide, which was 9 ft deeper than any pneumatic caissons had ever gone before. Upon the completion of this work he went to Charleston, S. C., to build the Cooper River Bridge, an exceptionally difficult piece of construction.

In October, 1929, he started the work on the Suspension Bridge over the Maumee River, at Toledo, Ohio, for Mr. Waddell, completing it in the fall of 1931. Mr. Allen's health compelled him to take a much needed rest at that time and he did not attempt to take up his work again until the summer of 1934, when he went to Chicago, Ill., to construct some of the plants for the new sewerage system built under Government supervision. He was only there a few months, however, when he was obliged to return to his home in Kansas City because of his health. His death occurred within a short time, on July 14, 1935.

He is survived by his widow, Katye (Ringo) Allen, a daughter, Mrs. Martha (Allen) Hyre, and a granddaughter Martha Kathryn Hyre.

This brief recital of Mr. Allen's work is rather inadequate, inasmuch as his whole life was wrapped up in his profession. His outstanding ability as an engineer, his devotion to his duty at all times, and his high ideals will be remembered by his many friends always.

Mr. Allen was elected a Member of the American Society of Civil Engineers on October 31, 1911.

JAMES PIERSON ALLEN, M. Am. Soc. C. E.[1]

Died September 11, 1934

James Pierson Allen, the son of Thomas Pierson and Sarah (Bell) Allen, was born at Charleston, S. C., on April 18, 1848. His early education was received at a private school in his native city. As a boy of sixteen, he saw service in the Confederate Army with the Citadel Cadets, remaining with the Corps until it was disbanded at the close of 1865. In 1866, Mr. Allen entered Furman University, at Greenville, S. C., from which he was graduated in 1869 with the degree of Bachelor of Philosophy. He attended the University of Virginia, at Charlottesville, Va., from 1869 to 1870.

In August, 1870, Mr. Allen entered the employ of the United States Engineer Department and for about five years was associated with its offices at Milwaukee, Wis., Detroit, Mich., and St. Paul, Minn. In the spring of 1875, he went to Peru where he was engaged on the construction of the Chimerlote, Hacuraz, and Pecuay Railroad, in the Andes Mountains. He returned to the United States in December of that year and engaged in farming in South Carolina until the fall of 1876, when he went to San Antonio, Tex., to practice general surveying and engineering. In July, 1878, he accepted an appointment as Assistant Engineer in the United States Engineer Office at Rock Island, Ill. While there, he was engaged in mapping 115 miles of the Mississippi River, from Savanna, Ill., to Burlington, Iowa. He continued work on the Mississippi River until November, 1880, having local charge of improvements near Fountain City, Wis., and Winona, Minn.

On March 1, 1881, Mr. Allen was appointed Assistant in charge of surveys for the United States Engineer Office, at Charleston, S. C. Later, he became Principal Assistant Engineer, having direct supervision of projects for the improvement of Charleston Harbor, Wappoo Cut, Salkahatchie and Edisto Rivers, in South Carolina, and the Altamaha River and Brunswick Harbor, in Georgia. He also had supervision of the fortifications of Charleston Harbor, which included the modernization of the batteries at Forts Sumter and Moultrie. His chief work, however, was the construction of the jetty system in Charleston Harbor, which stands to-day as a monument to his untiring energy.

---

[1] Memoir prepared by W. S. FitzSimons, Assoc. M. Am. Soc. C. E.

Shortly after the United States entered the World War, Mr. Allen was appointed District Engineer for the South Carolina District, and served in that capacity until January, 1919, when he resumed his duties as Principal Assistant Engineer.

He retired from the Government Service on August 20, 1920, at the age of 72, when the National Civil Service Law went into effect. In September, 1920, he opened an office in Charleston, for the practice of general engineering under the firm name of Allen and FitzSimons. This partnership continued for a period of about six years, after which Mr. Allen retired from active business.

Mr. Allen was recognized by all who knew him as a man of splendid character and high ideals. He loved his work and devoted practically all his time to engineering matters. Personally and professionally, he maintained a high standard of ethics, never swerving from a course he believed to be right. While he was severely just in his dealings with his subordinates, he inspired their respect by his integrity and impartiality. To those whose privilege it was to know him, his memory will always be cherished.

He was married on April 25, 1876, to Mary Malvina Bailey, of Charleston, S. C., and is survived by a son and three daughters.

Mr. Allen was elected a Junior of the American Society of Civil Engineers on March 5, 1879, and a Member on June 4, 1884.

WILLIAM WALLACE ATTERBURY, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 20, 1935

William Wallace Atterbury was born at New Albany, Ind., on January 31, 1866. He was brought up in Detroit, Mich. His father was the Rev. John Guest Atterbury, D. D., who renounced the practice of law to become a Presbyterian minister. His mother was Catherine J. Larned, daughter of Gen. Charles Larned, who was Attorney-General for the Territory of Michigan under Governor Lewis Cass; his grandfather was Lewis Atterbury, and his grandmother, Catherine Boudinot, niece of Elias Boudinot, at one time President of the Continental Congress.

After receiving a liberal preparatory education, and because of a family tradition, Mr. Atterbury entered Yale University, at New Haven, Conn., in the Sheffield Scientific School, from which he was graduated in the Class of 1886 with the degree of Bachelor of Philosophy.

After graduation he entered the service of The Pennsylvania Railroad Company on October 11, 1886, as an Apprentice in the Altoona (Pa.) Shops. Upon completing his apprenticeship, from 1889 to 1896, he served, successively, as Assistant Road Foreman of Engines on various divisions of the Pennsylvania Railroad System, Assistant Engineer of Motive Power, on what was then known as the Company's Northwest System, and Master Mechanic of the Pennsylvania Railroad Shops at Fort Wayne, Ind.

---

[1] Memoir prepared by a Committee of the Philadelphia Section, consisting of Edward Brinton Temple, *Chairman*, and Clark Dillenbeck, Robert Farnham, John Clifford Hodges Lee, and Wallace Nelson Mayhew, Members, Am. Soc. C. E.

On October 26, 1896, Mr. Atterbury was appointed Superintendent of Motive Power, and on October 1, 1901, he was advanced to General Superintendent of Motive Power, with jurisdiction over the Pennsylvania Railroad Lines East of Pittsburgh and Erie.

His wonderful executive ability was clearly demonstrated the following year (1902), during a period of great industrial activity, when he was called upon to clear a traffic jam which seriously affected freight and passenger movement through the Pittsburgh District. He was rewarded on January 1, 1903, by being appointed General Manager of the Pennsylvania Lines East of Pittsburgh and Erie. It was during this period that he came to understand both the needs and psychology of the employees, and contended thus early in his career that the employees had rights which were too often neglected.

Mr. Atterbury was appointed Fifth Vice-President of the Pennsylvania Railroad Company on March 24, 1909, and placed in charge of the Transportation Department. On March 3, 1911, upon a change in the organization of the Company, he was made Fourth Vice-President, and, on the same date, was elected a Director of The Pennsylvania Railroad Company. On May 8, 1912, when the practice of designating the Vice-Presidents numerically was discontinued, his title was changed to Vice-President in Charge of Operation. He occupied this position until November 15, 1924, when he was elected Vice-President of the Company, being advanced to its Presidency on October 1, 1925, on the retirement from active service of the late Samuel Rea, Hon. M. Am. Soc. C. E.

While Mr. Atterbury was Vice-President in Charge of Operation of the Pennsylvania System he was unanimously chosen to be President of the American Railway Association, on May 17, 1916. As the head of this Association he rendered invaluable service to the United States Government in connection with the transportation of troops and war material and supplies to the Mexican Border, as well as to the Atlantic Seaboard, thus, in a sense, paving the way for his later mission to Europe in the service of his country.

Shortly after the entry of the United States into the World War, the Commanding General of the American forces abroad included the following in a cable to the War Department:

> "Have made thorough study of railroad situation and am convinced that operation of railroads must be under man with large experience in managing commercial railroads at home. Successful handling of our railroad lines so important that ablest man in country should be selected."

The War Department thereupon chose Mr. Atterbury, and he was subsequently designated as Director General of Transportation of the American Expeditionary Forces, with the rank of Brigadier General. In this position he assumed charge of the details of organization and operation of the United States transportation requirements in France and their co-ordination with those of the other Allied Armies. His success in this difficult undertaking is attested not only by the testimonials of his superior officers in the Army, but also by the decorations which he received from his own and from foreign Governments.

In his autobiography, Gen. John J. Pershing, U. S. Army, said of Mr. Atterbury:

> "In our first conversation we ran over the problem in a general way. Much to my surprise, Mr. Atterbury seemed to be very familiar with the situation, and his personality, his force and his grasp of the difficulties of the task, and his willingness to understand it, appealed to me at once."

Mr. Atterbury sailed for Europe on August 18, 1917. He was commissioned Brigadier General in the United States Army on October 5, 1917, which appointment, three days later, was confirmed by the United States Senate. He returned to America on May 31, 1919, receiving honorable discharge from the Army the following day. By reason of his work with the American Expeditionary Forces he later received the following decorations:

United States..	Distinguished Service Medal.
France	Legion of Honor, Rank of Commander.
Great Britain..	Companion of the Most Honorable Order of the Bath.
Belgium.......	Commander of the Order of the Crown.
Serbia.........	Royal Order of the White Eagle.
Rumania	Grand Officer of the Order of the Crown.

Upon his return to the United States, Mr. Atterbury again took up his work with the Pennsylvania Railroad Company, and found himself in the midst of the greatest labor problems of his life. The interests of the Pennsylvania Railroad employees were always his interests. Consideration of the rights of those who labor was uppermost in his mind. In regard to this, he stated:

> "The World War brought home to me that what we fought for in '76, in 1812, in '61, in '98, and again in 1917-18, was real—that life, liberty and the pursuit of happiness were the inherent right of all. I had always known that it was my right, but I do not know that I had ever had so keen a realization that it was the right of every other fellow. I tried to put myself in the other fellow's place. What did that right mean to me, and what did it mean to him? It seemed to me that the following, at least, were essentials:
>
> "1.—Steady employment;
> "2.—A good wage;
> "3.—Time for recreation;
> "4.—Opportunity to elevate myself in my employment;
> "5.—A voice in determining the rules and regulations under which I should work;
> "6.—A fair division of any profits after a reasonable wage had been earned and a sufficient amount had been paid to capital to attract it to an expanding business."

These were the principles upon which Mr. Atterbury founded the plan of employee representation, which was designed to give the employees of the Pennsylvania Railroad Company an equal voice with the Management in the handling of their mutual affairs. The effect of this new policy in management brought substantial benefits not only to the Pennsylvania Railroad Company, and its employees, but also, generally, to the railroad transportation industry of the United States. This was his most prideful accomplishment. It laid the foundation for a spirit of fair dealing and co-operation which was largely responsible for the success with which the Pennsylvania Railroad Company was able to meet the depression period through which the country was passing at the time of his death.

During Mr. Atterbury's absence in France the railroads had been taken over and operated by the Federal Government. After he resumed his position as an Executive Officer of the Pennsylvania Railroad Company he proceeded with the plans for the re-organization of the Operating Staff incident to the consolidation of the former East and West Lines of the Company, and for the creation of separate regions for the operation of the System lines upon the return of the railroads of the country to their owners. The success of these changes was amply demonstrated in the safe, efficient, and economic operation of the entire Pennsylvania Railroad System since the termination of Federal control on March 1, 1920.

Increasing competition of other forms of transportation, and the current tendency of bringing the Government more actively into business management, largely due to the depression and the difficulties of financing large corporations, required Mr. Atterbury's constant attention as head of the Pennsylvania Railroad Company. To these and similar problems he devoted himself with resourcefulness, vision, and courage. It was his frequently asserted view that the Company should not consider itself as a railroad enterprise alone, but rather as a general carrier ready to encourage, develop, and utilize any form of transportation, or any combination of whatever forms of transportation that may meet the public needs. Practical demonstration of this view materialized through the Company's interest in the development of air lines, motor-bus lines, trucking activities, and in the collection and delivery of less than carload shipments of freight.

His contribution, therefore, to the development of American transportation, while it is fairly well known and recognized to-day, will not be fully appreciated in all its far-reaching significance for years to come. He left a stamp of progressive development on American railroads that even his contemporaries who were intimately associated with him, have not yet fully realized.

Following the death of Mr. Atterbury on September 20, 1935, M. W. Clement, President of the Pennsylvania Railroad Company, said of him:

> "He was one of the most far-seeing business executives of the country, recognized not only in his own field of transportation, but in the industrial and economic field generally. He had the admiration and affection of every one who was privileged to know him."

During Mr. Atterbury's incumbency as President of the Pennsylvania Railroad Company the many new problems confronting the railroad industry crystallized the necessity for a co-ordination of the activities of the railroad companies. From his suggestion grew the Association of American Railroads, which was organized to promote and improve railroad service in the public interest and to maintain the integrity and credit of the industry. The Association became effective on October 12, 1934, and now enables the railroad companies to present a united front in dealing with such problems to be met by the industry as a whole.

His courage in the face of obstacles is well exemplified by his prosecution of the work of electrifying the lines of the Pennsylvania Railroad Company between New York, N. Y., and Washington, D. C. Begun in 1928, the work was halted by the difficulty of financing brought about by the world-wide depression. Upon the offer of the Government to advance funds, Mr. Atterbury did not hesitate. He accepted the offer and pushed the work to a conclusion so that the lines were opened for operation in February, 1935.

At the re-organization meeting of the Board of Directors of the Pennsylvania Railroad Company on April 24, 1935, following the Annual Meeting of the Stockholders, Mr. Atterbury, because of ill health, declined to permit the placing of his name in nomination again for the Presidency. Had he lived and continued in this capacity, he would have been retired automatically from active service under the pension regulations of the Company on February 1, 1936. The Directors reluctantly acceded to his request, which thus closed the active official career of one who was, according to a Minute adopted that day by the Board of Directors, "distinguished not only by his able and faithful administration of the affairs of this corporation, but for his outstanding services to the Nation." He, however, retained his position as a member of the Board of Directors, and regularly attended the meetings.

Mr. Atterbury died unexpectedly on September 20, 1935, in the Bryn Mawr Hospital. "Apoplexy, following arteriosclerosis", was given as the cause of his death, in a formal statement issued by the attending physicians.

The funeral services held on the afternoon of Monday, September 23, at the Protestant Episcopal Church of the Redeemer in Bryn Mawr, Pa., were largely attended by relatives, friends, and heads of the principal industrial and transportation companies of America, and a large number of Pennsylvania Railroad employees, among whom were many who had served side by side with him in his early days of railroading. Interment was private, in the cemetery of the Old St. David's Church, near Radnor, Pa.

Mr. Atterbury was a staunch Republican and for years was a prominent figure in his party's politics in the State of Pennsylvania. In 1928, he became a National Committeeman from his State, but this post he resigned in 1930.

His character throughout his life did not change with his steady rise to prominence. When he was President of the Railroad Company, his office was as simple as that of any employee, and his home tastes were similar. He lived at Radnor, a suburb of Philadelphia, in a remodeled farm house, and also owned a large farm in the Chester Valley, to which he frequently motored, and on which he took great pride in raising dairy cattle and draft horses, more or less as a hobby. He played golf with the same enthusiasm he always displayed at work. Although he liked to dance and play cards, he disliked banquets and ceremonies of all kinds. He was much sought as a public speaker, but because of his position he invariably read an address which he had prepared in advance.

Among his business associates he was known as a great fighter, yet he had the utmost respect for those who fought him. He did not respect a man who could be won over too easily. He never took a decision until he was thoroughly familiar with both sides of a case. Once having said "no", however, he was extremely difficult to change. He was most determined in every stand he took to see that justice and right prevailed.

Mr. Atterbury was actively identified throughout his lifetime with the leading engineering, philosophical, economic, scientific, business, historical, fraternal, and military societies of the United States. He was a member of the Academy of Natural Science of Philadelphia; American Academy of Political and Social Science; American Legion; American Museum of Natural History (New York); American Society of the French Legion of Honor; American Philosophical Society; American Society of Mechanical Engineers; Franklin Institute of Pennsylvania; Historical Society of Pennsylvania; Indiana Society; Sons of the American Revolution; Military Order of the World War; National Aeronautic Association; Pennsylvania Academy of the Fine Arts; and the Society of American Military Engineers.

He was also a member of the Engineers Club, Manufacturers and Bankers Club, Philadelphia Club, Rittenhouse Club, and Union League, of Philadelphia; the Union Club of New York; and an Honorary Member of the Union League of New York; a member of the Merion Cricket Club, Haverford, Pa.; Gulph Mills Golf Club, Gulph Mills, Pa.; Seaview Golf Club, Absecon, N. J.; Radnor Hunt, Radnor, Pa.; the Corinthian Yacht Club of Philadelphia, Essington, Pa.; and the Gibson Island Club, Pasadena, Md.

In the halls of learning Mr. Atterbury was publicly recognized as an outstanding national figure. He was twice honored by Yale University in conferring upon him in 1911, the degree of Master of Arts, and in 1926 the degree of Doctor of Laws. Similarly, the degree of Doctor of Laws was conferred upon him by the University of Pennsylvania, Philadelphia, Pa., in 1919, by Villanova College, Villanova, Pa., in 1927, and by Temple University, in 1929. In 1932, he received the degree of Doctor of Engineering at the Pennsylvania Military College, at Chester, Pa.

Few men in American industrial and economic life leave behind such indelible achievements as those handed down to posterity by William Wallace Atterbury. His death marked the passing of a dynamic personality, one of the Nation's outstanding leaders in transportation, a man who served his country faithfully and well, and one who in his later years was the President of one of America's foremost railroads.

Pre-eminent in his chosen field of endeavor and endowed with all the qualities of genuine leadership, Mr. Atterbury well deserved the international reputation which he enjoyed. His place was as high in the respect of the railroad fraternity as it was in the affections of his close associates and the army of co-workers which he so ably led.

The entire career of William Wallace Atterbury ran true to American standards. From shopman's apprentice to the head of the railroad which he served for half a century, his deeds will live on to furnish inspiration and guidance to the coming generations.

He was married in 1895 to Minnie H. Hoffman, of Fort Wayne, Ind., who died in 1910. In 1915 he was married to Mrs. Arminia Rosengarten MacLeod, of St. Davids, Pa. He is survived by his widow, three sons, Malcolm, George Rosengarten, and William Wallace, Jr., and a daughter, Mrs. Elizabeth Connelly, of Radnor, Pa.

Mr. Atterbury was elected a Member of the American Society of Civil Engineers on March 2, 1909.

ALMON BYRON ATWATER, M. Am. Soc. C. E.[1]

Died March 6, 1935

The Atwater family is an old one in American history, the first member having settled in America in 1637. Almon Byron Atwater was a direct descendant of this early settler. He was the oldest of a family of three and was born in Sheffield, Ohio, on November 19, 1845, the son of John Todd Atwater and Matilda E. (Hill) Atwater.

After attending the common schools, Kingsville Academy, at Kingsville, Ohio, and Austenbury Institute, at Austenbury, Ohio, he entered the Engineering Profession by way of railroad construction work. His first engagement was that of Resident Engineer with the Canada Southern Railway Company, from April, 1870, to March, 1874. Next, he was Assistant Engineer with the Port Dover and Lake Huron Railroad Company, from October, 1874, to November, 1876. Mr. Atwater often told of the changing conditions which occurred at this period and commented on a very trite observation, substantially as follows: "Many well informed people about 1873 said America would never have prosperity again." In view of the fact that he lived during the acute period of the 1929–1935 depression, and through the 1873, 1893, and 1907 depressions, his prediction in the early Seventies must be of much interest to the present generation.

Mr. Atwater served as Chief Engineer of the Stratford and Huron Railroad Company, from November, 1876, to March, 1877, and from the latter date until May, 1880, as Superintendent of the Port Dover and Lake Huron and the Stratford and Huron Railroad Companies. Subsequently, he was General Superintendent and Engineer of the Georgian Bay and Lake Erie Division of the Grand Trunk Railway until May, 1882, at which time he was made Chief Engineer of the Chicago and Grand Trunk Railway. He was Superintendent of the Grand Trunk Railway from May, 1885, until July 12, 1898. At this time, he left the service of the Grand Trunk Railway Company and became Assistant General Superintendent of the Michigan Central Railroad, at Detroit, Mich. After serving with this Company until July, 1902, he again returned to the Grand Trunk Railway Company as Assistant to the President, with headquarters at Detroit. As the ranking railroad official of the Grand

---

[1] Memoir prepared by A. C. Everham, M. Am. Soc. C. E.

Trunk Railway Company in the United States, he had many duties to perform which gave him opportunities to show his executive ability, which was much needed during the period from December, 1902, to the date of his retirement, which was October 1, 1922.

Mr. Atwater's duties were largely executive and not engineering, although his many years of engineering training had particularly qualified him to guide the management of the Grand Trunk Railway Company in handling such difficult construction problems as important track-elevation work in Chicago, Ill., and Detroit, and other large cities. He also had charge of the completion of the Detroit and Toledo Shore Line Railroad from Toledo, Ohio, to Detroit and equipped it for steam service. He gave a great deal of his time to the building of the Grand Rapids Terminal Railroad; the new passenger station and bridge over the river at Bay City, Mich.; and also purchased considerable land at Detroit for terminal yard purposes. He gave considerable of his time also to the development of railroad facilities in Michigan, at the time of the expansion of the automobile business. Due to the fact that the Grand Trunk Railway was owned by English capital, it made his work additionally difficult, as it required careful negotiations to protect the railroad interests which were constantly being attacked by legislative and other utility controlling bodies.

Mr. Atwater was a civic worker of the highest type, but in no sense a handler of details. He knew very well how to delegate authority and have his railroad profit by this executive ability. On several occasions he had the opportunity and did escort Henry Ford and the late Thomas A. Edison on important trips. It is unfortunate that he did not record the very interesting history of these journeys as the philosophies that were exchanged by these two men, as described by Mr. Atwater, were unusually interesting. He regarded Mr. Ford as a remarkable executive. When the *Titanic* sank, it was Mr. Atwater's very sad duty to find and identify the body of the well-known President of the Grand Trunk Railroad System, Mr. C. M. Hays, who had been his life-long friend.

Mr. Atwater was a lover of the out-of-doors, having been a good golf player and continuing to play until he was 85 years of age. He was a Life Member of the Detroit Golf Club. He also belonged to, and was an active member of, a curling club in Detroit. He and Mrs. Atwater traveled extensively, having visited Iceland, Russia, Germany, Austria, France, and England during 1932 when he was 87 years of age. He was a great student and reader and left in his estate a very fine library of standard literature. He was, at one time, President of the Prismatic Club, of Detroit, an exclusive literary society.

He was a Mason, an Episcopalian, a conservative Republican, and an active member of the Sons of the American Revolution. His philanthropies were unusually quiet, carefully chosen, and of generous sums. He was one of the fortunate who profited by the development of the early air-brake patents and from this small beginning left an estate which was distributed among his nephews and nieces.

Mr. Atwater was married to Jane Thompson, of Welland County, Ontario, Canada, on July 2, 1872. They had no children. His only survivors are Dr. Carleton W. Atwater, of Indianapolis, Ind., Mrs. Maude Gerow, of Cleveland, Ohio, Mrs. A. C. Everham, of Kansas City, Mo., and Mrs. Barbara Leach, of Painesville, Ohio. He died March 6, 1935, in Pasadena, Calif., where he lived after his retirement from the railroad service on October 1, 1922.

He was a man of very definite ideas, but kindly. His executive ability, his spirit of fairness, and his clear thinking in dealing with those with whom he came in contact commanded their respect and admiration. Although quiet in his manner, he was firm in his decisions and positive in his ideas as to how work should be done. He will be remembered with gratitude by many engineers and railroad officials who owe to him their opportunities in life.

Mr. Atwater was elected a Member of the American Society of Civil Engineers on May 5, 1886.

HERBERT HOWARD BASSETT, M. Am. Soc. C. E.[1]

Died April 26, 1935

Herbert Howard Bassett was born in New Britain, Conn., on October 21, 1877. His parents, Milton Humphrey Bassett and Prudence Maria (Butler) Bassett, were long-time residents of that city, his father, a veteran of the Civil War, having been trained in the profession of the law. They were both of New England ancestry, devoted to their family and, at the same time, actively interested in the affairs of church and school and the general welfare of their city.

Herbert Howard Bassett prepared for college in the New Britain High School where he maintained a high standing. He entered Cornell University, at Ithaca, N. Y., in September, 1896, in the College of Civil Engineering, from which he was graduated in June, 1900.

His first work was with the American Bridge Company, in East Berlin, Conn., where he remained until January, 1903, when he joined the office force of Frink and Hazen, Consulting and Construction Engineers, in Baltimore, Md., a connection that was terminated by the great fire of February, 1904. For about six months, to September 1904, Mr. Bassett acted as Sewer Inspector for the Town of West Hartford, Conn., leaving this work to join the Berlin Construction Company, with which he remained until 1908. In August, 1908, he went with the Syracuse Bridge Company, at Syracuse, N. Y., for four years as Chief Engineer, changing to the Groton Bridge Company, at Groton, N. Y., in 1912, with which he remained until 1916.

In November, 1916, he was made Manager of the Worcester, Mass., Office of the Berlin Construction Company, and held this position until he was commissioned, in 1918, a Major of Engineers of the Construction Division of the United States Army, for service in the World War. In the fall of 1919, he returned to the Groton Bridge Company as Chief Engineer and remained with that Company until it went out of business in 1923.

---

[1] Memoir prepared by H. N. Ogden, M. Am. Soc. C. E.

During these twenty years, Mr. Bassett had intimate and direct contact with all the ordinary problems of structural design and had become thoroughly familiar with shop construction and field erection. He was well equipped, therefore, for his entry into a changed field that occupied him almost continuously for the remainder of his life. Retaining his residence in Groton, he acted as Consulting Structural Engineer to architects practicing in cities other than Groton, but within reasonable distance. He acted for Gibb and Waltz, of Ithaca, in developing the plans for the Baker Chemical Laboratory of Cornell University, a $1 000 000 building, involving many unusual and complicated steel details. He designed the steel for a number of buildings for which Mr. S. E. Hillgar, of Auburn, N. Y., was the Architect.

Of late years, Mr. Bassett's work had been almost entirely with Mr. C. W. Clark, of Cortland, N. Y., on the design of school buildings. His last work was with Mr. Clark in the preparation of plans for the State and Government project of the office which will serve as a Regional Wholesale Market for Central New York, located on a 60-acre plat in the City of Syracuse.

As Chairman of the Building Committee of the Ithaca City Hospital, the writer had occasion to estimate the ability of Mr. Bassett, both as a Designer and as a tactful co-worker. When the latter acted with Mr. J. Lakin Baldridge, Architect, of Ithaca, in the design of the five-story Nurses Home for the City Hospital, Mr. Bassett was rigidly insistent on ample strength, particularly at joints, and could not be moved from his position either by motives of economy or architectural composition. Mr. Clark says of him:

> "Aside from being a careful, experienced, competent engineer, Bert Bassett had a personality never to be forgotten by those who were so fortunate as to know him. His kindliness, high idealism, public spirit and friendliness will be remembered by me as long as I live."

In these few words Mr. Clark has characterized admirably Mr. Bassett. His work tended to isolate him from his fellows. His ability to become absorbed in his work and deaf to his surroundings was noticeable. Equally characteristic, however, was his friendliness and social gifts. He was a regular attendant at the evening meetings of the Ithaca Section of the Society, driving from Groton to Elmira, or Binghamton, and returning home, apparently indifferent to time or weather.

During the World War, he was as stated a Major in the Construction Division of the Army Construction Corps, and after the war he was an active member of Carrington-Fuller Post No. 800, American Legion, at one time Chaplain of the Local Post, and a Past Commander of the Legion.

Mr. Bassett was a prominent Mason, a Past Master of Groton Lodge, No. 496, F. and A. M.; Past Assistant Grand Lecturer of the Cayuga-Tompkins District; Excellent High Priest of St. John the Baptist Chapter, Royal Arch Masons, of Moravia, N. Y., and a member of Cortland Lodge of Perfection, A. A. S. Rite.

Mr. Edwin L. Harman gives this tribute to his activities in the Masonic Body:

"I never knew him to refuse any request for aid or assistance. His keen mentality, his wonderful memory, his ability as a lecturer, his clear concise judgment was ever at the service of the lodge or a brother in distress. He believed from the depths of his heart in brotherly love, relief, and truth, and endeavored to exemplify them in his daily life."

Mr. Bassett was a member of the Committee of Troop 10 of the Boy Scouts of Groton, and was active in the interests of that organization.

He was a member of the Congregational Church, regular in attendance, and for some years leader and teacher in the Men's Class in the Church School. The Rev. J. A. Goodrich writes of him:

"It was a joy for him to render any service and he never refused to do his part in any good work. Disappointment and reverses were met in a philosophical spirit and enabled him to live victoriously. A man of clear vision and sound judgment, he had the courage of his convictions and frankly gave expression to them. One of his outstanding characteristics was to see the good in others and he never spoke ill or unkindly of any one."

In 1906, he was married to Helen L. Davis who survives him, together with a daughter, Prudence, and a son, Ethan, of Springfield, Mass.

Mr. Bassett was elected a Member of the American Society of Civil Engineers on November 28, 1916.

ROGER DERBY BLACK, M. Am. Soc. C. E.[1]

DIED APRIL 12, 1936

Roger Derby Black was born at West Point, N. Y., on January 18, 1883, at which time his father was on duty at the United States Military Academy as Instructor in Practical Military Engineering and Commander of the Engineer Detachment. He was an Army boy and came from a family of West Point graduates and Regular Army officers. He was the son of the late Major General William Murray Black, U. S. Army, M. Am. Soc. C. E., the World War Chief of Engineers, and Daisy Peyton (Derby) Black. He was the grandson of Captain George H. Derby, Topographical Engineers, U. S. Army, who under the *nom de plume* of John Phœnix wrote "Phœnixiana" and "Squibob Papers", among the first books of American humor.

Roger Derby Black's early education was obtained at various Army posts and stations in the United States to which his father happened to be assigned. His secondary education was obtained at the Central High School, in Washington, D. C., in 1896 and 1897, and at St. Paul's School, Concord, N. H., in 1898 to 1900. He received an "at large" appointment to West Point in 1900 and entered the Military Academy on August 1 of that year. While at West Point he demonstrated his ability in both scholastic and military matters, being a first section man in one, resulting in his assignment to the Corps of Engineers upon graduation, and in the other, wearing chevrons for three years, as a Cadet Corporal, the Cadet Sergeant Major, and one of the six Cadet Captains in the Corps of Cadets. He was graduated from West Point in the Class of 1904 and was commissioned a Second Lieutenant in the Corps of Engineers.

---

[1] Memoir prepared by Colonel R. T. Ward, Corps of Engrs., U. S. Army.

Lieutenant Black served in the Corps of Engineers, United States Army, passing through all the grades: Second Lieutenant, 1904 to 1906; First Lieutenant, 1906 to 1912; Captain, 1912 to 1917; Major, May to August 1917; and September, 1917, Lieutenant Colonel, reaching that of Colonel of Engineers, National Army, on February 1, 1918. In July, 1919, he resigned his commission in the Regular Army to engage in engineering in civil life.

From his graduation in 1904 to the declaration of war against Germany, Colonel Black performed the varied military and civil duties chargeable to the officers of the Corps of Engineers, including engineering works performed by Engineer troops and river and harbor operations under the Engineer Department at Large.

As Second Lieutenant, his first service was with Company B of the 1st Battalion of Engineers, at Fort Leavenworth, Kansas, and in the Philippine Islands, at Fort William McKinley, where he was engaged upon military surveys, road, target range, and water supply works, and various strictly military duties. He left the Philippine Islands in the summer of 1906 and spent the next year as a Post-Graduate Student at the Engineering School, then at Washington Barracks, D. C. He was promoted to the grade of First Lieutenant in September, 1906. The year, 1907–08, was spent in garrison duty at Fort Leavenworth, with Company M, 3d Battalion of Engineers. From 1908 to 1910, he was engaged in survey, land defense, and fortification work with a detachment of Company M in the vicinity of San Francisco, Calif.

From 1910 to 1914, Lieutenant Black was on river and harbor work with station at Albany, N. Y. He was in immediate charge of the Northern Section of the First New York Engineer District, having charge of river and harbor projects in the vicinity of Albany, Lake Champlain, and the Upper Hudson River. In this work he developed and tested a detailed cost-accounting system, one of the first of its kind used in the Engineer Department and now in standard use in its essential features. He was promoted to the rank of Captain in February, 1912.

For the next two years Captain Black again served in the Philippine Islands as Commander of Company L and, later, as Adjutant, of the 3d Engineers. In addition to his company and regimental duties, he was in charge of a District of the Military Survey of the Island of Luzon and of topographical surveys of the environs of Manila.

In the spring of 1917, while on duty in the Office of the Chief of Engineers and as a member of the Board on Engineer Troops, he prepared the manuscript for the Engineer Training Manuals used during 1917 and 1918 by the divisions in training in the United States and overseas. He was promoted to the rank of Major in May, 1917, and in September, 1917, to that of Lieutenant Colonel.

During the World War, Colonel Black rendered invaluable service due to his detailed and intimate knowledge of military organization and military training methods. He was responsible for much of the training and organizational literature used by the troops, and participated actively in the training of Staff Officers and of Engineer troops, both in the United States and in France.

Among the first American troops called for service in France were Engineer Railway Regiments. These regiments had to be raised, equipped, trained, and sent overseas in a very short period of time and practically the entire officer personnel and all the enlisted personnel came, of course, from the American railroads. The very few Regular Engineer officers available for assignment to the units had to be specially qualified men. Major Black was one of the officers selected for this work in May, 1917. As Adjutant of the 13th Engineers, recruited in Chicago, Ill., he had charge of the multitudinous details of organization and training of the regiment and accompanied it overseas within three months after the initial organization. He served with the regiment until September, 1917, when the need for his organizational and training knowledge called him to service with the Expeditionary Staff at General Headquarters.

From September, 1917, to January, 1918, he was immediate Assistant to the Chief of Engineers of the American Expeditionary Force, in charge of personnel and training, and was employed upon matters relating to Engineer Staff organization. From January to May, 1918, while Colonel, commanding the 116th Engineer Regiment, he selected, organized, and operated the Engineer Replacement Training Center at Angers, France.

In June, 1918, being detailed a member of the War Department General Staff, War Plans Division, he returned to the United States and served at the Army War College, in Washington, D. C., acting as Instructor in the School for Divisional Staff Officers. After the Armistice, he was active in the drafting of plans for the re-organization of the War Department and the Staff Services which finally were, to a great extent, incorporated in the National Defense Act of 1920. He resigned from the Army in July, 1919, while a Colonel on the War Department General Staff.

The remaining years of Colonel Black's life were spent in the practice of civil engineering. Notwithstanding the exigencies of his private practice he soon found that his twenty years of military training could not be forgotten, and, in 1921, he applied for, and was commissioned as, a Lieutenant Colonel in the Engineer Section of the Organized Reserves; the following year he was promoted to the grade of Colonel. As such, Colonel Black was one of the strongest supporters and most enthusiastic members of the Engineer Reserve Corps. He was assigned to the command of the 342d Engineers in 1921, and retained command of this regiment until December, 1934, when having moved to Washington, outside the limits of the Second Corps Area, he had to relinquish command. Returning to New York City in the spring of 1936, he was again assigned to the command of the 342d Engineers, the official orders being issued on April 10, 1936, just two days before his decease.

Colonel Black was a valuable asset in the organization and training of the Engineer Reserve Officers in New York City. His regiment was of high efficiency and extreme loyalty. He was a man of unusual brilliancy and talent and had an engaging personality, which made him hosts of friends and attracted able personnel to his regiment. Much of the activity in military matters among the engineers in New York City is due to his enthusiasm and training ability. He never missed an opportunity to attend the Reserve Training Camps and his work and personality will long be remembered by the Engineer Reserve Officers in the Metropolitan Area. As a drill master he was equalled by few officers in the Army. His two-man squad drill, which he developed for the use of Reserve Officers, has been used repeatedly in camp and in inactive training with most excellent results. He was always willing to, and did, take an active and wholehearted part in having to do with the problem of national defense.

From the time of his resignation from the Regular Army in 1919 until his death, he spent the major portion of his time in and around New York City as a practicing civil engineer. He was an expert on waterways and was employed on a number of studies and reports as a Consulting Engineer in this specialty.

His first work in private practice was for H. L. Cooper and Company, and consisted of a special study and report on the economic value of improving the St. Lawrence River for deep-draft navigation and on the proper channel and lock characteristics to accommodate the anticipated commerce, without undue initial investment or necessity for future reconstruction.

From 1920 to 1924 he was President of, and organized, financed, and operated, the Roger Black Company, Incorporated, Engineering and Construction, and engaged in general contracting and speculative building projects in New York City and Long Island. He later became interested in the promotion of construction projects and engaged in real estate and building operations on Long Island. He was a Director of the Long Island Realty Investors Corporation. As partner in the firm of Leaycroft and Black, and, later, as Vice-President and Director of Colprovia Process, he was active in the development and promotion of "colprovia", a special form of bituminous paving, tested and used on various highways throughout the United States. He made special studies of Mississippi River revetments for the Merritt, Chapman and Scott Corporation. In 1932, he was engaged by the Engineer Department at Large of the U. S. War Department to make a special study on the relative merits of a high-level ship canal in comparison with a sea-level ship canal which was then under consideration for the New York-New Jersey Section of the Intracoastal Waterway, Raritan Bay to the Delaware River. This was a thorough and extensive study, including detailed analysis of possible tonnage, types of vessels, canal capacities, and general waterways economics, and is a most valuable addition to the voluminous studies and reports made upon this proposed waterway.

Upon completion of this work for the War Department, Colonel Black was engaged upon the initial organization and subsequent operation of the

Station Department of the recently completed Independent Subway System in New York City until 1934, when he was called to Washington and served as Chief of the Management Branch of the Housing Division of the Public Works Administration. Shortly before his death, he was transferred to New York City as Project Engineer of the Wards Island Sewage Plant.

Colonel Black was a man of vision and imagination. He was specially skilled in organization. His technical reports and studies are clear and complete and very valuable. He was a man of tireless energy and great initiative and had a wonderful faculty of making friends, being especially able to attract and understand the younger men. His sudden and untimely death at the age of 53 was a great loss to the Civil and Military Engineering Professions.

He was a Past-President of the New York Post of the Society of American Military Engineers; a member of the Loyal Legion; Past Commander, New York Chapter of the Military Order of the World War; a Mason; and belonged to the Army and Navy Club, of Washington, D. C. He was active in the Episcopal Church and was for some years a Vestryman of St. Marks-in-the-Bouwerie, in New York City. For his services in France he was decorated by the French Government as "Officier de L'Ordre de L'Etoile Noire."

Colonel Black died in New York City on Easter Sunday, April 12, 1936, of coronary and general arteriosclerosis from which he had suffered for a number of years. He was buried at West Point, N. Y., with full military honors, on April 14, 1936. The escort consisted of the U. S. Military Academy Engineer Detachment and the colors of his Reserve Regiment, the 342d Engineers, borne by officers of the regiment.

In 1907, he was married to Margaret Eveleth Smith, of Portland, Me. He is survived by his widow; a daughter, Helen Townsend (Mrs. Alan Gray), of New York; three sons, Lieutenant Roger Derby Black, Jr., Field Artillery, U. S. Army (Rhodes Scholar), John Murray Black, and Richard Winthrop Black; and by two brothers, William Murray Black, of Warrentown, Va., and Major Percy Gamble Black, Field Artillery, U. S. Army.

Colonel Black was elected a Junior of the American Society of Civil Engineers on January 3, 1905; an Associate Member on January 7, 1913; and a Member on September 9, 1919.

ALBERT NELSON BURCH, M. Am. Soc. C. E.[1]

DIED FEBRUARY 21, 1936

On the night of February 21, 1936, Albert Nelson Burch, a Member of the Society since 1929, passed away at his home in Sacramento, Calif. Recovering from an attack of pneumonia, his weakened body was unable to overcome the effects of complications that developed.

---

[1] Memoir prepared by W. A. Perkins, M. Am. Soc. C. E.

Born at Fayette, Iowa, on June 21, 1864, Mr. Burch was the son of Benjamin and Elizabeth (Rafter) Burch. He received his education in the public schools of that State and at the Peru, Nebr., State Normal School. The teaching profession for which he had prepared was not attractive to him, however, and he subsequently entered his real life profession with a special course at the University of Wisconsin, at Madison, Wis.

California attracted him in the early Nineties, and on January 1, 1898, he became Superintendent of the Stanislaus Water and Power Company, at Oakdale, remaining in this position for nearly ten years. On October 1, 1907, he was appointed Irrigation Engineer in the United States Reclamation Service and assigned to the Umatilla Project in Oregon, being transferred later to the Orland Project in his adopted State. He became Project Manager shortly thereafter, and under his régime this project was developed into one of the most successful of those within the scope of the Reclamation Service.

On October 1, 1921, Mr. Burch resigned his position on the Orland Project and was appointed a Consulting Engineer by the Reclamation Service. For the next six years, he was retained as a Consultant by the Service, and also was employed by the State Engineer of California from March 1, 1922, to December 1, 1923, as a Consultant and Special Investigator of problems connected with the study of the water resources of the State. During 1924 and a part of 1925, he was employed as Chief Engineer of the Hollister Irrigation District. Late in 1927, he returned to the State service as Supervising Hydraulic Engineer in charge of irrigation district matters and remained in that position until his last illness.

On October 9, 1898, at Oakdale, Calif., Mr. Burch was married to Ivy May Sivley who, with their daughter, Katherine, survives him.

He was a recognized authority in irrigation problems and did much in improving practice of the art. Naturally of a retiring nature, he was respected by all who knew him for his wide knowledge and sound common sense and loved for his unfailing kindliness and subtle sense of humor. His passing leaves a place among his brother members in the Society, and among his friends and associates, that can never be filled.

Mr. Burch was elected a Member of the American Society of Civil Engineers on July 15, 1929.

WILLIAM STODDERT CARUTHERS, M. Am. Soc. C. E.[1]

DIED NOVEMBER 1, 1935

William Stoddert Caruthers, the son of William Caruthers and Mary Jane (Stoddert) Caruthers, was born at Jackson, Tenn., on January 22, 1863.

Of his early education it is known that he attended the University of the South, at Sewanee, Tenn., from 1877 to 1880, and, later, was a student in engineering at the University of Missouri, at Columbia, Mo., which he attended in 1883 and 1884. At intervals during his University studies, Mr. Caruthers was engaged in engineering work as Rodman and Leveler.

---

[1] Memoir prepared by C. S. Pope, M. Am. Soc. C. E.

Following his studies at the University of Missouri he was engaged as Resident Engineer in charge of the construction on the Yazoo and Mississippi Railroad, completing a section fourteen miles in length during the years 1884 to 1886. His next engagement was as Resident Engineer during 1886 and 1887 on the Chicago, Rock Island, and Pacific Railway.

In 1888, Mr. Caruthers was engaged in general surveying practice in California, and during the same year he became Resident Engineer in charge of the construction of twenty-eight miles of track for the Oregon Railroad and Navigation Company, and on similar work, in 1889, for the Alabama Midland Railroad Company.

From 1890 to 1894, he was engaged in business in the State of Washington, and, from 1894 to 1898, was Chief Clerk of the United States Surveyor-General's Office, at Olympia.

He again returned to railroad work in 1899 as Resident Engineer in charge of line-revision surveys and construction between North Yakima and Spokane, Wash., for the Northern Pacific Railway Company, leaving this Company in the same year to become Resident Engineer for the McDonald Construction Company, on railroad construction.

In 1900, Mr. Caruthers was Engineer in charge of the substructure of a bridge over the Illinois River on the Illinois, Indiana, and Iowa Railway, under August Ziesing, M. Am. Soc. C. E. Also, during 1900, he was employed as Assistant Engineer on maintenance of way on the Union Pacific Railway.

In 1901, he was Resident Engineer in charge of the construction of fifty miles of the El Paso and Southwestern Railway, leaving this work to engage in private practice in Seattle, Wash., during 1902.

In 1903, he served as Resident Engineer in charge of construction of fifteen miles on the White River Line of the Missouri Pacific Railway, including tunnel and drawbridge work, and, in 1903 and 1904, he was Locating Engineer on the Memphis and Gulf Railway. He continued in railroad engineering work in 1904 as Locating Engineer on the Tennessee Central Railway.

In 1905, Mr. Caruthers was Assistant Engineer for the Kansas City Southern Railway Company, and, later, as Locating Engineer in Mexico on the Rio Grande, Sierra Madre, and Pacific Railway.

From 1906 to 1908, he was Assistant Engineer on the Western Pacific Railway in charge of location, and, later, of heavy construction in the Feather River Canyon, in California, including the bridges.

In 1909, he became Construction Superintendent on the Los Angeles Aqueduct, but, in 1910, he returned to railroad work as Division Engineer in charge of the construction of twenty-five miles on the Des Chutes Line, Oregon-Washington Railroad and Navigation Company.

In 1911, he again became Assistant Engineer with the Western Pacific Railway Company, and, later, Locating Engineer for the Dozier Construction Company on the West Side Railway in Sacramento Valley, California.

Mr. Caruthers' health was a constant source of concern, and it was necessary for him on many occasions to resign from agreeable work to seek a location where the climatic conditions were better suited to his well-being.

In January, 1912, he was appointed Division Engineer for the California Division of Highways at San Luis Obispo, Calif., and in August, 1912, assumed the duties of Division Engineer of Division III. He held this position from 1912 to 1920, and during the latter part of this period he also served as Highway Commissioner for the County of Sacramento, then engaged in the construction of a County Highway System. In 1920, he assumed the duties of Chief Engineer of the Sacramento County Highway Commission, and on the completion of this assignment, he again joined the California Division of Highways and was appointed Assistant Engineer on special assignments in highway location during the years 1923 to 1926. In October, 1926, he left the service of the State to engage in private practice in Oakland and Berkeley, Calif.

Mr. Caruthers' diversified experience with general construction in numerous changes of location, due largely to the fact that he never acquired a vigorous constitution, brought him into contact with a great many engineers, and especially with the younger men of the profession in whom he always evinced great interest and with whom he kept in contact throughout the greater part of his career. He was a man of unfailing courtesy and consideration, a true exponent of the old Southern school of gentlemen, and a consistent supporter of institutions for the advancement of the interests of young men, such as the Young Men's Christian Association, and other such organizations. His secret charities and the financial assistance he furnished to many people less provident than himself were guessed at, but never fully revealed until his death. He died as the result of a fall in an elevator during which he sustained a fracture which eventually proved fatal.

Mr. Caruthers was not married, but devoted himself to the care of his mother and sister who formed his family for the greater part of his life. His kindly personality made him respected and considered with the kindest feeling by all with whom he came in contact. He is survived by his sister, Mrs. Frances Wimberly, of Berkeley, Calif.

He was a member of the American Association of Engineers. He was a Mason, a Democrat, and a member of the Protestant Episcopal Church. He was also for many years a member of the Sutter Club of Sacramento.

Mr. Caruthers was elected a Member of the American Society of Civil Engineers on January 7, 1913.

JAMES ALANSON CHILDS, M. Am. Soc. C. E.[1]

DIED APRIL 13, 1935

James Alanson Childs was born in Fergus Falls, Minn., on April 15, 1886, the son of Henry W. and Alberta (Hakes) Childs. His father was a prominent attorney in Minnesota and served as Attorney General of the State. After receiving his preliminary education in St. Paul, Minn., Mr. Childs entered the University of Minnesota from which he was graduated in 1909 with the degree of Bachelor of Science in Civil Engineering.

---

[1] Memoir prepared by Frederic Bass, William N. Carey, and George M. Shepard, Members, Am. Soc. C. E.

Upon graduation, Mr. Childs entered the employ of the Minnesota State Board of Health as Assistant Engineer. In 1914 he was made Engineer, Division of Sanitation, Minnesota State Board of Health and, except for a short period during the World War, he continued in this capacity until 1927. In the Army he was commissioned a Captain in the Sanitary Corps, and served as Camp Sanitary Engineer at Camp Jackson, South Carolina.

His work with the State Board of Health was chiefly of a supervisory character, pertaining to water systems, sewerage systems, and water-pollution problems. It was during this period of service with the Board that the annual typhoid fever death rate in Minnesota was reduced from about 350 to less than 50, due quite largely to improvements in public water supplies brought about by the activities of the Board of Health. Although credit for this great improvement must be distributed among several persons, Mr. Childs was proud of the fact that he was associated with, and had a part in, this undertaking.

In 1927, Mr. Childs was selected to serve as Chief Engineer and Secretary of the Metropolitan Drainage Commission of Minneapolis and St. Paul, and had responsible charge of the investigation of the sewage disposal problem of the "Twin Cities." This work he has recorded in considerable detail in the four reports of the Metropolitan Drainage Commission, published in bound volumes, for the years 1928, 1929–30, 1931–32, and 1933.

In November, 1933, the Minneapolis-St. Paul Sanitary District was organized by authority of an Act of the State Legislature, with orders to proceed with the construction of a sewage disposal project. Because of poor health, Mr. Childs declined to be considered for the position of Chief Engineer of the new District, but was appointed Sanitary Engineer, a position which he held until the time of his death. For many years he had been deeply interested in the problem of sewage disposal for Minneapolis and St. Paul, and, in this connection, had served on the Committee on Metropolitan Affairs, of the Northwestern Section of the Society which Committee considered this question among others. His studies of river pollution, particularly as applied to the Mississippi River, in Minnesota, are well known to sanitary engineers.

In addition to the positions of responsibility mentioned, Mr. Childs was Assistant Professor in the Department of Preventive Medicine and Public Health at the University of Minnesota. He was also Collaborating Engineer, United States Public Health Service. He held memberships in Sigma Xi and Tau Beta Pi Fraternities, and the Central States Sewage Association, being on the Executive Board of the latter. He rendered service as a member of Committees of the Sanitary Engineering Division of the Society and was President of the Northwestern Section in 1929.

A recital of Mr. Childs' work and achievements yields an inadequate estimate of his life. He regarded his engineering work as a means of promoting public health and welfare. His influence in the community in which he lived extended beyond the visible results of his labor; it was always creative and constructive not only by outward manifestations, but also by its force in the lives of his associates. His unswerving devotion to his duty as he saw it, his honesty of purpose and action, and his high ideals will long be remembered by his many friends.

In 1912, he was married to Muriel Tappan, who, with a daughter, Muriel, and a son, Tappan, survives him.

Mr. Childs was elected an Associate Member of the American Society of Civil Engineers on April 18, 1916, and a Member on January 16, 1928.

ERNEST WILDER CLARKE, M. Am. Soc. C. E.[1]

Died April 24, 1935

Ernest Wilder Clarke was born at Syracuse, N. Y., on May 1, 1868, the son of William M. and Ella (Wilder) Clarke. He was educated in the public schools of Syracuse, Chicago, Ill., and Boston, Mass., and completed his education by graduation in 1887 from the English High School, at Boston.

Mr. Clarke was prepared and fitted for his future engineering career by employment with various engineers and City Departments in Boston and surrounding towns. This work gave him training and experience in city surveying, sewers, water supply, electric railroads, and rapid transit, and covered a period from 1887 to 1889, varying in length in proportion to the magnitude of the projects. The variety of this training fitted him for the more important work of his later life.

In 1900, Mr. Clarke went to New York, N. Y., where he was employed on the first rapid transit subways, on changing sewer locations.

From July, 1904, to June, 1906, he was with the Panama Canal Commission on sanitary work, first at Cristobal and later at Panama City; as Division Engineer he had charge of municipal sanitation work in Panama, Colon, and all towns across the Isthmus. Upon his return from Panama in 1906 he was engaged on water-works construction at St. Stephens and at St. Johns, N. B., Canada.

In 1906, Mr. Clarke joined the Engineering Corps of the Board of Water Supply of New York City, then actively engaged on the construction of the Catskill System. He was first assigned as Senior Section Engineer to the Croton Division which covered the Catskill Aqueduct from Peekskill to the Kensico Reservoir; later, he was for a short time Assistant to the Division Engineer on the construction of the Kensico Dam. When the White Plains Division was organized, he was promoted to the position of Division Engineer and completed the Aqueduct included in that Division. Thus, he was intimately familiar with the Catskill Aqueduct construction from Peekskill to Yonkers and, in addition, the preliminary construction of the Kensico Dam and its appurtenant works.

---

[1] Memoir prepared by George G. Honness, M. Am. Soc. C. E.

With this work completed, Mr. Clarke was engaged with the Quartermaster Corps, Construction Division, United States Army, in 1917. He was connected with the construction of Camp Upton on Long Island, the Fox Hill Hospital on Staten Island, and other World War projects in the Metropolitan District. From this connection, he went with the United States Shipping Board, with headquarters at Baltimore, Md., where he remained for three years.

In 1923, he joined the organization of Nicholas S. Hill, Jr., M. Am. Soc. C. E., as Designing Engineer and continued with Mr. Hill until 1932. Mr. Clarke then joined the New York City Board of Sanitation as Designing Engineer and served in that capacity until April 1, 1935, when he retired because of ill health.

He was a member of the New England Water Works Association, and of the New York State Sewerage Works Association.

Mr. Clarke was an active member and a Warden of St. John's Protestant Episcopal Church, of Pleasantville, N. Y., where he made his home.

He was married in 1893 to Ethel Lawrence Jones, of Boston, and is survived by his widow, a daughter, Mrs. George Knowles, two sons, Robert L. and John M. Clarke, and a sister, Mrs. George H. Tryon.

Mr. Clarke was elected a Member of the American Society of Civil Engineers on January 4, 1905.

RUEL KEITH COMPTON, M. Am. Soc. C. E.[1]

DIED JUNE 21, 1935

Ruel Keith Compton was born in Charles County, Maryland, on July 8, 1869, the son of Dr. Ruel Keith Compton and Rachel (Dement) Compton. He was graduated from Saint Johns Academy, at Alexandria, Va., when he was 19 years of age. In 1916, he received the honorary degree of Civil Engineer from Maryland State College.

Immediately following his graduation from Saint Johns Academy in 1888, Mr. Compton was engaged in surveying and other engineering work which added to his experience and outlook in his chosen profession. In 1890, he was made Assistant Engineer of Sewer Construction for the City of Baltimore, Md., which position he held for eight years. From 1898 to 1901, he held various engineering positions with, and supervised construction for, the United Railways and Electric Company, of Baltimore; the Pittsburgh and Alleghany Telephone Company, of Pittsburgh, Pa.; and the Johnstown Telephone Company, of Johnstown, Pa. In January, 1901, he returned to his former position as Assistant Engineer of Sewer Construction for the City of Baltimore, and remained in that capacity until May, 1905, when he was appointed Special Engineer in charge of the reconstruction of highways within the "Burnt District" of Baltimore, following the devastating fire of 1904, in which position he continued until November, 1906, when he was made Assistant City Engineer of Baltimore in charge of highway maintenance.

---

[1] Memoir prepared by G. M. Bowers, M. Am. Soc. C. E., and P. A. Rice, Assoc. M. Am. Soc. C. E.

His outstanding ability and knowledge gained in the field of street paving and highway construction merited Mr. Compton's appointment in May, 1911, as Chairman and Consulting Engineer of the Paving Commission of the City of Baltimore, in which capacity he was charged with the responsibility for all construction, administrative, and executive work of the Commission, and for the expenditure of millions of dollars for all classes of standard paving construction.

He resigned his Chairmanship of the Baltimore Paving Commission to enter the World War when he was commissioned in July, 1917, as a Major in the Corps of Engineers, U. S. Army, and assigned to Camp Meade, Maryland, where he was placed in charge of the construction of roads and buildings. Later, he was transferred to Curtis Bay (Md.) Ordnance Depot in charge of general construction work and was also made Disbursing Officer at that station. Subsequently, he was transferred to and placed in charge of roads at the Quarantine Station, at Baltimore; he also served as Executive and Summary Court Officer and, later, as Acting Construction Quartermaster at the Acid Plant, Little Rock, Ark. He was honorably discharged from the Army in June, 1919, and promoted to the rank of Lieutenant Colonel of Engineers, in the Reserve Corps.

After his discharge from the Army, Colonel Compton immediately returned to Baltimore and was re-appointed, in June, 1919, as Chairman and Consulting Engineer of the Paving Commission of that city. In 1924, he received from the Mayor of Richmond, Va., the offer of the position of Director of Public Works of the City of Richmond and again resigned his position as Chairman of the Paving Commission of Baltimore to accept Richmond's call. After having served nearly eleven years in this position, his death followed a sudden heart attack. It was a shock to the entire community in which he lived and worked. He was well known and beloved by a large circle of friends, far and near, for his characteristics of heart and manner, and as an engineer of recognized ability.

Throughout his official career, Colonel Compton developed a rare spirit of public relations that inspired the confidence of all those with whom he was associated or came in contact. As a public official he brought to his position real and lasting accomplishments through his professional ability, tact, and dignity.

His worth and standing in his profession is evidenced in the fact that he was a Past-President and Director of the American Society of Municipal Engineers; Past-President of the American Road Builders' Association; Past-President of the Engineers Club of Baltimore, and, at the time of his death, President of the Virginia Section of the American Society of Civil Engineers. He was also, at the time of his death, Chairman of the Paving

Brick Committee (SPR1) Simplified Practice, United States Department of Commerce, and Chairman of the Asphalt Committee (SPR4) Simplified Practice, United States Department of Commerce.

Colonel Compton was connected with the following social organizations and clubs: A member of the Commonwealth Club, of Richmond; Past-President, Southern Maryland Society, of Baltimore; member, Central Engineers Club, of Richmond; and a member of the Society of the Cincinnati.

He was married in 1894, to Elinor S. Hough, of Baltimore. He is survived by his son, R. Keith Compton, Jr., of Richmond, and by two sisters, Mrs. Roger Manning, of Accokeek, Md., and Mrs. Canfield Jenkins, of Charles County, Maryland.

Colonel Compton was elected a Member of the American Society of Civil Engineers on November 12, 1913.

ROBERT FULTON COWLES, M. Am. Soc. C. E.[1]

Died November 26, 1935

Robert Fulton Cowles was born in Cleveland, Ohio, on September 14, 1887, the son of Edward H. and Ella C. (Hill) Cowles. His family moved to Colorado and, in 1896, to California. His formal education was received in the Grammer Schools of San Diego and Los Angeles. His technical education was obtained through home study and experience, supplemented by an uncompleted course as a "Special Student" at Leland Stanford University.

Mr. Cowles' first engineering assignment was on the Los Angeles Aqueduct, in 1908. Beginning as a Draftsman, he became Assistant to the Location Engineer, and, later, Assistant to the Division Engineer in charge of construction, having responsible charge of engineer crews, cement testing, and concrete mixing and curing.

In 1912, he was appointed Chief Engineer of the Casa Grande Valley Water Users Association, in Arizona, on the survey and construction of a main canal, with a capacity of 1 000 cu ft per sec. At the conclusion of that work in 1913, he was employed by J. B. Lippincott, M. Am. Soc. C. E., in Los Angeles, on the survey and design of water and irrigation systems, including a water system at South Oceanside, Calif., and on hydraulic studies of surface and underground waters.

Mr. Cowles was retained by the Bureau of Light and Power, of the City of Los Angeles, in 1915, to take charge of the collection and preparation of data and the compilation of reports on seven potential hydro-electric projects in the Owens Valley and Mono Lake regions, in California. This assignment involved stream measurement and run-off studies, as well as the location of proposed reservoirs, dams, power plants, and transmission lines.

---

[1] Memoir prepared by William H. Nanry, Esq., San Francisco, Calif.

In 1916, he was employed by the late M. M. O'Shaughnessy, M. Am. Soc. C. E., on the Hetch Hetchy project, for the City of San Francisco, Calif., in charge of a topographical survey (40 sq miles), selection of core-drilling sites, tracing serpentine stratum, and locations for a power-house and the penstocks thereto, at Moccasin Creek.

Soon after the United States entered the World War in 1917, Mr. Cowles was commissioned as First Lieutenant of Engineers, U. S. Army, and served more than a year in France. As Commanding Officer of Engineers at Vau Claire, under Hugh L. Cooper, M. Am. Soc. C. E., he had charge of the rebuilding of an old monastery as a hospital, as well as the operation of water, steam heat, and electric power supplies. He was also in charge of the water supply, drainage, and sewage disposal at a large military hospital at Beau Desert.

On his return to civilian life in 1919, Mr. Cowles engaged in general engineering practice with offices in Los Angeles. He was retained to make a topographical survey of the 60 000-acre Gillespie Project, in Arizona, and extensive hydraulic studies of the holdings of the Sweetwater Water Company in San Diego County, in California.

In 1921, he was placed in charge of topographical surveys for the Arrowhead Lake Project, in California, and in 1922, he was appointed Chief Engineer of the South Coast Land Company, of Los Angeles, in general charge of land development and sub-division, the design, construction, and operation of extensive water supply and irrigation systems, and the supervision of street lighting and sewerage system installations.

After designing sewerage and water supply systems for Normal Heights, San Diego, Mr. Cowles was appointed, in 1925, as Engineer-in-Charge of the Bureau of Water Development, of the City of San Diego. During his régime he had charge of the design and construction of a 17-mile pipe line, 3 ft in diameter.

In 1928, he was retained by the J. P. Campbell Irrigation Company, California, for the design and construction of overhead irrigation systems. In 1929, for the Water Department of the City of Los Angeles, he served as Topographer on the Colorado River Project and participated in the extensive studies involved in that gigantic undertaking. For a short time in 1930, as Associate Engineer, United States Bureau of Reclamation, he participated in the study of the water resources of the Sacramento Valley, in California (Central Valley Water Project).

Mr. Cowles was appointed in 1930, Assistant Hydraulic Engineer, State Division of Water Resources, California, in connection with the administration of the Water Commission Act, and for investigations of the availability and use of water in the Napa and Santa Clara Valleys particularly, and elsewhere throughout the northern part of the State. It was during this period, that his health began to fail due to the ailments that finally caused his death.

He next, in 1934, served as Supervising Engineer, United States Coast and Geodetic Survey, at Kennett Reservoir, California (Central Valley Water Project). This was Mr. Cowles' last active professional work, although while hospitalized at Yountville, Calif., in 1935, he made some volunteer water studies for the hospital authorities of the proposed Rector Dam project.

On November 26, 1935, he passed away at the United States Veterans' Hospital, at Yountville. During his life he worked, with a high degree of professional ability, on several of the really great engineering projects in the West and with some great engineers.

Mr. Cowles was elected a Member of the American Society of Civil Engineers on August 16, 1929.

FRANCIS ELIHU CRANE, M. Am. Soc. C. E.[1]

DIED AUGUST 13, 1935

Francis Elihu Crane, the son of N. Martin Crane and Julia A. (Harris) Crane, was born at Elizabeth, N. J., on April 4, 1861. He was graduated, in 1885, from Union College, at Schenectady, N. Y., with the degrees of Bachelor of Arts and Civil Engineer.

Following his graduation, Mr. Crane taught in his Alma Mater. In 1887, he went to Amsterdam, N. Y., as Assistant Engineer on sewer construction. In 1889, he was made the City Engineer of Amsterdam and continued as such for about twenty-five years. This was at a time when the city was growing rapidly.

Afterward, he opened an office in Amsterdam, and engaged in private practice along sanitary and appraisal lines. He made plans for sewers and disposal works for several towns, and was called in on many appraisal cases, in which his fairness and clear thinking were of great value.

Mr. Crane was an active and highly esteemed member of the Presbyterian Church and filled responsible positions in it.

For years, he was a member of the County Historical Society, the local Board of Trade, and the Board of Education. Of him, the local paper truly stated,

> "It was characteristic of the man to do what fell to his lot efficiently, but without fuss or great show of effort. A Christian gentleman in every sense and a man of unusual attainments in his chosen profession, he commanded the respect and admiration of all with whom he came in contact.
>
> "Amsterdam is a better community for Mr. Crane's having been a member of it, and that is a fine thing to be able to say for any citizen."

His ability, kindly disposition, and good judgment endeared him to those who knew him, and they became his friends.

Mr. Crane was a member of the Society of Engineers of Eastern New York, and served on several of its committees. For years he represented his Class on the Graduate Council of Union College.

---

[1] Memoir prepared by William B. Landreth, M. Am. Soc. C. E.

On October 20, 1892, he was married to Emma W. Myers, of Amsterdam, who, with a daughter, Elizabeth, and a sister Sarah E. Crane, survives him.

Mr. Crane was elected a Member of the American Society of Civil Engineers on October 1, 1902.

JOHN FRANCIS CUSHING, M. Am. Soc. C. E.[1]

Died October 7, 1935

Born in Arapahoe, Nebr., on May 21, 1882, John Francis Cushing, the son of Francis Cushing and Flora (Patchen) Cushing, after receiving his preliminary education, including studies at the University of Nebraska, at Lincoln, Nebr., entered the University of Notre Dame, at Notre Dame, Ind., in 1902, from which he was graduated in June, 1906, with the degree of Civil Engineer.

The narrative of Mr. Cushing's progress and success in the engineering and business world should be inspirational to any reader. Born the son of a village blacksmith, learning this trade, and that of a cooper, while pursuing his elementary and High School studies, his educational ambition and industry mastered all obstacles, and secured to him university training for his splendid participation in the complex affairs of the modern world.

After his graduation from Notre Dame, Mr. Cushing entered the employ of the Barber Asphalt Paving Company as Engineer and Superintendent, accepting more responsible employment shortly thereafter as Field Engineer on the construction of a utility tunnel for the City of Chicago, Ill., upon the completion of which, he entered the ranks of the Great Lakes Dredge and Dock Company on October 14, 1907, and devoted his great talents to the affairs of that Company for the remainder of his life.

During his twenty-eight years of loyal service to the Great Lakes Dredge and Dock Company, as a consequence of his sturdy character, unusual industry, keenness of mind, and noteworthy application, he advanced persistently to the pinnacle of this great national organization, as follows: 1907 to 1910, Timekeeper and Field Engineer; 1910 to 1912, Construction and Cost Engineer; 1912 to 1918, Division Engineer; 1918 to 1921, Assistant General Manager; 1921 to 1922, Vice-President; and 1922 to 1935, President and Director.

Mr. Cushing's earlier work comprehended field construction, the development of cost systems and estimates, the formulation of tenders, and the investigations and reports related to construction progress. In later years, his efforts were concentrated upon executive problems, of which one of the outstanding evidences is a modern marine construction equipment, developed under a deeply thoughtful, long-term plan, the efficiencies and capacities of which are of international recognition. Such a development was, perforce, paralleled with the equally difficult task of selecting and training a highly skilled personnel, not only for design and construction, but for the safe and efficient operation of many radically new machines and devices. The passing of direct authority and responsibility to dependable individuals, the establishment of a runner-up system for each key position, and myriad other general administrative activities, were given Mr. Cushing's keen and constant supervision. Throughout his arduous life, a great interest in, and loyalty to, his associates and employees were manifestly uppermost in his mind. His encouragement and support were extended infallibly to the younger men whose aptitude and ambition for advancement attracted his attention. His striking accomplishments in these many and diverse phases of engineering and executive responsibilities insure him a most enduring and living memorial.

---

[1] Memoir prepared by a Committee consisting of J. E. Cahill, *Chairman*, E. M. Markham, Edward J. Kelly, W. W. DeBerard, and William P. Feeley, Members, Am. Soc. C. E.

Mr. Cushing's exceptional faculty for organization clearly indicated him as the outstanding leader in his industry, invariably respected as a strong character of definite aims, and honored by the friendship and confidence of all with whom he came into business association. His activities and energy were boundless, comprehending the entire scope of the marine construction business. He formed and led many groups, such as the River and Harbor Improvement Association, and others, representing the marine contractors in their many considerations related to labor unions, code affairs, and other matters of general welfare. Difficulties merely stimulated him to increased efforts and greater accomplishments. He was a man's man, deeply devoted to his family, and to his unusually wide circle of friends and associates.

Mr. Cushing was President of the Hydraulic Dredging Company, Incorporated, of Oakland, Calif., which venture he controlled as an individual. He was a Director of the Independent Pneumatic Tool Company, and of other business enterprises. He held memberships in the Western Society of Engineers, the Rotary Club of Chicago, the Edgewater Golf Club, and the Illinois Athletic Club, of which he served as President for two successive terms. His Alma Mater, the University of Notre Dame, in recognition of his achievements, selected him to serve as a member of its Board of Lay Trustees. He was a communicant of the Roman Catholic Church, and a member of the Knights of Columbus.

Some of the more recent outstanding projects completed under Mr. Cushing's direct supervision were the Chicago River straightening, Damen and Ogden Avenue improvements, South and Lincoln Park extensions, A Century of Progress and Skyride, at Chicago, extensive dredging contracts at New York, N. Y., Cape Cod Canal, in Massachusetts, Buffalo, N. Y., Toledo and Monroe Harbors, Ohio, the Calumet and Indiana Harbor steel breakwaters, in Indiana, and a multitude of river and harbor improvements throughout the Great Lakes and along the Atlantic and Pacific Coasts.

Mr. Cushing was the author of the technical paper, "Economical Design of Hydraulic Pipe-Line Dredge",[2] which gave complete data on the design of the 30-in. Diesel electric hydraulic dredge, *New Jersey*, built in 1930.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 625.

In 1931, he donated to the University of Notre Dame the beautiful structure known as the John F. Cushing Hall of Engineering, intending that it should represent his concrete expression of gratitude and appreciation of the assistance extended to him while a student. His benefactions to the worthy were many, with none finer than his financial assistance to numerous students struggling for an education.

The letter from Mr. Cushing, of April 16, 1931, to the President of the University of Notre Dame, in making his gift of the College of Engineering, is typical of his clear thinking and planning for the future. The following extracts are quoted therefrom:

"I conceive that an Engineer, speaking particularly but not exclusively of my own field of civil engineering, must be a man with a conscience in his profession. The gravest of all natural responsibilities are borne by him. He will be responsible for human safety and human lives. He must know his materials and his principles of construction. He must respect the one and be faithful to the other. The seriousness of this needs no elaboration. It is a matter of primary and essential honesty of workmanship but it has its roots in the character of the man. The engineer must know how to do it and have the strength of character to do it right.

"Engineering has written a glorious chapter in the history of progress in our time. The glory is not all of the past, it has not all been won. There are still great opportunities for those prepared to seize them. The field of service, indeed, is constantly broadening. Electricity, for example, seems always to be in its infancy. Nobody knows what the next day will produce. The same is true in regard to the extension of the principles of mechanics. We want adventuring minds in all departments of engineering. Where shall we look for these results except in men developed in schools like Notre Dame? The native genius, inventor, or discoverer is, no doubt, born, not made, but he alone would not get very far. Our best hope is the high level of professional intelligence and professional character developed in the colleges and technical schools of the land. It is there the thought needs to be instilled that men owe it to their profession, not to lay it down, finally, exactly as it was when they took hold of it, but to pass it on a finer thing, enriched and advanced, and more valuable to the world because of the use they have made of it."

In the John F. Cushing Hall of Engineering, directly opposite the entrance is a gray marble tablet treated in gold and colors in the manner of an illuminated manuscript, and bearing the inscription:

"With honor and gratitude Notre Dame cherishes the name of John F. Cushing, whose sympathy with the ideals of the University and generous interest in the high purposes of scholarship are enduringly recorded in the gift of this building for the service of learning and the greater glory of God."

Mr. Cushing's sudden death at the early age of 53, resulting from an airplane accident at Cheyenne, Wyo., on October 7, 1935, is a tragic and irreparable loss to his associates and multitude of friends.

On September 12, 1906, Mr. Cushing was married to his boyhood sweetheart, Harriet M. Webber. Mrs. Cushing and his seven beloved children, Francis, Paul, Jerome, Gregory, Mary, Martha, and Vincent, two sisters, Mrs. L. V. Jenkins and Mrs. Mary Mackenzie, and a brother, Marvin Noble, mourn their great loss, but fondly cherish his memory.

Mr. Cushing was elected a Member of the American Society of Civil Engineers on October 10, 1927.

ROBERT BENJAMIN DAVIS, M. Am. Soc. C. E.[1]

DIED JULY 31, 1934

Robert Benjamin Davis was born in Jersey City, N. J., on May 20, 1856, the son of Judge James N. Davis and Jane (Russell) Davis. He received his early education in the public schools of that city, completing preparation for his college course at Hasbrock's Classical and Commercial Institute in 1874. In 1878 he was graduated from New York University, New York, N. Y., at which time he delivered the Philosophical Oration and received the degrees of Bachelor of Science and of Civil Engineer. He was a member of Phi Beta Kappa.

While a student at the University Mr. Davis' interest centered in its musical activities. A voice of unusual quality, the inspiration received from his instructor, Dr. Leopold Damrosch, father of Dr. Walter Damrosch, led him toward a musical career. The demands of his professional practice soon proved this to be impossible, although for pleasure and relaxation he always turned toward the best that music afforded.

After his graduation from New York University, Mr. Davis began his life work in the Public Works Department of Jersey City, where he remained until 1880 when he became Resident Engineer for the Toledo, Cincinnati, and St. Louis Railroad Company. This work required surveys in Indiana and Illinois, necessary cross-sections for cuts and fills, designs for timber trestles over waterways, etc., with estimates for the work. Illness contracted in the swamps of that country compelled Mr. Davis to resign that position in 1881.

Upon recovery, he became Assistant Division Engineer on the West Shore and Buffalo Railroad, from 1881 to 1883. His duties in this position included general office work, the preparation of plans, profiles, calculations, estimates, etc. In 1883, he became associated with Frank H. Earle, a Civil Engineer, of Jersey City. To the general requirements of such an office were added surveys for road construction and the development of "New Town," in Roseville, N. J.—under Mr. Davis' supervision.

In 1884, he accepted the position of Assistant Engineer, with the Brooklyn Railway Company. As such, he made surveys of property adjacent to routes for elevated structures; designs for timber trestles in the yard of the Elevated Railroad; and plans for a machine shop. He also designed a coaling plant for locomotives and made the preliminary general drawings with detail steel drawings for the elevated structures.

In 1886, Mr. Davis became Principal Assistant to the Chief Engineer, the late George B. Cornell, M. Am. Soc. C. E., when responsibility was added to the work of designing foundations and structural steel, calculations and plans for track work, designs for station buildings, supervision of all plans for, and the construction of, various classes of work.

---

[1] Memoir prepared by Mrs. Robert B. Davis, Brookline, Mass.

In 1888, in order that he might be more closely associated with his friend, the world-renowned engineer, the late Charles C. Schneider, Past-President, Am. Soc. C. E., Mr. Davis accepted the position of Manager of the Bridge Department of the Pencoyd Iron Works, Philadelphia, Pa. This position required both professional and business knowledge in arranging the routine of work through the drafting-rooms and shops, with its supervision in all stages until shipped.

In 1894, Mr. Davis decided to enter private practice. Resigning from the Pencoyd Iron Works, the firm of Davis and Barnes was established, which continued until 1897. During that time, among various outstanding works, were the designs of the buildings comprising the plant of the Sessions Foundry Company, at Bristol, Conn., and the supervision of the construction. The main foundry building was at that time the largest of its kind east of Michigan. These buildings were of brick, with steel roof trusses and concrete floors. The work included the planning of the heating, plumbing, and ventilating systems and the supervision of their installation.

In 1897, Mr. Davis closed his private business in order that he might concentrate on that branch of his profession that for him held the greatest interest. Mr. Cornell, still Chief Engineer of the Brooklyn Elevated Railway Company, suggested to Mr. Davis that past experience in the Company, with accrued architectural knowledge, would be of value and once more he became Principal Assistant to Mr. Cornell. During that time Mr. Cornell frequently gave expression to his feelings of confidence in Mr. Davis' ability and of the conscientious performance of work which seldom if ever called forth criticism or discussion. The extension of the Elevated Railway had become urgent, and designs for the structural steel work and foundations were necessary, including direct connections of the Brooklyn Elevated with its New York Terminal. Mr. Davis took great pride and interest in this work.

In 1899, he was called to Boston, Mass., by Gen. William A. Bancroft, then President of the Boston Elevated Railway Company, for expert consultation on plans and equipment necessary for the extension of that road. These conferences required only a limited time, but mutual esteem and confidence developed which resulted in Mr. Davis becoming an outstanding figure in the construction and development of the Boston Elevated Railway, covering a period of more than thirty years. Beginning in 1899, Mr. Davis was associated with the late George A. Kimball, M. Am. Soc. C. E., Chief Engineer, as Designing Engineer in charge of plans covering a large percentage of structures. The items of this work are numerous: Bridges of various descriptions; power stations; elevated footwalk to the North Station of the Boston and Maine Railroad Company; and changes and alterations from inter-track and "island" stations to side-track stations. From 1900 to 1902, some of the most important works designed by Mr. Davis were the Atlantic Avenue Division of the original elevated structure, and the Lincoln Coal-Handling Plant, the entire design of which (except the towers) being under his direct charge and the construction under his personal supervision. The coal-handling plant included a coal-pocket of 5 000 tons capacity, connecting with a steel and concrete ash-pocket. The coal-pocket was to support towers, which necessitated a substantial wharf to hold such loading, and a dock of sufficient dimensions to accommodate coaling steamers. To obtain the latter required the construction of a heavy sea wall.

Other miscellaneous work came under Mr. Davis' supervision, such as elevated stations and platform extensions; changes and additions to the Sullivan Square and Dudley Street Elevated Terminals; the personal inspection of all bridges over which surface cars passed, as well as the solution of problems concerning the determination of safe loads and types of cars to be operated over certain bridges. During this period Mr. Davis occasionally spoke on the subject of "Elevated Railroads" to the students at the Massachusetts Institute of Technology.

From 1905 to 1912, as Engineer of Elevated Structures, he was in charge of plans and structures, such as car barns, machine shops, and extensions. His designs were used for the Forest Hills Extension of the Elevated Railway and for structures over Arbor Way. This work was done under his personal supervision. Other important works were the south approach to Washington Street Tunnel; reconstruction under operation of the City Square and Dover Street Elevated Stations; design of steel details for the Everett Extension of the Elevated Railway from Sullivan Square; calculations with estimates necessary for final judgment on the bridge over Mystic River and the lift-bridge over Malden River; and inspection for car safety in operation over highway bridges from 1914 to 1918.

After the death of Mr. Kimball in 1912, Charles S. Sergeant, Vice-President of the Elevated Railroad Company, assumed charge of the Department, Mr. Davis continuing his work under the title of Engineer of Structures. From 1918 to 1920 he was Consulting Engineer for the Company. These years covered work of a varied character, such as would demand the attention of professional experience and judgment. Mr. Sergeant, learning of the death of Mr. Davis, wrote:

> "It was a pleasure to be associated with so skillful an engineer who was also an accomplished gentleman. In his work I felt great reliance for it was competent, careful and safe and I can recollect no instance of error or failure in his designs. It was always a regret that he had not a wider field than was afforded with one company, one in which his capacity could have been better known. That he was of great assistance to us in the design and building of our elevated structures goes without saying and I shall always remember our pleasant association."

Edward Dana, Executive Vice-President and General Manager, writes:

> "Mr. Robert B. Davis will always be remembered by those who were associated with him on the construction of the elevated lines of The Boston Elevated Railway as a man of the highest moral character, strict integrity, and an engineer of unusual ability, ever willing and ready to offer advice and assistance in a most friendly and courteous manner."

Although repeatedly urged to enter broader fields of his profession, the lure of publicity or professional honor was not attractive to Mr. Davis. His unobtrusive personality is strikingly expressed in a tribute offered by his friend, J. R. Worcester, M. Am. Soc. C. E.:

> "Mr. Davis was over modest about his own ability and for that reason did not become well known among engineers as a leader, but his ambition evidently lay in doing faithfully and well everything that he undertook. I have always regarded him as a gentleman whom I was proud to call a friend."

These tributes convey to some extent the disregard Mr. Davis held for personal aggrandizement. A permanent home, the simpler forms of pleasure and relaxation after a day of service in worthwhile achievements, were to him sufficient. In 1919 there were evidences of failing health, and Mr. Davis retired from active professional work. Buying a farm in Wayland, Mass., he decided to spend his remaining years in the restful environment of country life. In a few years, however, with improved physical health, he felt an urge for old interests, and visions of subways and tunnels disturbed the quiet of the country.

In 1924 he became Designing and Consulting Engineer in the Transit Department of the City of Boston. From 1924 to 1933 some of Mr. Davis' outstanding works were: The Grosvenor Square Extension of the Boston Street Subway; the Dorchester Rapid Transit Extension; and the Sumner Traffic Tunnel under Boston Harbor, from the city proper to East Boston. The Dorchester Rapid Transit Extension was an extension of the old Dorchester Tunnel to Mattapan, mostly over the right of way of the Shawmut Branch of the New York, New Haven, and Hartford Railroad. The length of the Extension was about six miles; it consisted of substantially all new construction and was partly underground. Mr. Davis planned and supervised the relocation of the four tracks of the New Haven Railroad between Columbia Road and Savin Hill Playground, while maintaining traffic on four tracks for the Railroad Company. He also planned the relocation of the present steel span of Savin Hill Avenue Bridge, designing a new steel and concrete span and a temporary bridge for single passage of vehicles and foot traffic while alterations and additions were being made. On the Dorchester Rapid Transit Extension he designed two power sub-stations, one at Fields Corner and the other at Ashmont. These were followed by designs for the Charles Street Station, in Boston, the structural steel work for the alterations of a portion of the present elevated structure, including footbridges and stairways to stations, alterations to the Cambridge Bridge, in connection with the proposed station, and a design for a timber trestle for the use of elevated trains during new construction.

Mr. Davis designed the Harrison Sub-Station Building complete, including architectural as well as steel details; the Forest Hills Station galleries, stairways, and footbridges connecting with the New Haven Railroad Station at Forest Hills; the Ashmont Signal Tower and the Yardmen's Building in the Train Storage Yard on Codman Street at Ashmont; the over-pass at Columbia Station, Mattapan Superstructure; the under-pass of the Elevated Railway, at South Station; subway to South Station; and Mattapan Station, including all architectural, steel, and concrete details, with estimates for all the work mentioned. He designed the canopies over the platforms at numerous stations, including Columbia, Savin Hill, Milton, Crescent Avenue, and Mattapan Stations.

The Boylston Street Subway Extension was a mile in length entirely underground. On this subway Mr. Davis' work was chiefly the design of the steel work. He also designed the power sub-station at the North Station of the Washington Street Tunnel, and the one at Newbury Street of the Boylston Street Subway. It was during the construction of the Sumner Traffic Tunnel that Mr. Davis' health again began to fail and, in the early spring of 1933, it was obvious he could no longer tax his strength. The summer spent at Chatham, on Cape Cod, was of great benefit. The severe winter following proved this to be only temporary. Again, he was taken to the Cape, but grew rapidly weaker and on July 31, 1934, passed on as one sleeping.

The many tributes to his memory stress the exceptional attributes of his character, his high ideals, his faithfulness of purpose in the exacting demands of his profession, and to every duty he assumed.

Thomas F. Sullivan, M. Am. Soc. C. E., of the Transit Department of the City of Boston, wrote: "We had known each other for a long time and I admired him very much. Mr. Davis' passing is a source of regret to the entire organization."

Wilbur W. Davis, M. Am. Soc. C. E., Chief Engineer of the Transit Department, writes:

> "I wish to express my own comprehension of Mr. Davis' personal qualities as well as those of the other associates with whom he worked here in the Transit Department during his last nine years. * * * We found him to possess a personality so fine that the like is seldom met with. He was regarded with a high degree of respect by all. Mr. Davis' every act showed that which I can best express as a gentleman. * * * He was very modest, mild-mannered, and courteous to every one. His loss is deeply felt."

Thomas N. Ashton, a lawyer and engineer, for a time associated professionally with Mr. Davis, offers this tribute to his memory:

> "His journeying on ahead of us does indeed leave me with a sense of personal loss. It was my extremely good fortune to come into contact with Mr. Davis very early in my engineering activities. The examples which he set for me and the sound principles which he so generously and patiently imparted to my immature mind have left me with an inner feeling that he has been to me a 'father' in my engineering life. * * * I have met many leading engineers during my thirty years of engineering labors in different parts of Eastern United States, but these other leaders in engineering thought, have never somehow measured up to the enviable standard set by Mr. Davis in being just his own individual self as an engineer. * * * The structures which he designed have never failed to bespeak a more artistic and substantial product than those of his contemporaries. * * * At least, this thought has ever been my opinion as I weighed one structure against another during my periodic journeys about the several States."

On January 1, 1883, he was married to Effie Potter Wilkes, of Toms River, N. J. Mr. and Mrs. Davis celebrated their Golden Wedding in their home, at Wayland, Mass., on January 1, 1933. The surviving members of his family are his widow; a daughter, Mrs. Anita Davis-Chase, of Boston; a son, Paul B. Davis, of Wayland, and one grandson, Robert Laurence Davis.

Although reared under the influence of a Methodist Episcopal Church and home, Mr. Davis became a member of the Protestant Episcopal Church, at the time of his marriage.

After Mr. Davis had passed on, there was found in a billfold he always carried, the following lines of Josiah Gilbert Holland, carefully preserved on cardboard, but blurred by time. The sentiment fully evidenced Mr. Davis' attitude of mind:

"Men whom the lust of office does not kill;
Men whom the spoils of office cannot buy;
Men who possess opinions and a will;
Men who have honor; men who will not lie;
Men who can stand before a demagogue
And damn his treacherous flatterings without winking;
Tall men, sun-crowned, who live above the fog
In public duty and in private thinking."

This was his standard of manhood. As such he lived, as such he died.

Mr. Davis was elected a Member of the American Society of Civil Engineers on October 12, 1925.

BENJAMIN CURTIS DONHAM, M. Am. Soc. C. E.[1]

Died January 15, 1936

Benjamin Curtis Donham was born on August 4, 1873, in Rockland, Mass., the son of George E. and Sara A. (Studley) Donham. He was graduated from the Rockland High School in 1891 and from the Massachusetts Institute of Technology, at Boston, Mass., in 1895, with the degree of Bachelor of Science in Civil Engineering.

Following his graduation, Mr. Donham entered into active engineering work which soon took him to the Pacific Coast where he spent nearly three years on estimates and designs for the San Francisco Bridge Company. Later, he spent a year in irrigation engineering for the Spreckels Sugar Company, at Soledad and Spreckels, Calif., where he designed and constructed ditch and check systems for irrigating sugar-beet ranches, and superintended the construction of about 4 miles of 30-in. steel pipe line. In the six months, November, 1899, to May, 1900, he perfected and completed an irrigation system on the Gonzales Ranch, of the Gonzales Water Company.

In May, 1900, Mr. Donham went to Seoul, Korea, as Chief Engineer for the Collbran, Bostwick Development Company, in charge of the estimates, design, and construction of the Imperial Highway to the Queens' Tomb; the Seoul Water-Works (the first in Korea); the maintenance and extension of the Seoul Electric Railway which included 3 miles of construction extension and 12 miles of design extension; many important brick buildings, including those for the German Consulate, Young Men's Christian Association, etc. He made the complete designs and estimates for the new buildings for the United States Legation, which were accepted by the State Department in Washington, D. C., but the buildings were never constructed, owing to the Russian-Japanese War and the subsequent change from a Legation to a Consulate.

---

[1] Memoir prepared by N. C. Grover, M. Am. Soc. C. E.

In 1909, Mr. Donham returned to the United States and entered the employ of J. G. White and Company as Construction Supervisor in charge of the following work: Cuba Eastern Railroad—reconstruction of the railroad from Boquerm to San Lois, Cuba; San Joaquin Light and Power Company—hydro-electric development of 20 000 hp, at North Fork, Calif. (a few months of the early work); Tri-State Land Company—reconstruction and extension of the irrigation system to cover 57 000 acres; after May, 1909, he served as Secretary of the latter Company and was practically in charge of the management of its affairs, including an active selling campaign for the disposal of water rights for the entire area, as well as 24 000 acres of land which was owned by the Company; Upper Columbia Company—a company organized for developing lands in the Upper Columbia Basin, in Washington, of which he became Vice-President after May, 1910, in charge of its management as well as of the construction of its irrigation system covering Tract No. 1, Upper Columbia Orchards.

In 1912, Mr. Donham organized and was Senior Partner in the engineering firm of B. C. Donham and Company, the name of which was changed in 1919 to Donham-Adams Company. This Company took over from the J. G. White Engineering Corporation the management contract with the Tri-State Land Company of which Mr. Donham continued as Secretary until the formation of a Bondholders Committee. As member and Secretary of the Bondholders Committee, he had complete charge of the re-organization and refunding of the bond issue, purchase of stored water rights in the Pathfinder Reservoir from the United States Reclamation Service, formation of the Farmers Mutual Canal Company, and, later, the Farmers Irrigation District which took over all water rights from the natural flow of the North Platte River, as well as the storage rights from the Pathfinder Reservoir. In 1926, he completed the successful refunding of the Farmers Irrigation District bond issue and settled all differences between the Tri-State Bondholders Committee and the District.

In 1926, Mr. Donham organized and was President of the Air Filtration Corporation and took out important patents covering improvements in the art of dry-air filtration. This Corporation was sold to the American Air Filter Company in 1929. Thereafter, he was Vice-President and, later, President of the Electro Anti-Corrosion Corporation. As indicated by the trend of his professional work, he had in a marked degree the combination of qualities that produce sound engineering and successful business. He was a thorough engineer, an exceptional negotiator and diplomat, and a successful business executive.

Mr. Donham retired from active business about three years before his death because of failing health. For many years, he resided in Glen Ridge,

N. J., where he was actively engaged in civic affairs. He served six years on the Glen Ridge School Board, three as President, retiring in 1928. He resigned in January, 1936, from the Glen Ridge Board of Adjustment, on which he had served for eleven years. He was a member of the Borough Building Committee from 1927 to 1933, and the Municipal Plan and Art Commission from 1927 to 1930.

In addition to his engineering and business characteristics, Mr. Donham had those personal qualities of mind and heart that endeared him to a host of friends. Among that host was an unusually wide circle of intimate friends who were sincerely devoted to him because of his spirit of optimism, helpfulness, and loyalty. By his interest, advice, and assistance in many ways—tangible as well as intangible—he helped many over the rough spots with which the path of life is strewn. Those who knew him thus intimately will long miss him.

He was married on August 4, 1902, to Edith Alexandria McKean, of Alameda, Calif., who survives him. He is survived also by two sons—George Alden and Winfield Benjamin—and by a daughter, Dorothy Evelyn (Mrs. Frederick Page), all residents of Glen Ridge; also by two brothers, G. Herman and Wallace B. Donham, and by a sister, S. Agnes Donham.

Mr. Donham was elected an Associate Member of the American Society of Civil Engineers on January 2, 1901, and a Member on March 31, 1908.

GEORGE ALEXANDER MILLER ELLIOTT, M. Am. Soc. C. E.[1]

DIED DECEMBER 23, 1934

George Alexander Miller Elliott was born on October 21, 1880, at Wellington, New Zealand, the son of Robert Elliott and his wife, Isabel H. Elliott, *née* Booth.

As a child he came to San Francisco, Calif., with his parents, and attended the public schools in Berkeley, Calif. His collegiate education was obtained at the University of California, at Berkeley, and the University of Colorado, at Boulder, Colo. He was graduated from the latter in 1904 with the degree of Bachelor of Science in Electrical Engineering.

Immediately following graduation Mr. Elliott entered the Testing Department of the General Electric Company, at Schenectady, N. Y., where he took the requisite ten months' course, returning to San Francisco upon its completion.

During the next four years his engineering work was for the most part in connection with the design and construction of high-tension electric transmission lines in New Mexico and California. In the latter State he made surveys and acted as Construction Foreman for the Pacific Gas and Electric Company, secured the right of way for a high-tension tower transmission line from the Feather River to San Francisco Bay for the Great Western

---

[1] Memoir prepared by F. C. Herrmann and George W. Pracy, Members, Am. Soc. C. E.

Power Company, and was Superintendent of Construction of this line for Viele, Blackwell, and Buck.

In June, 1909, Mr. Elliott accepted the position of Superintendent of Operation and Maintenance of the Spring Valley Water Company, serving domestic water to the City of San Francisco and its environs. Subsequent to this date, his work was in hydraulics, either as Engineer, Constructor, or Executive. He remained with the Spring Valley Water Company for twenty-one years, serving, successively, as Superintendent, Chief Engineer, Vice-President, and Manager, with outstanding ability.

When the City of San Francisco acquired the properties of the Spring Valley Water Company in 1930, Mr. Elliott declined to continue as Manager of the System, and entered private practice as a Consulting Engineer, associating himself with Edward F. Haas and Frederick C. Herrmann, Members, Am. Soc. C. E., with offices in the Merchants Exchange Building, in San Francisco, where he was busily engaged in the practice of his profession to the time of his unexpected death.

The Spring Valley Water Company made many large additions and improvements under Mr. Elliott's direction as Chief Engineer. Among these was the construction of the Calaveras Dam and Storage Reservoir, with the Upper Alameda Diversion; a number of large pumping plants and transmission mains; the development of the underground waters of Livermore Valley; and a revamping of the distribution system in San Francisco. He was with the Spring Valley Water Company during a critical period of its history—times fraught with rate-fixing and litigation, together with the threat of the installation of a competitive municipal system. It was then that his characteristic fairness, firmness, and sound judgment were strikingly displayed. He was direct in methods and reasoning, never permitting non-essentials to make a problem or situation complex.

In 1917, he acted as Supervising Engineer, United States Army, on the construction of Camp Fremont, at Palo Alto, Calif., and of the tri-nitrotoluene (T.N.T.) plant, at Giant, Calif.

During his career Mr. Elliott was called in as Consulting Engineer at one time or another by practically all the privately owned public utilities of California.

From 1914 to 1930, he was engaged as Consulting Engineer for the San José (Calif.) Water-Works. He supervised the plans and construction of the principal improvements made thereto, including the pumping stations and four reservoirs.

Beginning in 1920 he served as a member of the Board of Consulting Engineers for the State Engineer of California in the study of the water resources of the State and their comprehensive development, which, in 1931, culminated in the proposed State Water Plan for the great Central Valley of California, with an estimated cost of $170 000 000.

While in private practice Mr. Elliott was called upon to serve in many undertakings. Among the important engagements were the following: Investigating the safety of many dams for the State of California; serving as Consulting Engineer for the Los Angeles County Flood Control District in the construction of the San Gabriel River Dam estimated to cost about $15 000 000; acting as Arbiter in the case of Rolandi *versus* the State of California to fix payments for the construction of the Klamath River Bridge; making an exhaustive study and report for the City of San Francisco on the future water requirements of the San Francisco Bay region, the water productivity of near-by sources of supply, and their utilization in conjunction with the Tuolumne River supply.

At the time of his death Mr. Elliott was actively engaged as Consulting Engineer for the Orange County Flood Control District in the preparation of plans for large flood-control reservoirs.

Mr. Elliott was very active in the affairs of the San Francisco Section of the Society, serving as its President during the year 1923. He served on the Committee of the Section which effectively and efficiently handled its funds for the aid and relief of engineers in distress in the San Francisco Bay region during the depression.

He was a member of the American Water Works Association, organizing the California Section of this Association in 1920, and serving as its President for the first three years thereof.

Mr. Elliott was a member of the University Club, the Family Club, and the Engineers Club, all of San Francisco. He held membership in the following fraternal organizations: Alpha Tau Omega College Fraternity; Berkeley Lodge No. 363, Free and Accepted Masons; California Bodies of the Scottish Rite; and Islam Temple of San Francisco.

Always interested in civic affairs, he was an active member of the Industrial Committee of the San Francisco Chamber of Commerce.

Mr. Elliott was married on October 12, 1909, to Rosemary Zeile, who survives him.

He was a staunch citizen, notably fair and firm, but withal generous, kindly, and understanding, having a high conception of proper ethics in his chosen profession.

Greatly loved by his many friends, and highly respected by his brother engineers, the Engineering Profession on the Pacific Coast suffered a great loss in his untimely demise.

Mr. Elliott was elected an Associate Member of the American Society of Civil Engineers on September 5, 1911, and a Member on June 24, 1914.

FRANK WILLIAM FLITTNER, M. Am. Soc. C. E.[1]

DIED OCTOBER 26, 1935

Frank William Flittner was born at Visalia, Calif., on August 14, 1893, the son of Henry Flittner and Mary (Ames) Flittner Trimble. He attended the Lowell High School, at San Francisco, Calif., and was graduated from the University of San Francisco (St. Ignatius College), with the degree of Bachelor of Science in Civil Engineering, in 1916. During the last few years he had taken a Correspondence Course in Law with the Blackstone Institute and received the degree of Bachelor of Laws in 1933.

---

[1] Memoir prepared by C. H. Sweetser, M. Am. Soc. C. E.

After his graduation from the University of San Francisco, Mr. Flittner worked with the Shell Oil Company for a time. On May 8, 1917, he entered the United States Army as Second Lieutenant, 4th Engineers. In the Army he served at Vancouver Barracks, Washington, Camp Greene, North Carolina, and in France, where he was wounded during an engagement at Ypres, in August, 1918.

Following his discharge from the Army as First Lieutenant, on May 8, 1919, Mr. Flittner had engagements with F. Rolandi, Contractor; the Standard Oil Company of California; and the Hawaiian Sugar Refining Corporation, on engineering construction. He was also employed by the California Railroad Commission, and the Cities of Berkeley, and San Diego, Calif., on valuation and assessment work. In 1929 and 1930, he was engaged in private practice on various surveying and estimating projects.

He entered the service of the United States Department of Agriculture, Bureau of Public Roads, on February 2, 1931, as Associate Construction Engineer, with headquarters at Phœnix, Ariz. In this service, he was assigned as Supervising Engineer on highway work in Southern Arizona and Southeastern California. During his connection with the Bureau, he was careful and thorough, and continually strove for high standards on all work coming within his supervision.

Frank Flittner will be long remembered in District No. 2 of the Bureau of Public Roads for his engineering ability, sterling character, and agreeable personality. In spite of periods of ill health and physical weakness, he carried on his work with diligence.

Mr. Flittner was a Mason, a Knight Templar and a member of Islam Temple Shrine, of San Francisco, Calif. He was also a member of the American Association of Engineers and the Society of American Military Engineers.

Death came unexpectedly after only a short illness, although he had had periods of poor health for several years. He is survived by his widow, Genevieve Perrin Flittner, to whom he was married on May 9, 1917, and by his mother, Mrs. Mary Trimble.

Mr. Flittner was elected a Junior of the American Society of Civil Engineers on November 21, 1921, an Associate Member on March 12, 1923, and a Member on October 30, 1933.

WESTON EARLE FULLER, M. Am. Soc. C. E.[1]

Died June 22, 1935

Weston Earle Fuller, the son of William F. and Dora A. (Howard) Fuller, was born in Phillips, Me., on July 27, 1879. He received his early training in the public schools of Portland, Me., and his engineering education at Cornell University, at Ithaca, N. Y., which in 1900 conferred upon him the degree of Civil Engineer. He was a member of the Alpha Tau Omega Fraternity.

---

[1] Memoir prepared by Chester M. Everett, M. Am. Soc. C. E.

After graduation he served as Instructor of Civil Engineering at Cornell from 1900 to 1902, and was then employed as Assistant Engineer of the Ithaca Water Company from 1902 to 1903. It was in connection with the building and operation of this very early example of a mechanical filter plant that he first came in contact with the late Allen Hazen, M. Am. Soc. C. E., and this association was destined to shape the course of the early part of his engineering career.

From Ithaca, Mr. Fuller went to Watertown, N. Y., as Resident Engineer for Hazen and Whipple on the construction of the mechanical filtration plant in that town, and upon the completion of this work he was transferred to Poughkeepsie, N. Y., to superintend the building of a slow sand filtration plant for the State Hospital for the Insane.

As a result of the excellent work done for Hazen and Whipple in the field supervision of these various plants, he was brought to the New York Office as Chief Draftsman in charge of all details of design. His progress there was rapid and, at the end of two years, in 1907, he became a Junior Partner and began to assume more and more responsibility, extending his activities from the direct supervision of design to the making of field inspections for new projects and the preparation of reports and direct contact with clients.

His acquaintance in the water-works field and his experience increased rapidly, and on January 1, 1915, the special value of his services was recognized by the inclusion of his name in the firm, which became Hazen, Whipple and Fuller, and this arrangement continued until September 1, 1922, when he resigned, and accepted the Professorship of Civil Engineering at Swarthmore College, Swarthmore, Pa.

The period of his association with Mr. Hazen was one of development and progress, first devoted to the practical problems of design and the construction of new works, and, later, to work in valuation and rate-making. During this portion of his life Mr. Fuller traveled over most of the eastern part of the United States and Canada, studying the water and sewerage problems of various communities and companies. He had much to do with the design of the slow sand filtration plant at Toronto, Ont., Canada, and prepared, on the ground, the plans and specifications for two new mechanical filtration plants at Ottawa, Ont., Canada. Neither of the latter was built, however, due to political controversy.

In the United States Mr. Fuller had full charge of the design and building of the new water-works, at Ogdensburg, N. Y., additional works at Watertown, the slow sand filters at Peekskill, and at Yonkers, N. Y., and took a prominent part in the design of the new water supply for Springfield, Mass., and the new 42-in. main from Lake Sebago to Portland, Me. He also developed all the main features of a report on the Passaic Valley Sewer, in New Jersey, which was actually built some years later, and of another on a large sewage disposal plant for Pittsburgh, Pa., proposed for location on Neville Island.

During this time Mr. Fuller took over all the work of the firm in Florida and designed the first filtration plant, of the gravity rapid sand type, at West Palm Beach, with the pumping station and other additions to this water-works system; he served the Miami Water Company for several years in the solution of its problems, and laid out the water and sewerage works for the newly developed Miami Beach area. He was responsible for the interesting and unique method of disposing of sewage at Miami Beach by pumping it into the rapidly flowing outgoing current of the sea channel at ebb tide.

In 1913, Mr. Fuller presented two papers of great value and interest to those engaged in water-works practice, the first of which, entitled "Flood Flows"[2] was presented before the Society, and the second, entitled "Loss of Head in Bends"[3], was read at a meeting of the New England Water Works Association. His paper on "Flood Flows", for which, in 1914, he received the Fuertes Graduate Medal from Cornell University, represented the result of much careful research, being an analysis of all the data available at that time as to the extent and frequency of the occurrence of floods. Empirical formulas were deduced, giving a concrete expression to the results of these analyses, which have been quite generally used throughout the United States and are known internationally. It is perhaps through this research on floods and the formulas for estimating their probable size, that Mr. Fuller had become best known throughout the Engineering Profession.

Although the early years of his work with Mr. Hazen were spent mostly in the practical problems of design, construction, and operation of water-works plants, Mr. Fuller found his greatest interest and was most successful in valuation and rate-making cases. He began this work at a time when the practice was relatively new and ideas regarding such matters, particularly the proper allowances for depreciation, were not nearly as well crystallized as at present. Mr. Fuller was one of the pioneers in establishing a more general understanding of these abstruse questions, and, as the years went on, he devoted more and more of his time to them. The first case of importance carried through directly by him for his firm was the rate case of the Hackensack Water Company. Another case of importance in which Mr. Fuller was a principal expert on the side of the consumer was that against the Commonwealth Water Company of New Jersey, and also one against the Interurban Water Company, of Westchester, N. Y. Most of Mr. Fuller's valuation and rate-making work was as an expert in the interest of the municipality or consumer, but in Durham, N. C., he represented the Durham Water Company and he also did considerable work for the Miami Water Company, in Florida. During the later years of his association with Mr. Hazen, Mr. Fuller's time was almost entirely given to valuations, rate cases, and damage suits.

---

[2] *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

[3] *Journal*, New England Water Works Assoc., Vol. 27 (1913), p. 509.

During the early part of this country's participation in the World War, Mr. Fuller served on the Staff of the Adjutant General of the State of New York, ranking as Captain in the Engineer Corps.

Later, representing his firm—Hazen, Whipple and Fuller—he headed a Staff of Engineers at Camp Dix, Wrightstown, N. J., on the design and supervision of construction, of the water and sewerage systems.

Following acceptance in 1922 of an invitation to head the Civil Engineering Department at Swarthmore College, he was made Chairman of the Division of Engineering of that college in 1924. During this period he continued to do substantial outside work largely in valuation and rate-making cases and including services on the side of the municipality in the case of the City of Elizabeth, N. J., against the Elizabethtown Water Company, of certain other communities in New Jersey against the Middlesex Water Company, and in the case of the Village of Mamaroneck, N. Y., and other communities against the Inter-Urban Water Company. During this time, also, he did substantial work for the Legal Department of the Board of Water Supply of the City of New York, and he also represented the North Jersey District Water Supply Commission in suits arising as a result of the building of the Wanaque Reservoir.

Although successful as a Professor at Swarthmore College, the increasing demand for his services as Expert Adviser in such cases as those just mentioned, led him, in June, 1929, to resign from the Faculty of Swarthmore College and once more to devote himself entirely to private practice. From this time until May 1, 1931, he carried on a private consulting practice with headquarters at Swarthmore. Much of his work was for New York City, but perhaps the largest and most interesting project was the taking over of the properties of the Passaic (N. J.) Consolidated Water Company by the newly formed Passaic Valley Water Commission. In this case his services and those of several other engineers resulted in obtaining from the Condemnation Commission an award closely approximating that given in their valuation. Out of this association came a contract between Mr. Fuller and Frank A. Barbour, M. Am. Soc. C. E., and the Passaic Valley Water Commission for engineering services in the design and construction of substantial additions to the plant, including a complete rehabilitation of the pumping station.

From 1928 to 1930, Mr. Fuller represented the State of Massachusetts in the Massachusetts-Connecticut case on the Connecticut River. In 1930, when the Tri-State case on the Delaware River came before Special Master Bruch, representing the Supreme Court of the United States, Mr. Fuller was retained to represent the water power interest for New York State.

On May 1, 1931, Mr. Fuller formed a partnership with Chester M. Everett, M. Am. Soc. C. E., the remaining partner of the firm of Hazen and Everett on the death of Mr. Hazen in July, 1930. This partnership with Mr. Everett continued until the time of Mr. Fuller's death.

During his association with Mr. Everett, Mr. Fuller's activities were mostly in connection with the work of revamping the properties acquired by the Passaic Valley Water Commission, at a total cost of more than $2 000 000, and in looking after several power-damage suits for the New York Board of Water Supply and the Metropolitan Water Board of Boston, Mass. He was also employed during this period as Engineering Expert to advise the Water Rate Case Committee on a water-rate case against the Commonwealth Water Company of New Jersey. The work was still in progress at the time of his death.

Mr. Fuller was a member of the American Water Works Association, Sigma Xi, Cornell Engineers, Engineers' Club, of Philadelphia, Pa., and Alpha Tau Omega, of New York.

In 1907 he was married to Bertha Palmer, of Ogdensburg, N. Y. Mrs. Fuller and his daughter, Ada Palmer Fuller, survive him. A son—Weston Earle Fuller, Jr.—died in 1927, at the age of 14.

Mr. Fuller was elected an Associate Member of the American Society of Civil Engineers on June 7, 1905, and a Member on December 3, 1912.

HARRY CARTER GARDNER, M. Am. Soc. C. E.[1]

Died January 23, 1935

Harry Carter Gardner was born on December 11, 1881, in Adams County, Nebraska, the son of William H. and Eva H. (Carter) Gardner. After his academic schooling, Mr. Gardner entered the University of Colorado, at Boulder, Colo., from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1906. In 1909, he received the degree of Civil Engineer from the University.

Mr. Gardner began his professional career as a Structural Steel Draftsman with the American Bridge Company, followed by similar employment with the J. R. Bowles Structural Steel Works. He was afterward Assistant Engineer on irrigation surveys in Eastern Oregon, and, on the completion of this work, he was Structural Steel Draftsman with C. G. Sheely, Bridge Contractor, at Denver, Colo.

In September, 1908, Mr. Gardner returned to the University of Colorado where he was a Graduate Student and Assistant Instructor. From September, 1909, until June, 1912, he was Instructor in Civil Engineering at the University of Pennsylvania, at Philadelphia, Pa. Mr. Gardner was engaged in designing and estimating on all kinds of structural steel buildings and bridges with Lewis F. Shoemaker and Company, Pottstown, Pa., from June, 1912, until February, 1915.

He became Chief Engineer with the firm of John H. Wickersham, Engineering and Construction, Lancaster, Pa., in February, 1915. He acquired an interest in this business, and his intimate association with the writer continued until his death.

---

[1] Memoir prepared by John H. Wickersham, M. Am. Soc. C. E.

Throughout his life Harry Carter Gardner proved the value of a Christian engineer. His technical opinions and designs were always sound, and his integrity was always above question.

On July 2, 1910, he was married to Jane Graham, at Philadelphia, Pa., and to them were born the following sons and daughters: Harry Graham, Richard Carter, Betty Jane, Barbara Mary, and Carter Samuel, who, with his widow, survive him.

Mr. Gardner was elected a Junior of the American Society of Civil Engineers on July 1, 1909; an Associate Member, on November 12, 1913; and a Member, on June 12, 1917.

ALLAN VINAL GARRATT, M. Am. Soc. C. E.[1]

DIED APRIL 30, 1932

Allan Vinal Garratt came from very early American stock. On his father's side, Peter Hallock reached this country from London, England, in 1640; the Garratts were but little later, while on the distaff side there were several generations of Vinals before the Revolutionary War, and representatives on both sides of the family were prominent in Colonial affairs and in the Revolutionary and Civil Wars.

Born in Boston, Mass., on December 11, 1857, the son of Dr. Alfred Charles Garratt, a Boston physician, surgeon, and medical author of note, and of Martha Bowker (Vinal) Garratt, Allan Garratt, while by no means an invalid, was not particularly strong, and his early education was acquired largely at private schools, notably Chauncy Hall. From 1876 to 1879 he was a Special Student at Massachusetts Institute of Technology and Lawrence Scientific School, following this with special studies at Harvard University in botany and geology under the famous Professor Nathaniel S. Shaler. He accompanied Professor Shaler, as his Assistant, on a geological survey of Kentucky.

On his return, the combined effects of the death of his mother, to whom he was particularly devoted, and the unfortunate outcome of a love affair, brought on a dangerous attack of what in those days was diagnosed as "brain fever." While still so ill that he had to be carried on shipboard, he sailed on the historic barque, *Sarah*, to the Azores. There he regained his strength, and then sailed to Maderia, where he made important botanical studies. Here, too, he made the acquaintance of an African sea captain and trader, supposedly dying. A born doctor, although without the degree, Mr. Garratt nursed the sick man back to health, and, in 1880 and 1881, accompanied him on a trading and exploring expedition up the Congo River in Africa. Here

---

[1] Memoir prepared by Alden B. Hoag, Esq., Holliston, Mass.

Mr. Garratt heard rumors of Alfred Aloysius Smith, later to become famous as "Trader Horn", but although the two expeditions came within a short distance of each other, the men did not actually meet.

The African trip was followed in 1883 and 1884 by an engagement to develop a salt mine in Santo Domingo. On that Island he made the original examination and report on the mine, including preliminary surveys for eighteen miles of railroad and dockage facilities at Barahona, and opened up some of the benches. The Company had many setbacks and difficulties, but eventually seemed on the verge of success, when, in the course of one of the periodical revolutions on the Island, a party of insurrectionists seized the plant just after the supply boat had left, and stripped it of everything portable, including the food. Mr. Garratt, who had suffered a broken leg during the affray, rode horseback ninety miles without rest across the Island, and succeeded in intercepting the boat, and getting it to return to the plant, although his horse had to be shot. This, coupled with the loss of an important shipment, caused the Company to abandon the mine.

Returning to the United States, Mr. Garratt set up as a Consulting Engineer, with offices and interests in Boston and New York, N. Y. During this period—from 1885 to 1887—he also represented the Volta-Pavia Battery Company, for which he made a number of installations; edited the periodical, *Modern Heat and Light*; and contributed technical articles to the *Electrical Review.*

His writings led to his selection as the first Secretary and Treasurer of the then National Electric Light Association, later the Edison Electric Institute, which position he held from 1887 to 1890, but he was more concerned with the duties of the office than its politics, so that in the latter year he failed of re-election. About this time he served as Chairman of the first Committee to draw up an Electrical Safety Code and of the first Committee on Wire Gauge Standards.

On October 20, 1887, he had married Mary Charlotte Wilder, of Boston, and with her he shared many of his next adventures, the scenes of which were in the deep West, then very much a frontier country. He went first to Spokane, Wash., as Chief Engineer of the proposed Spokane and University Heights Electric Railroad. Crossing the country during the last important Indian uprising, Mr. and Mrs. Garratt saw settlers fleeing with their goods across the plains, and on one memorable night the glow of burning ranches could be seen.

The sudden death of the head of the group of bankers handling the securities resulted in the abandonment of the railroad project, and Mr. Garratt became connected with the Portland, Ore., Office of the Thomson-Houston Electric Company, installing for that Company a hydro-electric plant for Waterville, Wash. It was during this installation that he first realized the need for an accurate water-wheel governor for such plants, and he began the study and research that led to his great contribution to Hydraulic Engineering. While still in the West, he revamped the electrical installation of the Palace Hotel, in San Francisco, Calif.

Returning to Boston in 1895, his next move was an interesting example of the part chance appears to play in life. Hearing that the Simplex Wire Company was looking for a Plant Superintendent, Mr. Garratt went to see about it. The position had already been filled, but in the course of a conversation following this discovery, it appeared that one of the executives was interested in a water-wheel governor a Mr. Lombard was developing. Mr. Garratt, immediately realizing that his work along this line would admirably complement the Lombard studies, offered to effect a combination, and the Lombard Water-Wheel Governor, long the outstanding American device of the kind, was the outcome.

From 1898 to 1920, he was Chief Engineer for the Lombard Governor Company, in the last eight years of that period being General Manager. He was in responsible charge of the design of the governors, of which about fifty types were developed, including the "actuator" design. So far as elements pertaining to regulation were concerned, many were of considerable intricacy and magnitude, involving much design of flumes, stand-pipes, surge tanks, regulating chambers, fly-wheels, etc During his fifteen years with the Company Mr. Garratt guided all construction and erection engineers in the field.

Refusing to establish a monopoly by withholding from the Engineering Profession the details of his research—a monopoly which could have been enormously profitable—Mr. Garratt freely placed at the disposal of all other workers in his field the result of his unique work, and by this means made possible the development of similar devices by the larger water-wheel makers. The result was that it became the custom for governors to be produced as an integral part of the wheel unit, and the demand for separate governors was greatly diminished. The chief credit for the basic studies, however, belongs to Mr. Garratt, a fact evidenced both by the Gold Medal awarded him personally at the St. Louis Exposition "for notable work in water-wheel governing", and by his articles on the subject, notably the chapters contributed to Mead's "Water Power Engineering" and to Lof and Rushmore's "Hydro-Electric Power Stations", and various papers before technical societies and in the technical press.

During the World War he served in Washington, D. C., and at the Naval Proving Grounds in Boston Harbor in experimental work on artillery fire-control devices, developing particularly a firing mechanism for anti-aircraft guns. He also served as Public Safety Commissioner, Fuel Administrator, and Treasurer of the Young Men's Christian Association fund of his home town, Holliston, Mass.

Following his departure from the Lombard Governor Company in 1920, Mr. Garratt served Lockwood, Green and Company, of Boston, as Construction Engineer, working on surveys, reports, and preliminary designs of a number of proposed water-power developments, including preliminary work on eight propositions to develop about 380 000 gross hp. Later, he returned to private consulting practice taking also the work of Eastern States Representative of the Redwood Manufacturers Company, of San Francisco, for which he designed redwood pipe lines. He was thus engaged up to within a short time of his death.

For Allan Garratt an adverse fate seemed always to have set definite bounds which were wholly without reference to his ability, energy, or courage. A brilliant engineer, whose contribution to his special field of hydraulics afforded notable and permanent advances, a man of untiring energy and enthusiasms, of unshakable courage and an astonishingly wide range of knowledge, a great executive and a born leader, and with marked business ability in many directions, he suffered, nevertheless, the misfortune through life of repeatedly becoming connected with projects which gave every promise of a most prosperous outcome, only to fail more or less completely because of some unanticipated and indeed unforeseeable turn of fortune entirely beyond his control.

His professional experience, his extensive travels, and his wide range of reading, coupled with an excellent memory, provided him with a rich fund of information, and gave his opinions, professional or otherwise, a well-deserved weight. As an acquaintance once put it: "Garratt is always sure of himself and the worst of it is, he is always right."

Excelling in sports calling for agility and skill rather than great physical strength, he was a superb horseman, a fine fencer (having studied under Zalinski, at the Massachusetts Institute of Technology), and an expert marksman. He also enjoyed fishing and sailing. Up until a year or two of his death he always appeared much younger than his actual years, and in the last months of his life his splendid courage in overcoming the infirmities of his physical condition was an inspiration to many who were ready to give up with less to contend with. He died almost "with his boots on", ready almost to the very last hour to go to his office and deal with the engineering problems he knew awaited him there.

A member at the time of his death, of the American Institute of Electrical Engineers, of the American Society of Civil Engineers, of the Harvard Engineering Society and of the Society of American Military Engineers, he had previously held membership, and, as was characteristic of his membership in any organization, had been very active in the Boston Natural History Society, in the Boston Scientific Society, in the Boston Society of Arts, and in a number of other scientific and social societies. A Mason, he was a member of Mount Hollis Lodge, in Holliston.

Besides his widow, Mr. Garratt left two daughters, Helen Lucy (Mrs. Alden B. Hoag) and Myrtis Manning (Mrs. Albert L. McManus), and four grand-children.

The records of hydro-electric development in the United States bear witness to his professional ability; of him as a man no better characterization can be given than the expression at the time of his death by a number of friends, widely separated and obviously quite independently: "He was a gallant gentleman."

Mr. Garratt was elected a Member of the American Society of Civil Engineers on March 7, 1921.

XANTHUS HENRY GOODNOUGH, M. Am. Soc. C. E.[1]

Died August 10, 1935

Xanthus Henry Goodnough, the son of Xanthus and Kate (Harley) Goodnough, was born in Brookline, Mass., on October 23, 1860. He prepared for college at the Brookline High School and was graduated from Harvard University in 1882. During his college course, not only was his scholastic record good, but he was also prominent in athletics, for four years being stroke of his Class crew which is reputed to have won all its races.

After his graduation Mr. Goodnough was employed for a short time by the Boston (Mass.) Main Drainage Commission, and then in general railroad work in the West. Returning to Massachusetts in 1885, he worked with the Massachusetts Drainage Commission on investigations concerning the North Metropolitan Sewerage System. In 1886, he entered the employ of the State Board of Health as an Assistant to the late Frederic Pike Stearns, Past-President, Am. Soc. C. E., Chief Engineer, and upon Mr. Stearns' resignation, in 1895, Mr. Goodnough was made Chief Engineer of the State Board of Health. This position he held until 1914 when upon the re-organization of that Board he became Chief Engineer and Director of the Division of Sanitary Engineering in what is now the Department of Public Health, and continued in this position until, owing to age limitation, he was retired in October, 1930. Upon his retirement, Mr. Goodnough invited Bayard F. Snow, M. Am. Soc. C. E., to join him in forming an engineering organization which, under the name of X. Henry Goodnough, Incorporated, has continued engineering practice, principally in the fields of water supply and sewerage. In this way, Mr. Goodnough kept in touch with engineering and sanitary matters up to his final illness.

During the thirty-five years that he was Chief Engineer of the Board of Health and the Department of Public Health, he guided that Board and Department ably and efficiently in matters of water supply, sewerage, sewage disposal, improvement of rivers, etc., and served as Engineer of some of the largest and most important public health investigations and projects ever undertaken by the State. His work of this character began, as stated previously, as an Assistant to the late Mr. Stearns during the investigations and the development of the plan for the establishment of the Metropolitan Water Supply System for Boston and the surrounding cities and towns. Thirty years later, from 1919 to 1922, he was Chief Engineer of a Joint Board which investigated the enlargement of this Metropolitan Supply by extending the system to the Ware and Swift Rivers. His recommendations relative to this extension were contained in an elaborate and able report. His plan for enlarging the System was at first rejected, and a second commission proposed an entirely different plan. Finally, after extended legislative hearings and much controversy between the proponents of these two plans, Mr. Goodnough's plan was adopted. Throughout these hearings he displayed the same able and adroit generalship always evident in his work. Upon the formation of the Metropolitan District Water Supply Commission to carry out this project, he was appointed one of its Consulting Engineers and after his retirement in October, 1930, through X. Henry Goodnough, Incorporated, he continued to render services in that capacity, even to the time of his death.

---

[1] Memoir prepared by Arthur D. Weston and Frank E. Winsor, Members, Am. Soc. C. E.

Among many other investigations made by Mr. Goodnough, the following may be mentioned as typical of his work: In 1895, he had charge of engineering work for improving the Concord and Sudbury Rivers and the rebuilding of bridges over these streams; from 1895 to 1897, he had charge of the investigations for the improvement of the Neponset River and the Fowl Meadows, and from 1911 to 1915, he was Engineer for the construction of this work; in 1896, he had general charge of an investigation for a sewerage system for Salem and Peabody, Mass.; in 1899 and 1900, he had charge of further investigations for a main sewer for the South Metropolitan District and a new outlet into Boston Harbor; in 1906 and 1907, he had charge of studies for the improvement of the Mystic River and Alewife Brook as well as designs for the improvement of the water supply of the City of Lynn, Mass.; in 1914, he made plans for the extension of the Metropolitan Sewerage System in the Charles River Valley; in 1916, he, jointly with the City Engineer of Lynn, planned a new sewerage system for that city; from 1923 to 1927, he was in charge of various special investigations for water supplies for Lawrence, Lowell, and Methuen, Mass.; and during the same years he had charge of planning a general sewerage system for Salem, Peabody, Beverly, and Danvers, Mass.

Apart from his work for the Commonwealth of Massachusetts, Mr. Goodnough was from time to time Consultant for various municipalities and water and sewerage districts concerning water supply, sewerage, and other sanitary engineering matters; among these, during 1907 and 1908, for the City of Boston, in regard to municipal waste disposal; during 1914 for the City of Providence, R. I., in regard to water supply, and for the Metropolitan Sewerage Commission of New York, N. Y.; and during 1926 for the County of Los Angeles, California, concerning sewerage.

On account of his intimate knowledge of all water supplies, sewerage systems, and rivers of the State of Massachusetts and his direction of engineering studies for the solution of a great variety of sanitary problems, he was pre-eminently known as an expert in public health engineering. His mastery of methods within his field made him a commanding figure in legislative committees before which he was often called for consultation and advice, and he was alert and skillful in presenting his point of view before these committees. He was an efficient executive and understood the delicate art of human engineering, how to deal with men and how to get things done. He was a lover of mountains, forests, streams, and outdoor life, an ardent fisherman, and a good companion.

Mr. Goodnough was the author of papers on various engineering subjects, including rainfall, stream flow, freshets, yield of water-sheds, ground-water supplies, drainage, disposal of sewage and municipal refuse, and, in

1921, was the recipient of the Dexter Brackett Memorial Medal of the New England Water Works Association for his paper on "Rainfall in New England."[2]

He was an Honorary Member of the American Water Works Association, and the New England Water Works Association; Past-President of the Harvard Engineering Society; and a member of the Boston Society of Civil Engineers, the Society of American Military Engineers, American Meteorological Society, and the American Geographic Society.

On October 5, 1892, he was married to Maria T. Dyer, who died on January 13, 1925.

Mr. Goodnough was elected an Associate Member of the American Society of Civil Engineers on May 6, 1896, and a Member on June 4, 1902.

WILLIAM CHARLES GOTSHALL, M. Am. Soc. C. E.[1]

Died August 20, 1935

William Charles Gotshall, Engineer and Scientist, was born in St. Louis, Mo., on May 9, 1870, the son of Daniel H. and Minnie (Wortmann) Gotshall. His great-great-grandfather, Michael Gotshall, of Lancaster County, Pennsylvania, was attached to Washington's Headquarters at Valley Forge and while on military duty lost his life in crossing the Schuylkill River. His grandfather, Daniel Gotshall, was an officer in both the Mexican and Civil Wars. His father served in Company F, 4th Ohio Volunteer Infantry, in the Civil War and, later, was first a newspaper editor and afterward a publisher of law books in St. Louis.

William Charles Gotshall worked in the office of his father's Publishing Company as a copy-holder and type-setter. Meanwhile, he took an intensive course of study under private tutors in mathematics, electricity, and engineering, and began his professional career as a Draftsman in the Metzger Iron Works, of St. Louis. Later, he was engaged as an Engineer in railway location and construction and, in 1892, entered the employ of the Missouri Electric Light and Power Company, of St. Louis, one of the pioneer alternating-current electric light and power plants (1 000-volt) in the United States. It was at this time that he laid the foundation for his career as an Electrical Engineer and engaged in much important original research and development work. While with this Company Mr. Gotshall made the first 1 000-hr incandescent lamp test for life and efficiency, using a lamp board starting with 1 000 sixteen candle-power incandescent lamps.

Through the wide interests of the Company's President, Samuel Dodd, Mr. Gotshall branched into the field of electric railways and soon became a recognized expert and authority on design, construction, and operation. The graphic method of showing construction and operation variations and activities was first utilized by him; it soon came into general use and is now the universal practice in construction work in almost every field of industrial and scientific activity.

---

[2] *Journal*, New England Water Works Assoc., Vol. 35, 1921, pp. 228–293.

[1] Memoir prepared by James J. Reilly, Esq., New York, N. Y., Prof. Frederick K. Morris, Mass. Inst. Tech., Cambridge, Mass., and Prof. William F. Bade, Univ. of California, Berkeley, Calif.

During 1893 he was a Government Engineer in charge of the work of riprapping and protecting 150 miles of banks on the Mississippi River. In 1894, as Chief Engineer for the Union Depot Railway Company, of St. Louis, he rebuilt and electrified the road, making the pioneer installation of the three-wire system on electric railroads. In this system, which can only be used on double-track roads, the track serves as the neutral wire. The current passes from one wire over one track downward through the car to the rails beneath, then rises through the rails and car on the parallel track to the negative wire above, thus completing the circuit in balanced condition and giving to each over-head wire and track a voltage of about 550 with a total line voltage of about 1 100. Although the system made a large saving in copper and eliminated electrolytic action on gas and water pipes, and was successful in St. Louis, the necessity of using dynamos in series and other mechanical difficulties, militated against its general adoption.

Later, Mr. Gotshall had charge of the location of the St. Louis and Eastern Railroad; the rebuilding and operation of the Cairo (Ill.) Electric Railway; the design and construction of the Belleville (Ill.) Electric Railway; the Marshalltown (La.) Railway and Lighting Plant; the Muncie (Ind.) Electric Railway; and the Grand Avenue Railway, in St. Louis. He was also Consulting Engineer on the construction of the St. Charles Railway, in New Orleans, La. During 1897 and 1898 he had charge of the conversion of the Second Avenue Railway, New York, N. Y., from a horse-car to conduit electric system, and then became President and Chief Engineer of the New York and Port Chester Railroad, which he designed and constructed, introducing pioneer improvements in high-speed electric traction. The Port Chester line, costing $25 000 000, was the first high-speed electric railway in the United States built entirely on its own right of way and entirely without grade crossings. After the completion of this railway in 1912, Mr. Gotshall engaged in the purchase and rehabilitation of railroad properties in the United States, Europe, and Africa, designing among others, a road from Cairo to Helouan, in Egypt.

Notwithstanding his varied and widespread professional interests Mr. Gotshall devoted much time to scientific activities and traveled extensively in the promotion of biological, geographical, and archæological research and exploration. Some of his most important work of this character was in exploration and development activities in Alaska, in behalf of the United States National Park System, and also in the Near East. Beginning in 1925 he was associated with Dr. William F. Bade in archæological explorations and excavations in Palestine where the site of the ancient Biblical City of Mizpah of Benjamin was unearthed eight miles north of Jerusalem; and, in 1926, a terra cotta head of Astarte, the Babylonian Venus, was found, the age of which is reckoned at nearly 3 000 yr. The limestone and clay wall of this ancient city was found to be 35 ft thick at the bottom, 29 ft thick at the top, and approximately 40 ft high. A narrow inner wall was also unearthed, and pottery of the Iron Age, storage bins, an Israelitish sanctuary, and a new double-cup type of Semitic pottery were found. The most important find was a jar handle on which was stamped a seal with three Hebrew letters meaning Mizpah, proving definitely that there had been discovered the correct ancient site of the Biblical Mizpah of Benjamin.

Mr. Gotshall was also active in athletic sports, rowing, fencing, boxing, and wrestling. He was one of the most skillful fencers in the United States, having won many medals with both the dueling sword and saber, including the National Championship in each. He was also a big game hunter, indulging in that sport in China, Mexico, Alaska, British Columbia, and the Canadian Rockies, and many exhibits of his skill are on view at the New York Athletic Club, Travers Island, New York, given to the Club by Mr. Gotshall. He had climbed all the glaciers in the Canadian Rockies and had ascended Yungfrau Yoch, in Switzerland, as well as the Chamonix Mountain, in France. He was also interested in aviation, and was an expert swimmer, being a recipient of the United States Life Saving Medal.

Among his diversions was the collecting of paintings and first editions of books of which he had a splendid collection, and which were left by will to the State Library, at Albany, N. Y.

In the World War period, he was a Major of Engineers, U. S. Army, serving as a Technical Transportation Expert in the laying out and construction of military roads, in railroad design and construction, and in the construction of Army camps.

He was the author of "Electric Railway Economics" (1904); the article on Railway Economics in the Encyclopedia Americana; and of contributions to technical and scientific journals. He was also deeply interested in heliotherapy and in two pamphlets, "Fasting and Efficiency" and "Heliotherapy with Fasting", he pointed out the virtues of abstemious eating with occasional periods of fasting and frequent sun baths.

Mr. Gotshall was a Fellow of the American Museum of Natural History and the American Geographical Society. He was also a member of the American Institute of Electrical Engineers and the American Association for the Advancement of Science. He was a 33d Degree Mason, and a life member of the Explorers, Lotos, and New York Athletic Clubs; the Automobile Club of America; Olympic Club, of San Francisco, Calif.; the Royal Automobile Club, of London, England; the Union Interalliée, of Paris, France; and the Army and Navy Club, of New York City. He was an accomplished linguist, speaking and writing German, French, Italian, and Spanish, in addition to his native language.

Dowered with a strong body to support any degree of hardship and effort, he had fertile vision and bold energy in carrying out his purposes. Such a career as his calls out a powerful opposition from many able men and well-intrenched interests. Risking everything in an uphill fight, he struggled forward against overwhelming odds to success, and to many successes. He was not bitter during the fight, nor boastful in victory. He opposed his enemies without hate; loved his friends loyally; he valued money for the service it enabled him to render, and he valued fame not at all. His world was an active world of realities, and everything interested him, calling forth dynamic response. Human problems interested him and he mastered five languages to deepen his contacts with his fellow men.

Largely self-educated, Mr. Gotshall lectured at several universities and aided their research progress—notably Rensselaer Polytechnic Institute, at Troy, N. Y., and Lehigh University, at Bethlehem, Pa. His lectures on the economics of electric railway engineering were published in the book previously mentioned, which filled a long-felt want in engineering literature. At the Massachusetts Institute of Technology, he was one of the Aldred Lecturers, and became a valued friend of President Stratton. In his will, he generously remembered schools and educators. His love of life urged him to study the art of living; and he wrote many papers on health and diet. All who knew his able mind and vigorous personality will feel a lack in their lives that no other friend may replace. The great frame and warrior face, with its bold earnest expression—the record of a fighting life—formed an inspiring picture.

He was married on September 15, 1897, to Countess Adelaide von Rathgen, who died on August 29, 1935.

Mr. Gotshall was elected a Member of the American Society of Civil Engineers on May 7, 1902.

FREDERICK PASSMORE GUTELIUS, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 12, 1935

Frederick Passmore Gutelius was born in Mifflinburg, Pa., on December 24, 1864, the son of Jacob and Mary (Passmore) Gutelius. He was a descendant in the fifth generation of John Peter Gutelius, Physician and Surgeon, who came from France in 1750 and qualified at Philadelphia, Pa.

Mr. Gutelius received his preparatory education in the public schools of Mifflinburg, and, later, attended Lafayette College, at Easton, Pa., receiving his degree of Civil Engineer in 1887. In 1914, the degree of Doctor of Science was conferred upon him by the same college. He was Captain of the football team in 1886.

He began his career in 1887 as Assistant Engineer on the construction of the Englewood, N. J., Sewerage System, joining the Pennsylvania Railroad Company in 1888 as Assistant Engineer in charge of the reconstruction of the Tuscarawas Tunnel in Ohio. Later, he was attached to the Maintenance-of-Way Department of that Company until June, 1890, when he went West, spending five years in Montana, first as Assistant Engineer on the Flint Creek Power Development, at Butte, where he remained for a year.

---

[1] **Memoir prepared by J. M. R. Fairbairn, M. Am. Soc. C. E.**

For a short time during 1891, he was Assistant Engineer with the Butte City Water Company, and during 1892 was in the private practice of Civil Engineering in that city. For three years, from 1893 to 1895, he was County Surveyor of Silver Bow County, Montana.

Mr. Gutelius went to Canada in November, 1895, as General Superintendent of Construction and Operation of the Trail Creek Tramway, at Trail, B. C., in which capacity he remained until the end of 1896, after which he was, from January, 1897, to March, 1898, General Superintendent in charge of construction and operation of the Columbia and Western Railway. In March, 1898, he was appointed Superintendent, Canadian Pacific Railway Company, in charge of operation and maintenance of the Columbia and Western Division, and from June, 1899, to June, 1900, he served as Resident Engineer, at Nelson, B. C. From 1900 to 1902 he was on special work, reporting to the Vice-President of the Canadian Pacific Railway Company, at Montreal, Que. His progress thereafter with the Canadian Pacific was rapid. He was appointed Engineer of Maintenance of Way of the System in 1902; four years later he was promoted to be Assistant Chief Engineer of the System, in which position he remained until August, 1908, when he was appointed General Superintendent of the Lake Superior Division, at North Bay, Ont., and subsequently, for a short period, held the same position in charge of the Eastern Division of the System at Montreal.

In January, 1912, Mr. Gutelius was selected as one of the Commissioners of a Royal Commission appointed to investigate expenditures and other matters in connection with the construction of the National Transcontinental Railway, and on the abolition of the Government Railways Managing Board, in May, 1913, he was appointed General Manager of the Canadian Government Railways, with all powers usually vested in the executive of railway corporations, reporting to the Minister of Railways and Canals of Canada.

He resigned this position in May, 1917, on his appointment as Vice-President of the Delaware and Hudson Company, with headquarters at Albany, N. Y. On the taking over of the management of the railways by the United States Railroad Administration during the World War, he was appointed Federal Manager of the Delaware and Hudson Railroad Company. On the relinquishment of that control on March 1, 1920, Mr. Gutelius was appointed Vice-President and General Manager of the Company and its allied properties. In the latter part of 1920, he was retained by the Ontario Government Commission inquiring into the proposed hydro-radial railway system. In 1923, he was appointed Resident Vice-President of the Delaware and Hudson Railroad Company at Montreal, in which capacity he remained until his death.

During his occupancy of this latter position, Mr. Gutelius established many friendships, and his loss is felt most keenly. He was a gentleman of quiet bearing, but had great decision of character, and had earned an international reputation as an engineer and railway executive. He was a capable, useful, and respected citizen, and his passing will be profoundly regretted.,

Mr. Gutelius is survived by his widow, Anna Walker Eaton, to whom he was married at Mifflinburg, on April 21, 1892, by a son, Frederick Passmore Gutelius, Jr., and by three married daughters, all resident in Canada.

He was a member of the Engineering Institute of Canada, and was prominent in Masonic circles at Mifflinburg, Pa.

Mr. Gutelius was elected a Member of the American Society of Civil Engineers on October 3, 1906.

JOHN VENABLE HANNA, M. Am. Soc. C. E.[1]

Died April 30, 1935

John Venable Hanna was born at Plattsmouth, Nebr., on January 1, 1864, the son of Thomas King and Judith Joyce (Venable) Hanna. When he was two years old his father, a wholesale merchant, moved his business and his family to Kansas City, Mo. John Venable Hanna lived in Kansas City until he entered Sheffield Scientific School, Yale University, at New Haven, Conn., from which he was graduated in 1885, with the degree of Bachelor of Philosophy. He again became a resident of Kansas City in 1906 and continued to make it his home until his death at the age of 70.

His father's wholesale business has been continued to this day. When his father died, his mother disposed of the family interests in the business, as, after a short trial, John Venable Hanna decided that he was not greatly interested in mercantile pursuits. From that time he was thoroughly and completely absorbed with construction work.

His experience took him through a variety of engagements, beginning as an Axeman on the Chicago, Burlington, and Northern Railway, which position he held from August, 1885, to July 1886. From July to November, 1886, he was employed as Assistant Engineer with the Colorado Railway Company. For the next two years, or more (May, 1887, to January, 1889), he was Assistant Engineer with the Current River Railroad Company and the Kansas City, Fort Scott and Memphis Railroad Company, following which, for six months (January to July, 1889), he served as Shop Inspector for the materials for the Thames River Bridge for the Providence and Boston Railroad Company. In April, 1890, he went West again and until November of the same year was engaged in mining in Colorado.

In January, 1891, Mr. Hanna returned to railroad work and until August, 1899, he was Assistant Engineer on the lines of the Kansas City, Memphis, and Birmingham Railroad Company. He then accepted a position in March, 1901, with the Fort Scott and Memphis Railroad Company as Assistant Chief Engineer which he held until September of the same year. Mr. Hanna then accepted a position as Assistant Chief Engineer with the St. Louis and San Francisco Railroad Company (the "Frisco Lines").

In December, 1906, he was appointed Chief Engineer of the Kansas City Terminal Railway Company, with headquarters at Kansas City, which position he retained until his death on April 30, 1935. As Chief Engineer of the Kansas City Terminal Railway Company, Mr. Hanna represented twelve trunk-line railroads, in connection with the construction of a $50 000 000 modern railroad passenger-freight terminal, a large part of which was built in a new location in Kansas City, Mo. and Kansas City, Kans. The amount of work done, its quality, the economical costs of the many different types of construction, and the speed with which the work was accomplished, all bear tribute to the care with which he supervised this gigantic undertaking. The importance of the work may be gained from the following figures: More than 50 viaducts valued in excess of $8 000 000 were built or rebuilt; 1 500 000 cu yd of steam-shovel excavation was moved several miles; a main-line railroad was lowered a maximum of 40 ft under traffic; a $5 000 000 passenger station second in size (at that time) to only one other, was constructed; a $1 000 000 sewer was built in the heart of the city; freight-houses; coach yard; a steam tunnel, a mile long; round-house; team tracks; main tracks; modern signal plants, all were constructed and brought to completion in an orderly scheduled manner creditable to all who were parties to the work and particularly to the Chief Engineer, John Venable Hanna.

---

[1] Memoir prepared by a Committee of the Kansas City Section, consisting of A. C. Everham, E. E. Howard, and C. E. Johnston, Members, Am. Soc. C. E.

The construction of this Terminal called for frequent and unending conferences with the Chief Engineer's Committee which represented the twelve property lines. At these meetings Mr. Hanna presided, and his ability to remember details, facts, and important contractual and ordinance obligations, made the work of the members of the Committee unusually simple and efficient.

The contacts with the City officials with whom Mr. Hanna dealt, were always of a nature to bring respect from those politicians who would ask for many more and greater concessions than they expected to get. His ability to command their respect when he declined to grant many of these unwarranted requests coming from these sources, gave him a position of diplomacy as well as of engineering.

Mr. Hanna was a lover of detail and was so thorough in his understanding of what he was ready to discuss, report, or present, that it was seldom he had to call for his associates to help him. His work and his method of handling it brought to him many friendships. Engineers, contractors, railroad officials, politicians, and prominent citizens believed John Venable Hanna was absolutely honest in all his dealings with his fellow men. He had many problems which tested his sterling character, and he did not fail. His monumental work in Kansas City is a splendid achievement and one of which his family should be proud.

His hobbies were few. In recent years, he had been much interested in painting, and painted quite a few pictures in water colors. At the time of his death, he was working on a painting of the Station site and Station building. He had been an ardent golfer for many years; a man of small physique, he did not play among the low par shooters, but he always played a fair game and was always pleasant company.

Mr. Hanna was a member of the Kansas City Country Golf Club, and the Yale Alumni Club of Kansas City; he was Past-President of the Engineers'

Club of Kansas City, and of the Kansas City Section of the Society. He was very active in the affairs of the Safety Council, and served as Chairman for many years on its most important Committees.

He was married in Kansas City, Mo., on November 2, 1892, to Marguerite Vaughan. He is survived by two daughters, Mrs. Margaret (Hanna) Lang and Mrs. Judith (Hanna) Gregory, and one grandson, John Hanna Lang, two sisters, Mrs. Luther Welsh, and Edith Hanna, and one brother, T. K. Hanna.

Mr. Hanna was elected an Associate Member of the American Society of Civil Engineers on May 3, 1893, and a Member on April 2, 1902.

MORRIS HANSFORD, M. Am. Soc. C. E.[1]

DIED JULY 17, 1935

Morris Hansford was born in St. Albans, W. Va., on December 6, 1865. He was the son of James Frazier and Annie (Noyes) Hansford who resided at the family home, which was known as "Ravenswood," overlooking the Kanawha River Valley. His father was engaged in farming and coal mining.

It was the custom at that time for parents to have tutors for their children, and Mr. Hansford received his first schooling from this source. He afterward attended the free schools until 1878. One of his first teachers was the Hon. William E. Chilton, former United States Senator from West Virginia, and present owner and publisher of the *Charleston Gazette*. He studied next under Professor P. B. Reynolds, from 1878 to 1883, at Shelton Academy at St. Albans. Although Mr. Hansford did not have the opportunity to gain a college education, he did acquire a thorough knowledge of engineering in the field and by constant study at home.

He began his practical experience on the location of the Upper Division of the New York Central Railway to Gauley Bridge, W. Va., under the direction of Mr. William C. Reynolds, serving as Rodman, Leveler, and Transitman from May, 1885, to November, 1886. Railroad and coke-oven construction consumed considerable of his time also. Mr. Hansford was employed as Topographer and Leveler on railroad location and construction from November, 1886, to September, 1888.

He entered the field of Mining Engineering in July, 1889, when he became associated with Mr. O. A. Veazey, of Pratt, W. Va. Until July, 1895, they were engaged in general engineering, in the location and construction of railroads, tipples, and inclines, and in the laying out of mining plants.

Mr. Hansford began his engineering career in the early days of the industrial development of the Kanawha River Valley which he lived to behold as one of the remarkable industrial centers of this generation.

From July, 1895, until April, 1899, Mr. Hansford was Mining Engineer for the Mt. Carbon Company, Limited, of Powellton, W. Va. As such he had full charge of the location and construction of tipples, inclines, and the opening of mines. In April, 1899, he joined the Charles M. Pratt Company, at Pratt, W. Va., and was occupied with the location of the Kanawha and Pocahontas Railroad and surveyed and divided 26 000 acres of land, continuing in that capacity until October, 1901.

---

[1] Memoir prepared by Howard A. Levering, M. Am. Soc. C. E.

Mr. Hansford was engaged in private practice, at Pratt, between October, 1901, and July, 1905, including railroad, tipple, and bin construction. During a part of this period, the firm was known as the Hansford and Burrell Engineering Company. It employed several engineers and draftsmen and performed a considerable volume of work. He became Superintendent of the Great Kanawha Colliery Company and the Eureka Colliery Company, in July, 1905, and completed that assignment in November, 1908, when he returned to private practice at Pratt, as a Mining Engineer, retaining the latter office until July, 1910.

He was made Superintendent of the Mt. Carbon Company, Limited, in July, 1910, and remained at Powellton, until December, 1914, when he accepted his first highway position as an Engineer for the Kanawha County Court, serving under P. J. Walsh, Assoc. M. Am. Soc. C. E., from June, 1915, to May, 1916, and participating in the construction of surfaced highways. From January, 1917, to 1923, Mr. Hansford was Chief Engineer with the W. E. Deegans Coal Interests, in charge of twenty-three coal mines, the location of forty miles of railroad, and the planning of various buildings, tipples, etc.

He then returned to private practice in which he was engaged from 1923 until September, 1925, when he joined the Engineering Staff of the State Road Commission in the Second District, with headquarters at Huntington, W. Va., under H. J. Spelman, M. Am. Soc. C. E., then Division Engineer. Except for a period of six months, Mr. Hansford served continuously with the Commission until the time of his death. During this period he was engaged in construction within the District and for a time was in charge of a survey party operating from the Charleston Division of Plans and Surveys.

Mr. Hansford was a splendid gentleman and served his profession faithfully and efficiently. He took a keen interest in every task and every assignment which confronted him in the pathway of life, and met them graciously. As an Engineer, he was extremely accurate, thoroughly dependable, and strictly honorable.

He was a Mason, a Knight Templar, and a member of Beni Kedem Shrine, Charleston, W. Va. He was also a member of the West Virginia Society of Professional Engineers, and a Director of Huntington Chapter. He was a Registered Professional Engineer in West Virginia. He was a member of Johnson Memorial Methodist Episcopal Church, in Huntington.

On March 26, 1890, he was married to Willia Lauck, who survives him. He is also survived by a son, Russell L. Hansford, of Marmet, W. Va., and a sister, Mrs. Philip Doddridge, of Berea, Ohio.

Mr. Hansford was elected a Member of the American Society of Civil Engineers on January 14, 1924.

FREDERICK NATHANIEL HATCH, M. Am. Soc. C. E.[1]

DIED NOVEMBER 13, 1934

Frederick Nathaniel Hatch was born in Chartiers Borough, Pa., on June 12, 1885, the son of the late Frederick Thomas Hatch, M. Am. Soc. C. E., and Alice Gertrude (Hill) Hatch.

After completing the High School course, in Logansport, Ind., he entered Rose Polytechnic Institute, at Terre Haute, Ind. By taking extra subjects during the first year and passing some of the first year's work by examination, he was enabled to complete the four-year course in Civil Engineering in three years and was graduated in 1906 with the degree of Bachelor of Science in Civil Engineering. Five years later, he received the degree of Civil Engineer from the Institute.

Mr. Hatch's father was for years Chief Engineer of the Pennsylvania Lines West of Pittsburgh, and it was quite natural, therefore, that the son should follow in his footsteps. Prior to his graduation in 1906, he had acquired about a year's experience in railroad engineering work, and his engagements for several years thereafter were on projects akin to railroading.

From July, 1906, to February, 1907, Mr. Hatch was Rodman and Transitman with the San Pedro, Los Angeles, and Salt Lake Railroad Company, at Salt Lake City, Utah, and from February to August, 1907, he was Field Engineer and Assistant to the Superintendent of Construction on a large concentrating works for the Steptoe Valley Smelting and Mining Company, at McGill, Nev. Although the pioneer days were supposed to have vanished before the advance of civilization, nevertheless in this desert country, far from human habitations, an occasional "bad man" loaded with bad whiskey could still produce thrills for a young engineer.

Later, he was Engineer on Maintenance of Way and Grade Reduction Projects of several other railroad companies until 1910, when he took a responsible position with Westinghouse, Church, Kerr, and Company (later, Dwight P. Robinson and Company) on the supervision of design and construction of industrial plants, railway locomotive terminals, shops, etc. Prior to the entrance of the United States in the World War, this firm constructed a number of plants for the production of munitions for the Allies.

During the World War, Mr. Hatch served with the American Expeditionary Force in France, as Captain of Engineers, first with the 312th Engineers at Camp Pike, Arkansas, and, later, with the 35th Engineers at Camp Grant, Illinois, and at La Rochelle, near Bordeaux, in France. The 35th Engineers was a shop regiment, recruited to build American freight cars. Although Captain Hatch greatly preferred to be at the front, he served his country faithfully far back in the interior, where his previous military training and experience were especially valuable to his regiment.

---

[1] Memoir prepared by James W. Skelly, M. Am. Soc. C. E.

Following his discharge from the Army in August, 1919, he was promoted successively to Major and Lieutenant Colonel, in the Engineer Reserve. After the war, he was employed in the office of the Building Commissioner of the City of St. Louis, Mo., until 1927, after which he was engaged as Construction Engineer with the Southwestern Bell Telephone Company until his death.

Colonel Hatch, as he was later known to his associates, gave much time and attention to military pursuits. He was President of the St. Louis Chapters of the Society of American Military Engineers, the Military Order of the World War, and the Reserve Officers Association. He was President of the Missouri Department of the Association in 1930. He was alert, well informed, and was considered an excellent engineer and soldier. He was positive, both in speech and action, and his writings show clarity and breadth of thought.

Colonel Hatch leaves a stepmother, Mrs. Nola P. Hatch; a sister, Alice K. Hatch; and a brother, William S. Hatch. He was never married. A side light on the kindly nature of a man who may have appeared to be cold and distant, even to his friends, is gained from the instance that on the death of his father, in 1920, he gave up his position in New York City and came to St. Louis that he might care for his stepmother, and this devotion continued to the end of his life.

In 1933, he suffered a severe attack of pneumonia, from which after several months he seemed to recover; but early in 1934, other serious maladies, diagnosed as abscesses of the brain and liver, made their appearance, and after a long battle, including several operations, he finally succumbed on November 13, 1934.

Colonel Hatch was elected a Junior of the American Society of Civil Engineers on June 4, 1907; an Associate Member, on February 4, 1913; and a Member on April 26, 1921.

DAVID CHRISTIAAN HENNY, M. Am. Soc. C. E.[1]

DIED JULY 14, 1935

A board of consulting engineers had been called to one of the large projects of the United States Bureau of Reclamation for the consideration of some of the important engineering phases of the project. They had been in session several days—days of trying discussion on points for which no precedents existed—days of give and take, for a report, unanimous if at all possible, must be made. All were men of ripe experience, technically trained; all with at least one, and some with several, scholastic degrees. The final *piece de resistance* hinged about certain phraseology in the report, and the one who had prolonged the discussion with righteous tenacity finally surrendered with, "If you want to know English correctly you've got to get it from a Hollander who couldn't talk a word of it when he came to this country." This, of course, was an exaggeration as Mr. Henny had studied English in college before he came to the United States in 1884.

---

[1] Memoir prepared by J. C. Stevens and J. L. Savage, Members, Am. Soc. C. E.

David Christiaan Henny was born at Arnheim, The Netherlands, on November 15, 1860, and was proud of his Dutch ancestry. His parents were David and Bernedina (Lorentz) Henny, his mother having been a cousin of the famous physicist, H. A. Lorentz.

He was educated at the Polytechnic School, at Delft, Holland, and was graduated with the degree of Civil Engineer in 1881. He had kept contact with his native country by membership in the Royal Institute of Engineers and by occasional visits there during the later years of his life.

Mr. Henny first came into national prominence in the early Nineties in connection with the manufacture of wood stave pipe. He served as General Manager and Chief Engineer of the Excelsior Wooden Pipe Company for ten years, and then for three years as General Manager of the Redwood Manufacturers Company, both of San Francisco, Calif.

Fresh from successful achievements in the redwood field he was taken into the organization of the United States Reclamation Service in February, 1905, and served as Supervising Engineer for the Pacific Division for four years, whereupon he was made Consulting Engineer for the same organization on intermittent service, available on call. The remainder of his life was devoted to private practice as a Consulting Engineer, in which capacity he maintained an office in Portland, Ore., from February, 1909, until his death.

Mr. Henny served as a member of a great many boards of Consulting Engineers for both governmental and private agencies in the United States and abroad on land reclamation, power, flood control, and allied problems. He was an authority on the design and construction of dams and there is scarcely an important dam in the West that has not been made safer and more serviceable as a result of his studies and advisory services. He was an indefatigable worker and no task was put off. Things were done now. Procrastination was not in his dictionary, which perhaps is the secret of his great capacity for accomplishment.

Two tasks will keep his memory ever green in the annals of engineering. One is his paper on "Stability of Straight Concrete Gravity Dams",[2] for which the Norman Medal was awarded to him posthumously by the Society, at the Annual Meeting on January 15, 1936, his son, Arnold L. Henny, Assoc. M. Am. Soc. C. E., being present to receive it. The other is the invention of the Henny Shear Joint, a special joint between the up-stream and down-stream faces of concrete blocks used in the construction of massive concrete dams. It was designed while he was on the Board of Consulting Engineers for the Boulder Dam. This shear joint is of such great importance that in order to keep it from being exploited he secured a patent on it and immediately gave the U. S. Bureau of Reclamation royalty-free use of his patent rights. Boulder Dam was the first in which the Henny shear joint was used, but it is being incorporated in the design of the Grand Coulee Dam and doubtless will be used on future massive concrete dams, particularly those in which the load is largely taken by cantilever action, as in the high, straight gravity type.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1041.

Mr. Henny was small in stature but of impressive dignity, and yet could relax on appropriate occasions into a delightful banter of sparkling wit and pertinent anecdote. An Engineering Board was examining the site of the Owyhee Dam in Eastern Oregon. After a "boiling" hot day in July, climbing over the still hotter rocks, the party found themselves at the water's edge. Mr. Henny began tugging at his shirt with, "We've examined everything else about this dam site except the water—let's go in swimming—and the last one in's a sissy." And they all did—raw.

At the entrance of the United States into the World War Mr. Henny offered his services to go over seas or serve elsewhere in any capacity in which he could be useful. His letter offering his services closed with the remark that he "would never be able to do enough for a country that had done so much for him." The reply he received was splendid and to the effect that such loyalty were better exercised in his chosen field at home than anywhere else, that there were plenty of younger men to do the fighting.

Oregon State College honored itself and him by conferring upon him a degree of Doctor of Engineering in 1933, and in the same year he was made an Honorary Member of the Royal Institute of Engineers of Holland.

Mr. Henny was most happily married in 1893, at San Francisco, to Julia Antoinette Hermanie Watzel-Brown. To them were born four children: David—who died in his senior year in college at Madison, Wis.; Frances Bernedina, George Christiaan, and Arnold Lorentz. Mr. and Mrs. Henny were great pals. She accompanied him on nearly all his trips whether in or out of the United States, and was probably the best known woman in civil engineering circles in the country. When she died on May 26, 1935, he died also, although he continued to walk around about his business, outwardly smiling and genial as usual, for two months longer.

The *Oregon Journal*, of July 16, 1935, paid a most worthy tribute to his memory:

> "D. C. Henny saw this vision of a greater Oregon. He saw Oregon like the Holland of his birth, fertile in its gardens and fields, and related to the world in trade. Yet, he saw it as Oregon alone can be, in the bold beauty of its mountains and shore and in the promise of its future.
>
> "So D. C. Henny worked with rivers and the land as a weaver would work with threads, weaving a bright and rich pattern of opportunity for to-day and for the generations that are to come.
>
> "In his recent leadership as Chairman of the Oregon State Planning Board, Mr. Henny had reached the climax of a life distinguished internationally as a hydraulic and reclamation engineer. For what many paid him large fees as a consultant, he gave without price to Oregon. Into the decisions and plans of Boulder Dam, Grand Coulee, and Bonneville, to mention only a few, went his penetrating wisdom. And he was Oregon's Commissioner in the Pacific Northwest Regional Planning Commission."

He was a member of the Committee of Engineering Foundation on Arch Dam Investigation and took an active part in supervising the construction and experimental measurements at the Stevenson Creek Test Dam, near Fresno, Calif., the results of which were published by the Society.[8] He was also Chairman of the Special Committee on Irrigation Hydraulics of the Society during the ten years of its existence.

Mr. Henny was elected a Member of the American Society of Civil Engineers on September 7, 1887. He served a term as Director for the 12th District beginning in 1920, and a term as Vice-President from Zone IV beginning in 1932.

VIVION ROSE IRVINE, M. Am. Soc. C. E.[1]

Died December 16, 1933

Vivion Rose Irvine, the son of Hugh Rose and Mollie (Vivion) Irvine, was born in Dallas, Tex., on April 4, 1885. He was a descendant of that William de Irvine who married a daughter of Robert the Bruce of Scotland. The Irvine family came to America in the early part of the Eighteenth Century and settled first in Pennsylvania and then moved on to the Valley of Virginia. It furnished soldiers to Washington for service in the Indian Wars and in the Revolution. Descendants moved on into Tennessee and eventually settled in Texas when that region was a Republic.

Mr. Irvine's primary schooling was obtained at public and private schools in Texas; at Bingham Military Academy, Asheville, N. C.; and at the Lawrenceville School, Lawrenceville, N. J.; later, he attended the University of Texas, at Dallas.

After leaving the University of Texas in 1906, he entered the service of the Southern Pacific Lines as Rodman on a locating party. He was soon promoted to the position of Instrumentman and, later, to that of Assistant Engineer on Construction. For two years, 1908 and 1909, he was in private practice at Marshall, Tex., engaged in general engineering work, but in 1910 he was back in railroad work where he was to remain until 1917. During this seven-year period he served as Locating Engineer on the New Iberia and Northern Railroad; as Assistant Engineer with the Florida East Coast Railroad Company, on maintenance of way and on the construction of its Kissimee Valley Branch; and, finally, with the Texas and Pacific Railroad Company as Assistant Engineer on Maintenance of Way and Valuation.

From May, 1917, to October, 1919, he was in the Army. Mr. Irvine had applied for a commission in the Reserve Corps, United States Army, in 1916; he was commissioned a Captain, Engineer Section, Officers Reserve Corps, on February 23, 1917, six weeks before the United States entered the World War, and was ordered to report to the Citizens Training Camp, at Leon Springs,

---

[8] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3.

[1] Memoir prepared by L. M. Gray, M. Am. Soc. C. E.

Tex.; he was transferred on May 16, 1917, to the 7th Reserve Engineers (later, designated the 17th Railway Engineers), and was relieved from active duty on May 19, 1917. He was re-assigned to active duty on September 2, 1917, and ordered to report to the Engineer Training Camp, at Fort Leavenworth, Kansas; he was transferred on December 10, 1917, to Company A, 35th Engineers; was relieved from duty with the 35th Engineers and ordered to Hoboken, N. J., on January 22, 1918; sailed from the United States for overseas service on January 31, 1918, on the S. S. *Adriatic*; was assigned to the 116th Engineers; was transferred, on March 3, 1918, to the 14th Engineers and assigned on June 13, 1918, as Commanding Officer, Company A, 14th Engineers. He participated with his organization in the Somme Defensive and the Aisne-Marne and Oise-Marne Offensives; was relieved from duty with the 14th Engineers on September 27, 1918, and returned to the United States, October 10, 1918, on the S. S. *Agamemnon*. He was ordered to report to the Commanding Officer, at Camp A. A. Humphreys, Virginia, and was assigned to duty with the 2d Engineer Training Regiment, on October 21, 1918. He was transferred, on February 25, 1919, to the office of the Chief of Engineers, at Washington, D. C., and was honorably discharged on October 13, 1919, at Washington, with the rank of Captain, Engineers, United States Army.

While on duty in the office of the Chief of Engineers, Captain Irvine revised and rewrote the Manual on Light and Standard-Gauge Railroads as a textbook for Army instruction. After his discharge from the Army he was appointed Major, Engineer Section, Officers Reserve Corps, on December 12, 1919; he accepted on December 24, 1919; and was re-appointed in the same rank on December 12, 1924, but declined the appointment.

From October, 1919 to April, 1920, Major Irvine served with the Department of State in charge of the selection of railroad personnel for service with the Russian Railway Service Corps in Siberia; from May, 1920, to June, 1921, he was Supervising Engineer with the Quartermaster Corps, U. S. Army, in charge of the construction of water-works, buildings, and sewers at Camp Bennings, Georgia, a $1 250 000 project.

In July, 1921, he accepted an assignment to go to Colombia, South America, as Representative of the Seldon Breck Construction Company, of St. Louis, Mo., and thereafter remained in that country continuously until 1932. He was made Vice-President of the Breck-Parrish Engineering Corporation (incorporated September, 1921, under the laws of Colombia, with headquarters at Barranquilla) and had charge of all the engineering and construction undertaken by that Company, including the design and construction of a 100-bed hospital, a reinforced concrete dam, water-works system for Barranquilla, the development of an extensive new residential addition to the city, the paving of the down-town section, and other work in connection with the modernization of this city of 150 000 inhabitants.

The complete transformation of this sleepy, tropical city, with unpaved streets, inadequate water and sanitary facilities, into a thoroughly modern municipality with well paved streets, a plentiful supply of pure water, adequate sewers, and ample residence sub-divisions, was affected in the 10-yr period from 1921 to 1931. Most of this work was initiated by Mr. Karl C. Parrish, and the greater part of the construction work was done by his Company of which Major Irvine was Chief Engineer. In 1925, the Breck-Parrish Company became associated with Winston Brothers, of Minneapolis, Minn., in the construction of the Antioquia Railroad to the Cauca River and Major Irvine went up country to assist on this work. He was associated with this project, which involved some of the heaviest construction in the Andes, until its completion. In 1929, he went to Cali, to become Manager of an urbanization project in that city, and was there until 1932 when the condition of his health necessitated his return to the United States. In the fall of 1933, he accepted a position as Engineer Inspector with the Public Works Administration, and was assigned to Dallas, where he died shortly after his arrival.

In Colombia, where Major Irvine lived for eleven years and where his most important work was done, he was one of the best known of foreigners; speaking Spanish fluently he was as popular with the Colombians as with the Anglo-Americans. He was an engineer of exceptional ability, and in addition to his engineering qualifications he possessed the human qualities that endeared him to his associates and friends. He had the happy faculty of meeting people and of enjoying social intercourse; it is doubtful whether anything he ever did gave him greater pleasure than the laying out and building of the nine-hole golf course for the Barranquilla Country Club. Whenever distinguished Americans visited Colombia, Major Irvine was invariably selected to head the Committee appointed to look after their entertainment. In a country where entertaining is a fine art, he was the perfect host. Major Irvine's death is a loss to the Engineering Profession, and he is mourned by a host of friends.

He was a Mason, a Shriner, and a Knight Templar; a member of the Anglo-American and Country Clubs of Barranquilla, Colombia, and of the Union and Campestra Clubs of Medellin, Colombia.

He was married on June 10, 1911, in St. Augustine, Fla., to Frances Elizabeth Ransom, who survives him; he also left a daughter, Mary Delia Irvine.

Major Irvine was elected a Member of the American Society of Civil Engineers on May 28, 1923.

EDWARD CLARENCE JORDAN, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 15, 1935

Edward Clarence Jordan was born in Westbrook, Me., on March 17, 1846, the son of Samuel and Eunice Q. (Seal) Jordan. His father was a prominent citizen of Westbrook and, at one time, was Postmaster of Portland, Me.

After receiving his early education in the public schools and at Westbrook Seminary, Mr. Jordan entered the office of Anderson and Bonnell, in Portland, to study for an engineering career. One of the partners, Mr. John Anderson, was a prominent Railroad Engineer and, at one time, Railroad Commissioner of Maine. Two years later, Mr. Jordan entered Union College, at Schenectady, N. Y., where he studied under Professor W. M. Gillespie who at that time was conceded to be one of the leading Engineers in the United States. Mr. Jordan was graduated from Union College in 1868, with the degree of Bachelor of Science in Civil Engineering. While at college he was elected to Kappa Alpha Fraternity.

---

[1] Memoir prepared by Henry I. Jordan, Esq., Portland, Me.

Immediately after his graduation Mr. Jordan went West to enter the employ of the Central Pacific Railroad Company in its early construction across the country; it was the first railroad line to connect the Atlantic and Pacific Oceans. His first position was that of Leveler on location, the work starting from Salt Lake City, Utah, westward, and from California, eastward, to a meeting point. He soon became Transitman and, later, in 1869 and 1870, Assistant Engineer on location and construction with the Company, in California, Utah, and Nevada, and had the good fortune to be in charge of the Division where the rails met—an occasion for an imposing ceremony. The last tie laid was of highly polished California laurel wood with a silver inscription. The last railroad spike was of solid gold, and a silver hammer was used to connect the telegraph wires. When the President of the Railroad Company struck the wire a corresponding click was heard all over the United States, announcing that the railroad from the Atlantic to the Pacific was finished.

After this interesting experience, Mr. Jordan became Locating and Resident Construction Engineer with the Northern Pacific Railroad Company in Minnesota, North Dakota, and Montana, from 1870 to 1872, when he returned to Portland, Me. In 1873 he opened an office for general engineering practice in Portland, specializing largely in hydraulics. One of his first experiences was on harbor work for the Federal Government.

He designed and constructed a sewerage system for the Town of Old Orchard, Me., in 1883 and 1884. In 1891 and 1892 he laid out and supervised the construction of the Maine Mile Track, called Rigby, at that time considered to be one of the best race tracks in the country. He designed and constructed the dam at North Gorham, Me., for the Portland Electric Light Company, from 1899 to 1901, and the dam at Mallison Falls, at Windham, Me., in 1905, for the Robinson Woolen Mills. He also designed and installed a water supply system for the Hebron Sanatorium, in 1909. At the famous Poland Springs, owned by Hiram Ricker and Sons, by whom Mr. Jordan was employed for all the firm's important projects, he laid out the sewerage system, water supply system, much of the road system, a private railroad, and a golf course. He had to do with many other hydraulic and sanitary engineering projects in his long practice of more than sixty-two years.

However, the largest proportion of Mr. Jordan's practice was in municipal and real estate surveys, many of which were contested boundary line cases, and his vast knowledge of real estate law enabled him to satisfy and settle many such disputes without recourse to the Law Courts. He was known to remark many times that it took more research, study, and judgment to settle such difficult cases properly than it did to design a dam. A quotation from a newspaper refers to him as follows:

> "Mr. Jordan has a marvelous memory for facts and figures, and he knows the history of this section as probably no other man does for the reason that he is the oldest engineer now in service, and has had occasion to survey and map most of this country during his experience, hereby actually working out by his own hands much of the data that others have to trust to records to find."

While abroad in 1881, and again in 1892, to inspect and study sanitary conditions in European cities, Mr. Jordan learned much that was helpful to him in his professional career. It was while he was in Europe the second time that he was appointed City Engineer of Portland, much against his will. He was prevailed upon to accept the office, however, and during his tenancy brought about many needed reforms. He made surveys and gave expert testimony in Court proceedings on several flowage cases incidental to the raising of dams.

For many years, he was the Engineering Member of the State Board of Health and, at one time, served as President of the Board. He was a member, until it ceased to exist, of the Maine State Water Storage Board created in 1909 to facilitate the building of reservoirs. He was also a member of the Commission for the Improvement of Back Cove which resulted in the construction of Baxter Boulevard; a member of the American Public Health Association; President for some years of the Portland Fraternity, a local benevolent association; a Charter Member of the Maine Association of Engineers; and a member of the Portland Civic Club, the Cumberland Club, the Portland Country Club, and the Portland Economic Club. He was also a member of the State Commission appointed to investigate and report on Portland Harbor. In 1896, he was a Delegate to Indianapolis, Ind., in the Palmer and Buckner campaign.

During the World War Mr. Jordan was appointed an Associate Member of the Naval Consulting Board by the Secretary of the Navy, the Hon. Josephus Daniels, and was Chairman for the State of Maine of the Board arranging for Organized Industrial Preparedness.

Mr. Jordan was a man who took a vital interest in all civic and State improvements, and was a respected and constant writer to the newspapers in regard to them. That he spared neither time, strength, nor money to fight for a cause which seemed right to him, was clearly evidenced by his flying trip home to Portland from Ormond, Fla., where he had gone for his usual winter vacation and golf, to oppose a proposition of the railroad to build a new terminal within the limits of the City of Portland, which, had it been allowed, would have created an appalling smoke nuisance and real estate damage to one of that city's most promising residential sections.

Mr. Jordan was a faithful attendant at the First Parish Unitarian Church to which he gave freely of his time and professional skill as well as his money. Thoroughness in research was the means of discovering for his Church the fact that its Trustees could justly claim a few feet of land in the rear of their lot, about which they did not know, but which they needed very much indeed for an addition to their Parish House.

No biography of this Engineer would be at all complete without reference to his very wide knowledge and appreciation of the best in literature. His books were his companions, especially so after the death of his wife. His ability to quote from so many standard works was an accomplishment in itself. He was outstanding as a high type of gentleman, scholar, and engineer.

He was married to Eliza Payson Thomas, in 1874, who died two years later. In 1882, he was married to Marcia Dow Bradbury, who died in 1923. He is survived only by his nephews and their families.

Mr. Jordan was elected a Member of the American Society of Civil Engineers on May 7, 1890.

IRVING PATTERSON KANE, M. Am. Soc. C. E.[1]

DIED NOVEMBER 20, 1935

Irving Patterson Kane was born in Gittings, Md., on January 2, 1886, the son of James G. Kane and Leonore (Patterson) Kane. His early life was spent in Gittings, a suburb of Baltimore, Md. He attended the public schools of Baltimore County and, in 1903, entered St. John's College, at Annapolis, Md., from which he was graduated in 1907, with the degree of Bachelor of Science. He then entered the Massachusetts Institute of Technology, at Boston, Mass., and was graduated in 1910 with the degree of Bachelor of Science in Sanitary Engineering.

After leaving the Massachusetts Institute of Technology, Mr. Kane was employed for a short time with the Baltimore and Ohio Railroad Company and the Lehigh Valley Railroad Company. In May, 1912, he entered the service of the Sewerage Commission of the City of Baltimore and was engaged until February, 1915, on designs, estimates, and specifications, in particular, for intercepting sewer work in Baltimore. From February to December, 1915, he served as Assistant District Engineer on the International Joint Commission under Professor Earl B. Phelps, making preliminary layouts, with cost estimates, for intercepting sewerage systems for Detroit, Mich., and for other cities and towns on the Detroit and St. Clair Rivers, as well as treatment-plant studies. This work was done in connection with the studies of remedies of the pollution of boundary waters, and the results of the investigation were published in the report made by Professor Phelps to the International Joint Commission.

---

[1] Memoir prepared by Langdon Pearse and Leslie C. Whittemore, Members, Am. Soc. C. E.

In 1916 and 1917, Mr. Kane served as Assistant Engineer with the Seaboard Air Line Railroad Company, and then with the Western Maryland Railroad Company. In May, 1917, he entered the United States Army, serving as Captain and then as Major and Commanding Officer, Company A, 305th Engineers, and also, later, with the 45th Engineers, for fourteen months in France. He was mustered out in August, 1919.

From November, 1919, continuously until the time of his death, he was employed first as Assistant Engineer and then as Engineer of Treatment Plant Design with The Sanitary District of Chicago, Chicago, Ill., the major part of the time being in immediate charge of design and plans of treatment plants, in particular, the Calumet, North Side, West Side, and Southwest plants, as well as the Northbrook, Glenview, and Morton Grove plants, exclusive of electrical, mechanical, and architectural work. In this connection, Mr. Kane was also interested in the design of several intercepting sewers. At the time of the litigation between the Lake States and the hearings before the Master, the Hon. Charles Evans Hughes, Mr. Kane was in charge of preparing general studies and estimates for the entire sewage treatment program of the Sanitary District, and also with plans and estimates for the Engineering Board of Review. He was active in developing various special features of the plants, in particular, a machine for stripping sludge on a large scale from air-drying beds. A new type of bed was developed, in units 80 ft wide and 1 000 ft long.

Mr. Kane was not a writer, but was intensely interested in the details of design and the development of sound data. His chief interest was in his work, in which he was very thorough and painstaking. One of his principal hobbies was financial research and in this field he took a lively interest in economics and various current problems. He had a keen mind and thought problems through with good judgment.

Never having married, and having lived with his bachelor brother, in Chicago, during the last fifteen years of his life, Mr. Kane took a deep interest in his mother's welfare, spending his vacations at the family estate at Gittings, near Baltimore. Although quiet and reserved, and not socially inclined, he was well liked by his associates. He was always interested in the outside activities of the younger men in the office, although not actively participating in them.

During the last eight years of his life, Mr. Kane suffered from a very serious eye ailment which, at times, threatened to destroy his sight. Notwithstanding this affliction, he applied himself energetically and patiently to his work and few, even of his most intimate associates, knew the extent of the handicap under which he was laboring. His general health began to fail during 1935, and on October 31, he applied for leave of absence and entered the Presbyterian Hospital in order to recuperate and endeavor to restore his health. Unfortunately, it proved too late. He died very suddenly on the evening of November 20, 1935.

Mr. Kane was elected an Associate Member of the American Society of Civil Engineers on December 6, 1915, and a Member on December 3, 1928.

ERNEST AVERY LAMB, M. Am. Soc. C. E.[1]

DIED FEBRUARY 1, 1935

Ernest Avery Lamb was born in Hastings, N. Y., on December 6, 1865, the son of Lucian B. and Eliza Ann (Caulkins) Lamb. He received his preparatory school education at Mexico Academy, Mexico, N. Y., after which he taught in the public schools for several years. In 1889, Mr. Lamb entered Union College, at Schenectady, N. Y., and was graduated in 1893, with the degree of Civil Engineer.

He entered the service of the State of New York as Rodman in September, 1894, and was assigned to the Middle Division Office of the State Engineer's Department, at Syracuse, N. Y., where he was employed on the improvement of Madison County canal feeders, the re-building of three locks on the Black River Canal, preliminary surveys and estimates for special canal work, and construction work at Seneca Lake Outlet. In 1896, Mr. Lamb was promoted to the grade of Leveler and was engaged principally on the improvement of the Erie Canal, known as "The Nine Million."

He left the service of the State in May, 1898, and until May, 1900, was employed as Engineer for a contractor on the construction of the Albany and Southern Railway (third-rail electric). This work involved, among other features, a masonry dam, a long viaduct, and two steel penstocks $\frac{3}{4}$ mile in length.

Mr. Lamb then returned to State employment at Albany, N. Y., and was engaged in making preliminary surveys and estimates for the proposed Barge Canal Improvement. In January, 1901, he went to Pittsburgh, Pa., where he was employed for eighteen months by the American Bridge Company on structural work. He then accepted a position with W. G. Wilkins Company, Engineers and Architects, as Superintendent and Engineer on plant construction for the W. W. Lawrence Company, Paint Manufacturers, in Pittsburgh.

In April, 1903, Mr. Lamb returned to the New York State service as Assistant Engineer. In June, 1906, he was appointed Resident Engineer and, for the next three years, was employed principally on highway work. In August, 1909, he took charge of the Mohawk River Residency which included fifty-four miles of Barge Canal construction. From 1915 to 1919, he was in charge of Barge Canal Residency No. 4, covering the territory between Schenectady and the Oneida County Line, comprising about fifteen construction contracts.

In 1919, Mr. Lamb was appointed Engineer-Secretary of the New York-Pennsylvania Joint Interstate Bridge Commission, with headquarters in Albany, a position which he held at the time of his death.

On November 29, 1894, he was married to Margaret M. Boylon, of Worcester, N. Y. Mrs. Lamb died in October, 1919. On December 6, 1922, Mr.

---

[1] Memoir prepared by Charles S. Sterling, M. Am. Soc. C. E.

Lamb was married to Kathryn McKay Gilbert, of Albany, who survives him, with three children by his first marriage: Marion E., Mildred A., and Joseph M. Lamb. There is also one granddaughter, Shirley E. Lamb.

Mr. Lamb was a member of the Madison Avenue Reformed Church, of Albany, Ancient City Lodge No. 452, F. and A. M., and the Albany Sovereign Consistory. He was also a member of the National Geographic Society, the National Society of Professional Engineers, and the Berlin Mountains Fish and Game Club.

He had been in failing health for some time prior to his death. He was able to attend to business, however, until late in November, 1934, and died rather suddenly at his home in Albany, on February 1, 1935.

Ernest A. Lamb was a quiet, unassuming Christian gentleman. He was kind and sympathetic, and interested in people whose pathways were beset with difficulties and troubles. His passing marks the end of a life of service. He is missed and mourned by his circle of friends.

Mr. Lamb was elected an Associate Member of the American Society of Civil Engineers on September 7, 1904, and a Member on September 9, 1919.

WILLIAM CASWELL SMITH LEMEN, M. Am. Soc. C. E.[1]

DIED APRIL 7, 1935

William Caswell Smith Lemen was born at Collinsville, Ill., on December 19, 1873. He was the son of Clarence J. and Sarah Catherine (Smith) Lemen, and his forebears were pioneers in the State of Illinois. He first attended Union Academy, at Morganfield, Ky., and on graduation from that school he entered the College of Engineering, University of Illinois, at Urbana, Ill. There, he received the degree of Bachelor of Science on completing the course in Civil Engineering in 1895.

Mr. Lemen began his engineering career as a Recorder and Instrumentman for the Mississippi River Commission, with headquarters at St. Louis, Mo. For the first year, he was a member of the Drafting Department of the Commission, and for the next three years, was engaged in field and office work. From July, 1899, until August, 1900, he was a Topographer in the United States Engineer Office, at St. Paul, Minn. Here, he was engaged in the work of surveying the head-waters of the Mississippi River.

Returning to St. Louis in August, 1900, he again joined the Mississippi River Commission as Gauge Inspector on the Lower Mississippi. From April, 1901, to November, 1902, he returned to his home State to act as City Engineer and Superintendent, of the Municipal Electric Light and Water-Works, at Paris, Ill. At Paris, he constructed street paving, sanitary sewers, and water mains, and installed a new pumping plant which represented a city investment of approximately $500 000. After this interesting experience in a new field, he again resumed work in the Mississippi Basin, this time as Chief of Party on a cadastral survey of the reservoirs of the head-waters of the Mississippi River.

---

[1] Memoir prepared by Col. Charles W. Weeks, U. S. Infantry, Fort Benning, Ga.

In the following year, however (November, 1903), Mr. Lemen entered the sphere of engineering activity that was to occupy the next fourteen years of his life. By transfer he became Junior Assistant Engineer to the Principal Assistant Engineer, U. S. Engineer Office, Savannah, Ga. In this position, he had charge of surveys and various construction works. In August, 1910, he became Assistant Engineer, and in April, 1912, Principal Assistant Engineer.

In this office, he had general charge of the supervision of all improvements in the District, and also had direct charge of the Savannah Harbor and Inside Waterway. His supervision also included repairs and construction of bank-protection works, training walls, stone jetties, and wharves, the design and construction of hydraulic dredges, and snagging and construction plants. He was also responsible for the monthly and annual reports and the proper expenditure of all appropriated public funds for his work, including one large special project on the Inland Waterway System, at Brunswick, Ga. He was also the author of numerous special reports.

In 1917, when the United States entered the World War, Principal Assistant Engineer Lemen became, on June 21, Captain Lemen, of the Corps of Engineers, U. S. Army. In July, 1918, he became a Major, and on October 24, a Lieutenant Colonel. During this period, also, he became the Officer in charge of the Kearny United States Engineer Depot, at Newark, N. J., and Depot Engineer and Assistant Storage Officer of the Port of New York, N. Y. He afterward prepared a paper on this work entitled "Construction and Reorganization of U. S. Engineer Supply Depot, Kearny, New Jersey."[3]

Honorably discharged as an emergency officer in October, 1919, he was again commissioned a Major in the Regular Army, Corps of Engineers, as of July, 1920.

Major Lemen's army career continued to be as full of interest as his previous years. From November, 1920, until September, 1922, he was United States District Engineer, at Jacksonville, Fla., for which position he was particularly fitted by his experience in the near-by Savannah District. From late in 1922, and during the ensuing year, Major Lemen attended the Engineer School at Fort Humphrey, Virginia. He then served from July, 1923, to April, 1925, as Engineer Supply Officer and Assistant Department Engineer, at Fort Hayes, Ohio.

Then followed a tour of foreign service, and with it a change from staff to command duty. For the year from April, 1925, to March, 1926, Major Lemen was Commanding Officer, 2d Battalion, 3d Engineers, at Schofield Barracks, Hawaii. His second and third years of foreign service, however, found him, first as United States District Engineer, at Honolulu, Hawaii, and Department Engineer, Hawaiian Department, and from September, 1926, to August, 1928, he devoted his entire time to the latter position.

---

[3] *Military Engineer*, May–June, 1930.

On leaving Hawaii, Major Lemen became Assistant Professor of Military Science and Tactics, Engineer Unit, Reserve Officers Training Corps, University of Illinois, Champaign-Urbana, Ill., his old school. Here, among familiar scenes, he continued active duty until 1932, when, after a sick leave of several months, he was retired with his war-time rank of Lieutenant-Colonel, on December 31, 1932. Lt. Col. Lemen spent the greater part of his remaining years at Interlachen, Fla. He died in that city on April 7, 1935.

He was married at Evansville, Ind., on December 19, 1896, to Olive Belle Jutton. He is survived by his widow and the following children: Catherine Neil Lemen (Mrs. A. B. Rowe), Wilhemina Lemen, and Orian Gregg Lemen.

During his career before the World War and as an officer in the Corps of Engineers, Colonel Lemen was always public-spirited, ever ready to lend his aid and to co-operate to the full in undertakings in which he could be of assistance. He was most agreeable socially and altogether a fine type of citizen. He was an ardent and proficient golfer, and both official and companionable contacts with him were always pleasurable. His home was always open to his friends.

He was a member of the American Association of Engineers, and the American Society of Military Engineers. He was a Royal Arch Mason, and Past Exalted Ruler of the Benevolent and Protective Order of Elks, and a member of the Presbyterian Church.

Colonel Lemen was elected an Associate Member of the American Society of Civil Engineers on July 10, 1907, and a Member, on March 14, 1916.

FREDERICK WILLIAM LOVELL, M. Am. Soc. C. E.[1]

DIED JULY 25, 1934

Frederick William Lovell was born at Bloomington, Ill., on January 26, 1872. His father, Thomas Lovell, whose birthplace was Swineshead, Bedfordshire, England, came to Canada as a young man and, later, migrated to Towanda in Central Illinois, where he met and married Mary Ellen Ricker. In 1883, the family moved to Iowa and, later, to California.

Frederick William Lovell was the second of five children born on the Towanda farm. He attended the primary schools at Towanda and Gibson, Ill., and at Humboldt, Iowa, and was graduated in 1891 from the Iowa City Academy. He studied Civil Engineering at the State University of Iowa, at Iowa City, Iowa, from which institution he was graduated in 1894, having completed the course in three years with high honors.

He spent the years from his graduation until 1898 as Draftsman with the firms of Purdy and Henderson, of Chicago, Ill.; Brown-Ketcham Iron Works, Indianapolis, Ind.; and the Elmira Bridge Company, Elmira, N. Y.

In 1898, Mr. Lovell began his connection with the McMyler Manufacturing Company, of Cleveland, Ohio, which, later, became the McMyler Interstate Company. For this Company he designed all structural work and had supervision of the details of such in the office. Typical of the work of the Company at this time was the building of twelve ore-conveying bridges, each 450 ft long, supported on two towers, for the Lorain Steel Company, and the construction of car-dumping machinery for the Wheeling and Lake Erie Railroad Company. From 1901 until 1922, Mr. Lovell served as Secretary, as Chief Engineer, and as Vice-President of the Company, with supervision of all engineering work, both structural and mechanical, covering a wide range of problems in the design of engines, machinery, steam plants, and electrical apparatus. Many patents in the United States and foreign countries covering improvements in coal and ore-handling machinery, such as car dumpers, locomotive cranes, bridge conveyors, buckets, etc., were issued to him. The outstanding developments in coal and ore-handling devices took place largely within his life time, and he made important contributions to them. The Company also designed and fabricated structural steel for bridges and buildings.

---

[1] Memoir prepared by E. W. Crellin, M. Am. Soc. C. E.

Throughout his professional career, Mr. Lovell was a conscientious and tireless worker. His persistence and success in solving unfamiliar technical problems were remarkable. A notable instance of his resourcefulness in time of great stress occurred during the World War, when without previous experience his Company made 8-in. shells for the British and American Governments and became the largest producer of such shells in the United States.

From 1922 until his death, Mr. Lovell was engaged in consulting practice, making a specialty of the design of car-dumping machinery and other appliances for the rapid and economical handling of coal, ore, and similar materials. As already has been intimated, he was a Mechanical Engineer as well as a Civil Engineer, and had from his long experience an intimate knowledge of the mechanical as well as of the structural and economic problems involved in the design of such machinery. He spent much of his time in travel in the United States, Alaska, Mexico, and South America, and in Europe. His wide experience in his own field and his discernment in the study of commercial and political backgrounds gave his observations great value for his friends and business associates.

Much of his enthusiasm, after the World War and during the depression, was given to assisting young people to obtain their education and training. For many of them Mr. Lovell made possible a college education and an artistic career. A special fondness for young people made him a kindly figure in private life, as his experiences and travels made him a dominating personality as an engineer and executive.

During his entire residence in the City of Greater Cleveland, he was a devoted member of the First Baptist Church. His gifts thereto were numerous, and he gave both of his time and his work, unstinted, during the erection of the new church building in 1929.

His death from heat prostration while traveling in Iowa came very suddenly during the severe summer of 1934. Hs is survived by his widow, Eva (Glass) Lovell, to whom he was married in 1899, and by one son, Wheeler Glass Lovell, a member of the Engineering Profession. He is also survived by his brothers, Walter Danville Lovell, M. Am. Soc. C. E., Robert Lovell, and Judson Lovell, and a sister, Lucy Lovell.

Mr. Lovell was elected a Member of the American Society of Civil Engineers on June 6, 1906.

IRA WELCH McCONNELL, M. Am. Soc. C. E.[1]

Died January 7, 1933

Ira Welch McConnell, the son of James Calvin and Cecilia (Welch) McConnell, was born on October 17, 1871, of a family of pioneers who settled in Shell City, Mo., soon after the Civil War. This country was then on the frontier. Mr. McConnell's mother, who is now (1935) in her ninety-seventh year and still enjoys an active life, has told and written of the many interesting experiences of the pioneer family of those days. His father, in addition to being a farmer, operated a general store in Butler, Mo. In his boyhood, Ira McConnell helped his father in the store and gained his preparatory school training at Butler Academy.

After several years in the United States Railway Mail Service as a Postal Clerk, Mr. McConnell had accumulated a fund which was to take him to college. He was then 22 years old. Shortly after he entered the College of Civil Engineering of Cornell University, at Ithaca, N. Y., in 1893, the bank in which his money was deposited failed. Having embarked on his college career he would not stop. From that point forward he earned his entire college expenses by doing odd jobs, and as the first General Manager of the Cornell Co-Operative Society, which was formed during his Junior year.

The traits of character which later made him eminent in his profession were soon recognized by all with whom he came in contact. In his quiet and effective way he became a leader, not only among the civil engineering students, but in his entire Class. Before his Senior year it was already a foregone conclusion that he would be selected as Chief Engineer of the Civil Engineering Survey, a recognition by his fellow students of his qualities as an organizer. His work in this connection was outstanding. Throughout his college course his scholastic standing was always good, and he was elected to membership in Tau Beta Pi and Sigma Xi during his last year in college.

A friend and classmate, Charles F. Hamilton, M. Am. Soc. C. E., has written of him:

> "As I review Mac's career at Cornell, there is most evident the splendid character and high qualities which in his after life brought him to the head of his chosen profession.
>
> "As a friend and classmate he was without an equal—kind, considerate, thoughtful, self-effacing, thoroughly dependable under all circumstances, gifted with an unusual brain, perfect poise, and splendid sense of values, always seeking and enjoying the higher and better things of life. To have

---

[1] Memoir prepared by George Schobinger, M. Am. Soc. C. E.

intimately known him and worked with him is one of the finest memories I treasure of my college days."

After his graduation from Cornell University in 1897 as a Civil Engineer, Mr. McConnell served as Instructor in that Department for two years. During these six years at Cornell he formed many of the friendships and associations which lasted throughout his life. These associations were extended to the under-classmen and students who felt his leadership and, later, became associated with him or had business relations with him in his engineering work. There is probably no Cornell graduate of the past forty years who was better known to Cornell men than Ira McConnell.

He left Cornell to become a Contractor's Superintendent. During the following three years, he served in that capacity in various parts of the United States. He then became Professor of Engineering at Missouri School of Mines, at Rolla, Mo. After one year in that institution, he embarked on his active business career, being then thirty-two years of age.

Mr. McConnell entered the United States Reclamation Service as Project Engineer in charge of the Gunnison Tunnel, one of the first large works of that Service, and, at the time, one of the longest and largest tunnels in the world. Within a few years he became a Supervising Engineer, having charge of the Central District including Colorado, Wyoming, South Dakota, Utah, and adjacent States. He remained in the U. S. Reclamation Service for a total of six years and then resigned in 1909 to become Chief Irrigation Engineer of the J. G. White and Company, which Company at that time was active in irrigation work. Louis C. Hill, M. Am. Soc. C. E., an associate during this period, writes as follows:

"I have known McConnell for about 25 years or more. He was an able organizer, and he had a sense of humor that carried him by, and everybody else with him, any kind of a disaster. He played the game on the dead square. His Uncompaghre tunnel was one of the most difficult tunnels to drive. * * * I think he was the ablest man we ever had in the Reclamation Service."

J. H. Quinton, M. Am. Soc. C. E., an associate in the U. S. Reclamation Service, says of him:

"I first met Mr. McConnell when he was 32 and I was 53 years old. He had been employed as assistant to the Engineer of the Uncompaghre Project of the U. S. Reclamation Service. He had just completed the field survey for a location of the Gunnison Tunnel, the main feature of that Project. I was then a Consulting Engineer in the Service, and * * * was allowed to select the engineer to be placed in charge of the construction. I selected McConnell, and my choice proved well founded.

"I early recognized his fitness for the position, and gave him a 'free rein'. He is entitled to all the credit for the engineering, and successful construction, of the Gunnison Tunnel—six miles long, and a most difficult piece of work. He was in charge of it from beginning to end, and it is a lasting monument to his ability in construction.

"* * * He had all the qualities that go to make a successful engineer: A good disposition, sound common sense, magnanimity, integrity, ambition to excel, and untiring energy in the discharge of his duty. He was a most lovable character, and his comparatively early death was a distinct loss to the engineering profession."

In 1910, Mr. McConnell became Vice-President and General Manager of the Idaho Irrigation Company, a private project. Shortly afterward he became Hydraulic Engineer for Stone and Webster Engineering Corporation. He remained with that Company for about five years, becoming its Chief Engineer in 1917. Mr. George O. Muhlfeld, an associate during this time, speaks of him as follows:

> "Mr. McConnell was highly skilled and broadly experienced on engineering and construction work, and in addition to an excellent business ability he possessed and utilized an unusual amount of common sense. He was painstaking and untiring in his work and he had the faculty of not only remaining unruffled even under the most exacting and turbulent conditions but of smoothing out difficult and strained situations. He was a man of sterling character and excellent personality, was eminently fair in all his dealings and loyal to his associates. Mr. McConnell was liked by all who knew him, and the news of his sudden death in Buenos Aires brought a keen sense of loss to the large group of individuals who were proud to be known as his friends."

In 1918, Mr. McConnell became General Manager for the American International Shipbuilding Corporation at the Hog Island Shipyard, Philadelphia, Pa. Few people can appreciate his accomplishment in that position. Industry in the United States had become almost chaotic as a result of the sudden expansion from European war orders and the disjointed control in the early days after the United States entered the World War. Hog Island was no better and no worse than others, but through his efforts it became a smoothly working production machine. If the war had continued, this organization would have been the largest production plant in the world, but the Armistice brought the work to a sudden stop.

Late in 1918, Mr. McConnell joined in the formation of Dwight P. Robinson & Company, Incorporated, as Senior Vice-President and Chief Engineer with headquarters in New York, N. Y. This association continued for about ten years, when the Company was merged with others to form United Engineers and Constructors, Incorporated. He continued as Senior Vice-President with this Company until 1932.

His activities as Executive Vice-President of Dwight P. Robinson & Company, Incorporated, cover the entire program of that Company for the 10-year period from 1919 to 1928. A careful and thorough organizer and leader of men, a diplomat *par excellence,* a highly gifted engineer, and, at the same time, an extremely practical and hard-headed construction man, he was also thoroughly versed in finance and in the negotiations which precede and make possible the development of large projects. A catalog of his activities during these ten years is beyond the scope of this memoir, but the cost of the work, for the conduct of which he was responsible during this period, amounted to more than $150 000 000.

From 1921 to 1924, Mr. McConnell handled the work done by Dwight P. Robinson & Company, Incorporated, for the Brazilian Government. A leading newspaper of Fortaleza, the capital of Ceara, Brazil, speaks of him as follows:

"From the time when Mr. McConnell first became active among us in 1922 in the preparatory work for construction of the great irrigation systems in the southern part of this State, Mr. McConnell became known as a great friend of Brazil, dedicating himself with great success to the study of our most important problem and becoming thoroughly acquainted with our economic situation. We consider his death a great and sad loss for Brazil, since in our opinion his co-operation would have been for us most useful and necessary in the ultimate solution of our most important problem. Few Americans could attain the high level which Mr. McConnell held with relation to the interests which join Brazil to North America. We convey through these lines our sympathy and condolences to Dwight P. Robinson & Company."

During this period he was also responsible for the construction of the United States Embassy in Rio de Janeiro. The Hon. Butler Wright, later Minister of the United States to Uruguay, was Commissioner of the United States on this work. Mr. Wright says of him:

"I welcome with appreciative gratitude the opportunity which you afford me to pay tribute to my good friend the late Ira W. McConnell, with whom it was my good fortune to be associated at the time of the construction of the permanent and temporary buildings erected by the Government of the United States in Rio de Janeiro at the time of the Brazilian Centennial Exposition—the former of which is now the American Embassy in that capital. Mr. McConnell was at that time engaged in superintending, on behalf of the firm of which he was so distinguished a member, the erection and completion of these buildings—which proved to be a particularly difficult and delicate task due to the fact that buildings intended for exposition purposes were ultimately to be transformed into the Embassy residence and office and, further, to countless irritating complications arising from changes in plan, adaptation to changing circumstances, and other annoyances which can only be fully appreciated by those who have had to contend with similar circumstances. In my capacity of a Commissioner of the United States, charged with oversight of the entire undertaking, individual and official co-operation and intimate personal friendship were the essential considerations for success.

"In the enjoyment and fruition of these relations I owe much to Mr. McConnell, for during our association from August, 1922, to March, 1923—or thereabouts—I found his wide experience, his integrity and honesty of thought and purpose, his cheery philosophy and his delightful sense of humor contributed in a most unusual degree toward the final success of an undertaking of which all those who participated therein may well be proud. In short, the association was an unusual and pleasurable experience for me, and from it grew a friendship in which I took great pride and pleasure."

During the four years (1928–1932), in which he was a resident in Buenos Aires, Argentine Republic, Mr. McConnell attained a unique position in that community. There was probably no other American who was so widely known and thoroughly admired on the entire East Coast of South America. During this period perhaps the major accomplishment was the development of the second and largest subway system in that city constructed for the Central Railroad and Terminal Company. This work seemed to be a natural outgrowth due to Mr. McConnell's early interest in foreign developments, in the course of which a number of buildings, as well as industrial and utility plants, were constructed in South America by Dwight P. Robinson & Company, Incorporated, under his direct supervision. His admirable organizing ability was never better shown than in his handling of foreign construction. This activity, however, kept him away for long periods from his associations in the United States.

When the subway was completed, Mr. McConnell was appointed Director and General Manager of the Central Railroad and Terminal Company of Buenos Aires. He occupied this position at the time of his death.

His associates in the Buenos Aires Central Railroad and Terminal Company prepared and engrossed on parchment, and sent to Mrs. McConnell, the following resolution expressing their admiration for him and their grief at his loss:

"In the City of Buenos Aires, on the 28th day of the month of January, 1933, the Board of Directors of the Company met under the Chairmanship of the President, Dr. Teofilo Lacroze. There being present Directors Louis A. Rocca, C. P. Billings, Graham Steel, Emilio A. Godoy, and F. O. Cartwright. The meeting was called to order at 17 o'clock.

"The President stated that it was the unanimous decision of the directors that this meeting be held for the exclusive purpose of rendering a tribute of gratitude, respect and affectionate remembrance to the late Mr. Ira W. McConnell, former director-general manager of the Company.

"The President stated that I. W. McConnell, a man of great capability and kindness, leaves a vacancy in the company difficult to fill, and in the hearts of his friends memories which will endure throughout their lives as pleasant remembrances of a great man and friend, who knew how to win the affection of all who had the privilege of association with him.

"These sincere sentiments caused the President to propose that the Board honor the memory of their late associate, Mr. Ira W. McConnell, by rising and rendering one minute of silent homage, have engraved on parchment a copy of the minutes of this special meeting, to be signed by all the Directors and sent to his wife and sons."

Charles W. Comstock, M. Am. Soc. C. E., a lifelong friend and associate, writes of Mr. McConnell as follows:

"The most outstanding trait of Mr. McConnell's character, the one that more than anything else made him universally loved and respected, was his innate and invariable sense of fairness. He was quick to grasp and to appreciate other views than his own and to give them full and sympathetic consideration. He did not consider it his duty nor was it ever his purpose to out-trade another in any negotiation. He aimed only to reach a conclusion which should be fair to all concerned.

"This attitude was not paraded for effect; it was instinctive—an integral part of his nature. It was evident at all times whether the matters under consideration were relatively trifling or of great moment.

"If one looks beyond Mr. McConnell's profound and extensive knowledge of technical engineering for some further explanation of his professional success, perhaps the most important element was his skill in building an organization. He did not expect to find men without faults. He was as quick to recognize their weak points as their strong ones, and he was a master hand at so placing them as to minimize the effects of their weaknesses while allowing full play to the exercise of their special abilities.

"He never emphasized his own part in any work. Always he aimed at success for the organization and if some mischance later gave credit for that success to an assistant he was never resentful."

H. G. Balcom, M. Am. Soc. C. E., a lifelong friend, says of him:

"I first met him in the fall of 1894 when we were sophomores in the College of Civil Engineering at Cornell University. He was then very jolly and care free and readily drew people to him and made them like him, in some cases almost to the point of idolizing him. Underneath his general exterior we all knew and admired his sound judgment. In school work, it always seemed to me that he was more interested in learning essentials than he was in high marks. It is small wonder that the Senior Class elected him Chief Engineer and that the faculty recommended him for Sigma Xi. Even in college he had a vivid and forceful way of expressing his ideas.

"After graduation I saw very little of him for a number of years. When he came east, * * * he called upon me. He was the same jolly fellow I knew in college, but I also saw he had developed into a hard-headed business man. He told me what his title was to be in his new position. I asked him how much salary that counted for. In his characteristic way he said 'Not a damn cent'.

"We were thrown most closely together at Hog Island during the War, and for several months he was my direct superior. In his painstaking and judicial way, he studied department after department and perfected a smooth-working organization. At last he was put in charge of 'shop design and production' which covered all engineering features of the ships and also the purchasing, inspecting and bringing the ship material to the yard. Here he perfected an organization that was a model of excellence, in spite of the fact that he was constantly subjected to the criticism of the Shipping Board. No man could have accomplished this who did not have a much higher regard for work well done than he did for holding his position. His whole career at Hog Island impressed me as that of an almost super-man. * * * The least and perhaps the most I can say is: 'He was a brilliant and an honest man, a genial companion and a loyal, helpful friend.'"

Perhaps no one was more intimate with Mr. McConnell in personal and engineering matters than John C. Hoyt, M. Am. Soc. C. E., who thus epitomizes his estimate of his lifelong friend:

"If I were to sum up the secret of Ira McConnell's success I would say that it was due to unusual native ability supplemented by a broad education obtained both through study in schools and by experience. With this he had the fullest wholeheartedness with which his frank and unassuming ways attracted people to him."

No more fitting summary of Mr. McConnell's philosophy toward life and his fellow man could be given than a few words which were included in his will as advice to his sons, John and Charles: "Honors to the unrighteous are empty. For him who pursues his duty in honor and fidelity there can be no failure."

On January 9, 1933, the *New York Herald-Tribune* printed on its editorial page an appreciation which in a few words gives a full and rounded appraisal of his qualities as an engineer and as a man:

"The death of Ira W. McConnell in Buenos Aires removes a figure known to few of his home-keeping fellow countrymen beyond the engineering fraternity. Though he built the long Gunnison Tunnel in Colorado and the large Pathfinder Reservoir in Wyoming, he had the engineer's dislike of publicity, and the sight of great waters diverted or impounded for the service of men was all he asked of fame. Like the Roman engineer who left his name on a single stone in the bridge of Alcantara, he was satisfied to leave the glory of his achievement to those for whom he worked.

"In South America, the field of his later activities, few Americans have been so well known or so honored. Not only were his consummate technical abilities recognized all along the east coast of the continent, but a rare personality that made him more than a highly skilled engineer won him the strong confidence of governments and laborers alike. For he was diplomat as well as engineer, and had an extraordinary facility for working with strange peoples without offending their susceptibilities. When he set up his camps in the drought-ridden lands of northeastern Brazil, which he was to turn into another Egypt by a series of cyclopean irrigation works, and sufficient workers failed to appear, he summoned the famous Padre Cicero, whose influence alone could move the minds of the people throughout the dry country of the sertão. It was through the friendship and understanding which engineer and priest instinctively felt for each other that he was able to marshal the army of workers necessary for the vast enterprise. That it finally failed of fruition and left the desert country strewn with uncompleted dams was no reflection on the masterly hand of McConnell or the loyalty of his devoted associates, but was due to the exhaustion of the inadequate funds * * *.

"Ten years ago, as a diversion from his larger undertakings he built the American Embassy building at Rio de Janeiro. The crowning achievement of his career was the completion last year of the Lacroze Subway in Buenos Aires, and when he died, a few days ago, it was in the harness as supervising director of the road which he had dug beneath the Argentine metropolis. The engineer, with the friendly twinkle in his shrewd eyes and the laugh that could disarm the suspicious reserve of high officials or the timid awe of a simple laborer, was in his way a more effective envoy of the best in his country than the generality of ambassadors hedged about by the formalities of protocol."

Mr. Dwight P. Robinson, who knew him intimately from 1908 until his untimely death, pays him this tribute:

"No words can adequately picture Ira Welch McConnell. One had to know him to realize his splendid worth. While even casual contact with him left a favorable impression, one had to be associated with him in the discharge of common responsibilities to attain a true measure of his fineness, of the crystal clearness and cleanness of his soul. He had in overflowing measure everything that his loving friends have attributed to him—courage, ability, winsomeness, integrity, selflessness—but away beyond those he had that something so rare that made him a man in God's likeness. To have been his partner and to have won his trust is an inspiration for all time."

Mr. McConnell is survived by his widow, Grace (Bowerman) McConnell, and his two sons, John and Charles.

Although he did not claim membership in any church, his religion was Christian in its highest sense and recognized the brotherhood of man; it was a religion broader in its concept and more far-reaching in its effect than that which is bound by creed and dogma.

He was a member of the following associations and clubs: Cornell Society of Engineers, New York; American Association of Engineers; Society of Marine Engineers and Naval Architects; Sigma Xi, Tau Beta Pi, Kappa Sigma; Cornell University Club, Engineers Club of New York, Uptown Club, and the American Club of Buenos Aires. He was also a member of the Masonic Fraternity and of the Benevolent and Protective Order of Elks.

Mr. McConnell was elected an Associate Member of the American Society of Civil Engineers on December 7, 1904, and a Member on September 3, 1913. He also served as a Director of the Society from 1921 to 1923.

LUIS MATAMOROS, M. Am. Soc. C. E.[1]

DIED JANUARY 18, 1934

Luis Matamoros was born in the little Town of Atenas, in the west central part of Costa Rica, Central America, on June 20, 1859. The oldest child of six and the only son of Juan Matamoros, Lobo, and his wife, Josefa Sandoval Rodriguez, he attended the graded school in Atenas and then went to San José, the Capital, for his High School work. Upon his graduation, he entered the Technical Institute at San José and so great were his talents in the profession he had decided to follow, that during his last two years as a student at the Institute, he was made Assistant Instructor in Mathematics and Physics. He was graduated with the degree of Bachelor of Arts and as a Land Surveyor.

Young Matamoros sought higher engineering knowledge and selected the Ecole d'Ingénieurs de Université de Lausanne, in Switzerland, as his Alma Mater, from which he was graduated with the degree of Civil Engineer on December 12, 1882. He returned to Costa Rica in 1883.

From 1883 to 1886, Mr. Matamoros was General Manager of the Pacific Railroad of Costa Rica, and in the latter year he was asked to act as Chief Engineer for Costa Rica on the Boundary Conference between Costa Rica and Nicaragua, on which work he remained until 1889. In this year he was made Director General of Public Works of Costa Rica. In this same year, he was sent to Washington, D. C., to advise the Costa Rican Legation on the question of the Nicaraguan Canal, which was then up for important discussion.

In 1893, while still Director of Public Works, Mr. Matamoros had one of the thrills that come once in a life time and which he recited to the writer as late as 1933. The Intercontinental Railroad Commission, of which the late Alexander J. Cassatt was President, had been created and field parties, aided by the United States Government and in charge of that incomparable locating engineer, the late William F. Shunk, were headed for South America from the United States, and, of course, they must pass throughout the length of Costa Rica from Nicaragua to Colombia (later the Republic of Panamá).

Mr. Matamoros lost no time in contacting Mr. Shunk and was as quickly rewarded by being placed in charge of a section of the work in Costa Rica. A genius in picking men and getting the best out of them with a few kind words, Mr. Shunk conferred on Mr. Matamoros this honor, which the latter loved to recall in his retirement and which unquestionably went with him, in great satisfaction, to the very end.

In an official report on the Intercontinental Survey which was printed in permanent book form by the United States Government, much credit is given to Luis Matamoros for the successful completion of the Costa Rican Section of this important undertaking.

---

[1] Memoir prepared by John K. Flick, M. Am. Soc. C. E.

Mr. Matamoros' tenure as Director General of Public Works continued until 1902, when he was elected to the National Congress of Costa Rica, which office he held for a four-year term.

Returning to active duty in his profession, he was Chief Engineer in charge of the construction of the Pacific Railroad, as well as Municipal Engineer for the Capital City, San José, from 1906 to 1910. Although he had served his country in the National Congress for a time he never neglected his private practice of civil engineering, which, during the more active years of his life, was of considerable scope.

During the ensuing four years, 1910 to 1914, the Boundary Commissioners again sought Mr. Matamoros' advice and engineering skill, this time in the parley between Costa Rica and the new Republic of Panamá. As Chief Engineer for his country he was called to the Legation in Washington on important missions, both pertaining to engineering and diplomacy in the interest of Costa Rica.

Having been compelled to spend much of his life away from his home and his family, Mr. Matamoros now decided to settle down in San José and devote more of his time to his growing private practice. Therefore, until 1921, he accepted no active engagement which would take him away from his loved ones for any length of time.

Again heeding the call of his country, Mr. Matamoros was appointed and accepted the post of Chief Engineer and Member for Costa Rica, of the International Commission for the location of the boundary line between Costa Rica and Panamá, in accordance with the award of the late Chief Justice White, of the United States Supreme Court. This assignment lasted nearly two years.

With advancing years, Mr. Matamoros wisely declined to consider any more offers calculated to overtax his faculties and retired to his home and study. His engineering library was the best in Costa Rica, and nothing pleased him more than to spend his days reading and chatting with a few callers. He loved to tell of the visit to San José of the late Leonard Metcalf, M. Am. Soc. C. E., for the purpose of investigating and reporting on the water supply of the Capital.

Mr. Matamoros was the author of the following pamphlets: "Memoir on the Figure of the Celestial Bodies" (First Prize at the Academy of Lausanne); "Theory of the Formation of the Mountains of the Globe"; and"Theory of Earthquakes"; as well as several pamphlets on Mathematics and Physics. He was a member of the Associacion Amicale des Ingenieurs, the Boston Society of Civil Engineers, the New England Water Works Association, and Past-President, Facultad de Ingenieros en Costa Rica.

On May 8, 1887, Luis Matamoros was married to Angelina Loria Yglesias, in San José, who bore him six children, three boys and three girls, of whom a boy, Luis, died in infancy. There are sixteen grandchildren. One son, Juan Matamoros, is a graduate in Civil Engineering from Lehigh University, at Bethlehem, Pa.

Mr. Matamoros was elected a Member of the American Society of Civil Engineers on October 4, 1905.

MARSHALL MORRIS, M. Am. Soc. C. E.[1]

Died March 24, 1935

Marshall Morris was born at Jefferson Mines, Ala., on September 16, 1877. His father was the late Marshall Morris, Sr., M. Am. Soc. C. E., and his mother was Tinie (Witherspoon) Morris, of Longview, Tex.

Most of Marshall Morris' early life was spent in Louisville, Ky. After graduating from the Manual Training High School, at Louisville, he attended Rose Polytechnic Institute, at Terre Haute, Ind., and Vanderbilt University, at Nashville, Tenn., Class of 1899. He was a member of Chi Chapter of Kappa Alpha.

Mr. Morris started his business career as a Rodman with the Corps of Engineers, United States Army. Later, he was with the Breckenridge Asphalt Company, and the Louisville Bridge and Iron Company. He also served as Assistant Engineer for the Louisville and Nashville Railroad Company, at Louisville, and in the same capacity on the Memphis, and on the Cincinnati, Divisions of the System. These activities extended from 1897 to 1906. From 1906 to 1909, Mr. Morris was employed as Efficiency Engineer for the J. B. Speed Company Coal Mines in Kentucky.

In 1909, he moved to Texas, turning his attention to the building construction field, and in this endeavor (in addition to his private engineering practice), served as General Superintendent of various large building projects. Some of the more prominent buildings on which he was engaged are: The Mills Building, at El Paso, Tex.; The Blind Institute Buildings and Confederate Womens Building, at Austin, Tex.; Hodges-Neal Building, and Gholson Hotel, at Ranger, Tex.; and the San Antonio Arsenal (1918 addition), the Blue Bonnet Hotel, the Incarnate Word College Buildings (1928 additions), and the San Antonio Municipal Library, at San Antonio, Tex.

Mr. Morris specialized in reinforced concrete design and construction and was known throughout the State as an authority on the subject. He studied constantly and kept abreast of the advancement of concrete design from its earlier stages. He was particularly appreciated by the Building Industry for his knowledge, thoroughness, and painstaking execution of details. His handling of men was as noteworthy as his accomplishments in construction. While erecting a building he was also modeling and shaping men of character and giving them a deeper, keener insight into their chosen profession. He was never too busy to give a helping hand.

At the time of his death, on March 24, 1935, he was serving as Resident Engineer Inspector for the Public Works Administration on projects at Dallas, Tex.

Although quiet and unassuming, Mr. Morris always made and retained a host of friends wherever he went, who recognized his honest, straightforward, clear-thinking, friendly manner.

---

[1] Memoir prepared by Messrs. Preston P. Brooks, and J. F. Johnson, Austin, Tex.

On May 21, 1919, he was married to Margaret Groos, of Kyle, Tex. Besides his widow, he leaves a sister, Mrs. George A. Haynes, of Indianapolis, Ind., and a brother, John F. Morris, of New York, N. Y.

Mr. Morris was elected a Member of the American Society of Civil Engineers on February 1, 1910.

ROBERT BROOKS MORSE, M. Am. Soc. C. E.[1]

Died January 31, 1936

Robert Brooks Morse, Chief Engineer of the Washington Suburban Sanitary District, Hyattsville, Md., died on January 31, 1936, of septicemia, in a hospital at Washington, D. C. His death marked the close of a career exemplifying the finest qualities associated with the Engineering Profession. Diffident in approach, generally silent of speech, and imbued with the highest sense of public service, Mr. Morse carried on a long professional career productive of more permanent usefulness to the State of Maryland than perhaps any single individual resident therein. As is always the case with persons of great modesty, the State of Maryland perhaps would be the last to recognize the validity of this statement, when more outspoken, more popular, and less effective individuals absorb the public spotlight.

The contributions of an engineer in public life such as Mr. Morse, devoting an entire lifetime to the development of public administration for the welfare of the citizens of the State, are generally buried in the archives of technical societies and of legislative halls. Fortunately, history discloses these contributions, and the permanent imprint of men of this type assumes the significance which those familiar with Mr. Morse's career believe it deserves.

Robert Brooks Morse was born on September 13, 1880, at Montpelier, Vt., and was the eldest son of the late Professor Harmon N. Morse, of Johns Hopkins University, at Baltimore, Md., and Caroline Augusta (Brooks) Morse. He was educated at the Baltimore City College and was graduated from Johns Hopkins University, in 1901, with the degree of Bachelor of Arts. He was a student at the University of Maine, Orono, Me., in 1902, and, in 1904, he received the degree of Bachelor of Science from the Massachusetts Institute of Technology.

He began his engineering experience as a Draftsman in the Bureau of Construction and Repair, United States Navy Department, Washington, D. C., in 1904 and 1905. Later, he became Draftsman, Assistant Engineer, and Assistant Division Engineer, of the Sewerage Commission of the City of Baltimore from 1905 to 1910, and then Assistant Sanitary Engineer of the Metropolitan Sewerage Commission of New York, N. Y., from 1910 to 1912, on plans and studies for eliminating the pollution of New York Harbor.

In 1912, when Mr. Morse was appointed Chief Engineer of the Maryland State Department of Health, he started an organization responsible for the control of the water supply and sewerage systems in Maryland. That Division became one of the pioneers in the sanitary engineering field in the United States. He held this office from 1912 to 1922, and during that period wrote the Maryland Water and Sewerage Law which has stood the test of time for twenty-two years and has served as a model for legal enactments in a number of other States. It remains on the legislative books to-day as one of the important factors in sanitary administration in the State of Maryland.

---

[1] Memoir prepared by Abel Wolman, M. Am. Soc. C. E.

During this period, he collaborated in the preparation of the Washington Suburban Sanitary District Act, in 1918. This act, too, was drawn with little or no precedent for guidance in creating the pioneer sanitary district in Maryland. It, too, has been used as a model in the formation of similar districts, both within and without the State. In the direction of the Washington Suburban Sanitary District, Mr. Morse showed the highest degree of originality and skill in the many intricate engineering details involved in the administration of that agency.

Always on the alert to depart from orthodox principles and methods, where consistent with sane and logical engineering practice, he conceived and patented the design of a concentric steel filter plant assembly, recently constructed at Burnt Mills, in the Washington Suburban Sanitary District. The plant has attracted international attention as one of the most novel and ingenious water filtration plant structures in the world. It is mentioned here solely to indicate the breadth of vision, the originality of thinking, and the ever-present desire to avoid being hampered by precedent.

Mr. Morse was also the co-holder of patents for efficient methods of pumping sewage and for a special cast-iron cut-in fitting for use in making sewer line connections.

He was a conferee of the New Annex Advisory Commission, Baltimore (1919); a member of the Annapolis, Md., Sewerage Commission (1920); of the Maryland Park and Planning Commission (1927); of the Regional Water Supply, and Drainage and Sewerage Committees of the National Capital Park and Planning Commission, Washington, D. C. (1929–1930); of the Water Resources Commission of Maryland (1931–1933); and a member of the Sub-Committee on the Maryland-Washington Region of the State Planning Commission of Maryland. Mr. Morse had been in private engineering practice since 1910, serving as Consulting Engineer to the Baltimore Sewer Department, on sewer system valuation; to Annapolis and Laurel, Md., on improvements to the water systems; and to a number of other communities and private enterprises in matters of water supply, sewage disposal, and land development. He testified a number of times as an expert witness in matters pertaining to sewerage, sanitation, water supply, and power cases.

As a member of the American Water Works Association, Mr. Morse was Chairman of the Publication Committee and a member of the Committee on Water Service Pipes. He represented the American Society of Civil Engineers on the Committee for Standardization of Manhole Frames and Covers; was a member of the Committee on Clay and Cement Sewer Pipe of the American Society for Testing Materials; and a member of the Committee on Municipal Contract Forms of the American Society of Municipal Engineers.

He was the author of the section on "Metropolitan Water Districts", and co-author of the section on "Relation Between Filtered Water Storage and Filter Capacity", of the Manual of American Water Works Practice, as well as the author of a number of papers on water and sewerage matters in technical journals. He was a member of the American Water Works Association, the New England Water Works Association, American Society of Municipal Engineers, National Conference on City Planning, American Association of Engineers, Engineers Club of Baltimore, Phi Beta Kappa Fraternity, Manor Club, Beaver Dam Club, and a Fellow of the American Public Health Association.

Indefatigable in work, strong in character, keen in intellect, endowed with a sense of personal responsibility for public service, Mr. Morse leaves the State permanently indebted to his activities. Ever helpful to those associated with him, in a friendly and unassuming manner, he leaves behind him a legion of friends in all walks of life.

He was married in 1902 to Caroline E. Ross, of Nashua, N. H., and is survived by his widow, a daughter, Mrs. Julian Ashton Devereux, of Ruxton, near Baltimore, a grand-daughter, Caroline Vail Devereux, and a sister, Dr. Mary Elizabeth Morse, of Baltimore.

Mr. Morse was elected an Associate Member of the American Society of Civil Engineers on June 30, 1910, and a Member on September 2, 1914.

WILLIAM MULHOLLAND, M. Am. Soc. C. E.[1]

DIED JULY 22, 1935

The morning of July 22, 1935, marked the closing of the glorious career of one of the truly great members of the Engineering Profession.

William Mulholland was born in Belfast, County Antrim, Ireland, on September 11, 1855, the son of Hugh and Ellen (Deakers) Mulholland. His early life was spent in Dublin, where his father was connected with the Government mail service. He began his education in the National Schools and, later, attended the Christian Brothers College in that city. At the age of fifteen, after preparing himself by a special course of study of mathematics and navigation at the hands of a private tutor, Mr. Mulholland went to sea. After four years before the mast, he became dissatisfied with a sea-faring life and determined to come to the United States to take up a different career in a new country, having visited some of its Atlantic Coastal cities during his nautical years.

Landing in New York City, on June 9, 1874, Mr. Mulholland went directly to the Great Lakes where he resumed his career as a sailor during the summer and worked in the lumber camps near Manistee, Mich., in the winter. The following year, 1875, he went to Pittsburgh, Pa., where he made his home with his uncle, and was employed in the latter's dry goods store.

---

[1] Memoir prepared by H. A. Van Norman, M. Am. Soc. C. E.

During his residence in Pittsburgh, he read a book, Nordhoff's "California", which so aroused his youthful interest that, in December, 1876, shortly after his twenty-first birthday, he and his brother set sail from New York City, for the land of his dreams. Arriving at Colon, Panama, they left the ship and, to save the $25 railroad fare, walked the forty-seven miles across the Isthmus, following the railroad to the City of Panama. There the brothers joined the crew of a ship that sailed to Acapulco, Guerrero, Mexico. At that port another ship was taken which bore them to their destination, San Francisco, Calif., where they landed in 1877. After a few days in San Francisco, they started for the San Joaquin Valley the land of wonder and beauty that had been so vividly portrayed to Mr. Mulholland by the book he had read in Pittsburgh. At Martinez, they obtained horses and rode down through the Valley, passing through Bakersfield, and finally reaching Los Angeles.

This little Spanish city (at that time of less than 9 000 inhabitants) surrounded by vineyards and citrus groves through which meandered a tiny willow-banked river (which later came to play such an important part in his life) so impressed him that he determined to make this place his home; and near the little Town of Compton, on the outskirts of Los Angeles, he began his long career of water production and distribution by digging Artesian water wells with a hand-drill, subsequently installing the first water system for the town which is now the City of Long Beach. The following winter months were spent prospecting near Erhenberg, Ariz., and there Mr. Mulholland first saw the Colorado River which, forty-five years later, he planned to utilize as a new source of water supply for the City of Los Angeles.

Returning to Los Angeles in the spring of 1878, he went to work for the Los Angeles City Water Company, one of the companies which at that time had a franchise to supply the city with water. The Los Angeles River was the source of supply, and the distribution system consisted of one small reservoir with a capacity of 3 000 000 gal, together with a series of open ditches, which in Spanish were termed "zanjas." Here, really began that which later developed into one of the most unique and successful lives of professional and public service that a man could desire. Starting as a humble "zanjero", or ditch-tender, whose duty was to keep the ditches clear of brush and foreign material, his talents and qualities of leadership were soon recognized, culminating in his appointment as Superintendent in 1886. In 1898, the franchise under which this Company operated expired, and Mr. Mulholland continued to serve as Superintendent through the following years of litigation that preceded the ultimate purchase of the existing works by the City of Los Angeles in 1902. After the transfer to the new ownership, Mr. Mulholland continued to serve in his former capacity.

During his fifty years of meritorious service to the people, he achieved a distinction unprecedented in the history of water development and waterworks construction. Keeping pace with his city of adoption, realizing its potentialities, anticipating its needs, he by his foresight and dynamic leadership, brought about in his lifetime, by the construction of one of the largest and most unique water systems in the world, the unrestricted development of an overgrown village to the fifth largest metropolis in the United States.

From an original distribution system containing a few thousand feet of open ditches, supplied by a single reservoir with a capacity of less than 10 acre-ft, to a system of more than 3 800 miles of pipe and 65 reservoirs and tanks capable of storing more than 53 000 acre-ft of water (the most of which was conceived and completed during his last thirty years of service) was, in itself, an achievement which, no doubt, will never be duplicated.

In addition, in 1908, Mr. Mulholland began the construction of that remarkable project that was to bring to him world-wide recognition and appreciation by the commercial world as well as by his professional associates. Completed in 1913, in less than the estimated time of construction and below its estimated cost, the Los Angeles Aqueduct, the largest structure of its kind in the world, established a successful precedent for long-distance water transportation for the profession for generations to come. This system in addition to its 240 miles of conduit and siphon, contains 68 000 acre-ft of primary and control reservoir storage. The difficulties to be overcome and the daring and unusual features incorporated in the construction of this monumental piece of work have long been familiar to the profession and, consequently, they will not be discussed herein. However, mention must be made, in connection with this work, of that great quality of leadership and ability possessed by Mr. Mulholland—which, unfortunately, is so infrequently possessed by other great engineers—a leadership that enabled him to appear before and verbally present his idea to a more or less disinterested laity; arouse and convince it that the sum of $24 000 000 which he was asking for the construction of this project, and which in those days was considered an unheard of amount of money, was really based on sound, far-sighted judgment, and was not merely an engineer's dream; and that the successful completion of this project was feasible and vitally necessary for the future growth of the city.

Mr. Mulholland also gained great distinction by his successful construction of large earth dams for the creation of required reservoir storage, establishing a precedent thereby for the profession in the matter of high earth dams. In all, he personally conceived and supervised the construction of twenty-seven dams of this type.

In 1923, realizing that in a few years the potential water supply that could be obtained from the Sierra Nevada by means of the Los Angeles Aqueduct would prove inadequate to provide for the needs of the rapidly growing city, he turned for a new source of supply to the Colorado River, which he had first seen in the year of his arrival in Los Angeles. Under his direction, 60 000 sq miles of territory theretofore unmapped were surveyed by plane-table and studied for the location of possible routes for an aqueduct having a capacity of 1 500 sec-ft. The result of this work has been expressed in the construction of an aqueduct by The Metropolitan Water District, to which all maps, surveys, studies, and data were given upon the formation of that organization, an association of thirteen Southern California cities.

Mr. Mulholland acted as Consulting Engineer to the Cities of Sacramento, San Francisco, Oakland, and the East Bay District, in California, and for Seattle, Wash., during the development of their respective water supplies. He also acted in a similar capacity on numerous smaller projects throughout the Southwest, as well as Consultant for the City of Los Angeles with respect to the construction of its Outfall Sewer. He served as a member of the Engineering Advisory Board on Water Resources and Development of the State of California.

Of the personal side of Mr. Mulholland, enough good cannot be said. Self-schooled for the most part, this remarkable individual early in life learned that Mother Nature was the one Great Engineer whose precedents could be followed safely. This, coupled with his keenly observant nature and remarkably retentive memory, contributed largely to the success of his career. In the process of digging his first well in Southern California he encountered a tree and various fossils more than 600 ft below the surface. This inspired a study of geology which gave him authoritative recognition in that branch of science later in life. The desire to protect and beautify the reservoirs and dams he had built, led to an intensive study of botany that left him in possession of authentic knowledge of the flora indigenous to California as well as to those of foreign countries of similar climatic and soil characteristics.

A seldom disclosed but nevertheless ever-present deeply poetic nature, the birthright of his Celtic forebears, made Mr. Mulholland a diligent and appreciative student of the classics. The works of Pope, Carlyle, and Shakespeare gave him his great understanding of mankind and human nature. "Hamlet," his favorite play, provided him with the following precept on which he patterned his life and from which there was no deviation:

> "This above all: to thine own self be true,
> And it must follow, as the night the day,
> Thou canst not then be false to any man."

These habits of self-application and a highly developed sense of observation, coupled with the most remarkably retentive memory with which the writer has ever been in contact, no doubt contributed largely to his tremendous fund of natural and technical knowledge.

It was the writer's great privilege to have enjoyed the professional and social association of Mr. Mulholland for more than twenty-five years, during the period of his greatest activity. It was his remarkable will and personality that made his tremendous accomplishments possible. His absolute fairness, his honesty, and his sincerity were outstanding. He enjoyed a loyalty from those who worked with him and under him that was a tribute to the man he was.

Despite his extraordinary capabilities and his tremendous accomplishments, he was a man of extreme modesty. The writer vividly recalls the day of the dedication of the Los Angeles Aqueduct. After years of appearing before the public and speaking in behalf of the necessity and feasibility of this project; after bearing the burden of heckling and skeptical opposition during the formative years of the planning of this work when considerable doubt was cast that water would actually be brought to the city as he said it would, as well as during the period of construction when the tremendous responsibilities of overcoming the seemingly insurmountable difficulties encountered engendered a load that no one man should have shouldered—yet his dedicatory address delivered when the gates were opened and the first water flowed from the Owens Valley down the Cascades into the San Fernando Reservoir was, "There it is. Take it."

In later years an incident that occurred shortly before he was stricken was very typical of Mr. Mulholland. The writer and he were standing on the San Fernando Dam overlooking the San Fernando Valley that had been transformed from a desert waste into the garden spot that it is to-day as a result of the water he had brought there by means of the Los Angeles Aqueduct. Silently he gazed out over the verdant expanse for a few minutes, and then he said, "The fact that the Valley has developed as it has is compensation enough for all of us." That terse statement was characteristic of him. If the job was well done, that was all he asked.

On July 3, 1890, Mr. Mulholland was united in marriage to Lillie Ferguson, to which union five children were born. He is survived by his children: Rose Mulholland, Mrs. Lucille Mack, Mrs. Ruth Wood, and Thomas and Perry Mulholland.

In December, 1928, he retired from active service, but still continued to serve the City in an advisory capacity until the time he was stricken.

As a tribute to his work, the University of California in 1914 conferred upon him the honorary degree of Doctor of Laws. Mr. Mulholland was a Charter Member, and acted as third President, of the Los Angeles Section of the Society; a member of the Pacific Association of Consulting Engineers; an Honorary Member of the American Water Works Association; a Charter Member of the Engineers and Architects of Southern California; a member of the Seismological Society of America; and an Honorary Member of the National Association of Power Engineers. He was also an Honorary Member of the Tau Beta Pi Fraternity, and a member of the California, Sunset, and Celtic Clubs.

At its meeting on July 29, 1935, the Board of Directors of the Los Angeles Section of the Society unanimously passed the following resolution:

"*Whereas,* July 22, 1935, the Supreme Engineer of the Universe engraved another name on his roster of public servants, that being William Mulholland; and,

"*Whereas,* during his lifetime he constructed a greater monument to his capabilities than can now be erected to his memory; and

"*Whereas* throughout his long career he combined his faculties with human qualities, which made him universally loved as well as respected, and by his devotion to the common welfare reflected credit upon his chosen field of endeavor; and

"*Whereas,* the Engineering Profession, in its entirety, and in particular the Los Angeles Section of the American Society of Civil Engineers, of which he has been a member since its inception and its third President, has suffered an irreparable loss; now, therefore,

"*Be it Resolved,* that the Board of Directors, acting for the Los Angeles Section of the American Society of Civil Engineers, express its profound grief and convey to the members of his family its deepest sympathy for the deprivation of his counsel and friendship and that a copy of this resolution be forwarded to the members of his family."

Mr. Mulholland was elected a Member of the American Society of Civil Engineers on February 6, 1907.

EDWARD TOWLER MURCHISON, M. Am. Soc. C. E.[1]

DIED MAY 8, 1935

Edward Towler Murchison was born in Ripon, Wis., on November 22, 1888, the son of Murdock William Murchison and Clara (Eddy) Murchison. He received his primary education at Englewood High School, at Chicago, Ill., from which institution he was graduated in 1906. Circumstances at the time prevented his completing his education which was started at the University of Washington, at Seattle, Wash. His educational career, although not completed at the University, was supplemented by intensive study after the usual working hours, while engaged in his several engineering positions.

As a Rodman from June, 1906, to July, 1907, Mr. Murchison was employed on the Topographical Survey of the Illinois River Valley for the Sanitary District of Chicago, Ill. This engagement was followed by his employment as a Rodman on the construction of the Grand Trunk Pacific Railroad, on the main line through Manitoba and Saskatchewan, Canada, and following that work as a Topographer on the location of the Canadian Northern Pacific Railroad on the main line in British Columbia. In June, 1909, Mr. Murchison had his first position in responsible charge of work when he was made Assistant Engineer of the Powell River Paper Company, 80 miles north of Vancouver in British Columbia, on its heavy mill, dam, and railroad construction program. On this assignment he had charge of the field work and was in entire charge of the project in the absence of the Chief Engineer. On the completion of this project, he became Assistant Engineer for Ray and McKean, Engineers, at Seattle, Wash., and had charge of surveys and construction on a real estate development at Factoria, Wash.

From April to December, 1911, Mr. Murchison was an Assistant Engineer with the San Benito County Highway Commission, in California, after which he became associated with the South Park Commissioners of Chicago, as Assistant Engineer on tunnel construction. In January, 1913, he entered the service of the City of Chicago, and for four years was actively engaged in the design and construction of sewers, in the Southern Division of the city. In December, 1916, he was transferred to the Technical Staff of the Committee on Finance of the City of Chicago, as one of the engineers who made engineering reports and investigations. He was engaged in this capacity when he was called to serve his country in the World War. After entering the Service in 1917, he became a candidate engineer in the Officers' Training Camp of the United States Army, was commissioned a First Lieutenant of Engineers, and following duty with various organizations in the United States, went overseas as Engineer Officer in Charge of Construction of the 39th Division, American Expeditionary Force.

Following his discharge from the Army, Mr. Murchison returned to Chicago, in January, 1919, and re-entered the service of the City with the

---

[1] Memoir prepared by the late George C. D. Lenth, M. Am. Soc. C. E.

Technical Staff of the Department of Finance. In December, 1919, he was assigned as Junior Engineer on sewer design and construction in the South Division of the Board of Local Improvements of the City of Chicago, which position he retained until April, 1921, when he became Assistant Engineer for the Sanitary District of Chicago, in charge of sewer construction, reconstruction of canal banks, and the preparation of engineering reports and sewer design. In March, 1923, Mr. Murchison resigned his position with the Sanitary District of Chicago and became Assistant Superintendent of Building Construction with the Commonwealth Edison Company, of Chicago. He had charge of the field work and the construction of several large electric power plants in Chicago.

From May, 1925, to May, 1926, he was in private practice as a Civil Engineer in Florida. Returning to Chicago he was, from May, 1926, to January, 1929, Assistant Chief Engineer of the Krenn and Dato Construction Company in charge of the design and construction of municipal utilities, including complete charge of sewer and water contracts as Construction Superintendent in various parts of the Central West. Following his work with the Krenn and Dato Construction Company, Mr. Murchison became associated with the Century of Progress Exposition, at Chicago, and, for four and one-half years, he was in charge of the design and construction of all underground utilities; plumbing within buildings; water and sewerage pumping stations; water and sewerage systems; and the pavements for all roadways.

Throughout his career as an engineer, he was honored and respected by all his friends and engineering associates, and was a tower of strength to all with whom he came in contact. On his last work at the Century of Progress Exposition, at Chicago, Mr. Murchison had the courage to pioneer in many phases of this important work, and, as a result, effected economies in design and construction that saved enormous sums of money.

In 1917, he was married to Maude Louise Jansen, who survives him, with a son, Robert, and a daughter, Ruth.

Mr. Murchison was elected an Associate Member of the American Society of Civil Engineers on April 3, 1922, and a Member on December 26, 1933.

FRANK AMENDE MUTH, M. Am. Soc. C. E.[1]

DIED JANUARY 31, 1936

Frank Amende Muth was born in Kirksville, Ky., on January 27, 1887, the son of Edward Godfrey and Elizabeth Carroll (Tevis) Muth. After his preparatory education, he attended the University of Missouri, at Columbia, Mo., from 1906 to 1910, and received the degree of Bachelor of Science in Civil Engineering from that institution. He also did post-graduate work at the University of Missouri, as well as at Tulane University, in the College of Commerce, at New Orleans, La.

---

[1] Memoir prepared by a Committee of the Louisiana Section, consisting of E. S. Lanphier and B. H. Grehan, Members, Am. Soc. C. E.

Mr. Muth began his engineering work as Surveyman with the United States War Department in 1909, for the period from June to September. From June to September, 1910, he was Surveyman, with the United States Reclamation Service, on the Milk River Project, at Malta, Mont. From September, 1910, to July, 1911, he taught for one term in the Civil Engineering Department, at the University of Missouri, and from July, 1910, to July, 1911, he served as Assistant to Dean H. B. Shaw, Construction Engineer on the water-works system, at Columbia, Mo.

As an Aide in the United States Lighthouse Service, at Staten Island, New York, Mr. Muth made surveys, designed for signal layouts, clockwork, and mechanisms, made photometric tests, inspected engineering materials for steel buoys and vessels, at steel mills, including the supervision of the construction of a concrete lighthouse at Huntington Harbor, New York, as well as a concrete and steel casing around a 167-ft brick tower, at Fire Island, New York. His work also included tests of oil engines and air compressors, the construction of coast-protection devices and riprap protection at lighthouses, and the rebuilding and restoring of lighted structures. From December, 1914, to July, 1919, he was Assistant Superintendent, Office, Lighthouse Inspector (this designation later was changed to Superintendent of Lighthouses), Eighth Lighthouse District, at New Orleans, La., where he was engaged on the design and supervision of construction of lighthouse structures, consisting of lighthouses, beacons, dwellings, and wharves. From July, 1919, to November, 1935, he was First Assistant Superintendent, Eighth Lighthouse District, with increase in responsibility in design, and in charge of the supervision and control of field repair and construction forces. At the time of his death, Mr. Muth was serving in the capacity of Superintendent of Lighthouses, Seventeenth District, at Portland, Ore.

From June 14 to December 8, 1924, Mr. Muth was granted six months leave of absence by the Lighthouse Service to perform the work of revising the Building Code of the City of New Orleans.

He was elected a member of the Louisiana Engineering Society on October 1, 1915, and was appointed Secretary of that Society on January 20, 1923, in which office he served continuously for nearly thirteen years, until his departure from New Orleans, in November, 1935.

For many years Mr. Muth served as a member of the Board of State Examiners for Civil Engineers practicing in the State of Louisiana. He was also a member of the Board of Appeals on Building Code.

He was a member of the Propeller Club, of New Orleans; a Commander of the Boy Scouts of America, New Orleans Council (1926 to 1931); and a member of the Rotary Club of New Orleans.

He was married on July 16, 1913, to Allie Lewis Frank, and is survived by his widow, two sons, and a daughter.

Mr. Muth was elected an Associate Member of the American Society of Civil Engineers on October 10, 1916, and a Member on January 18, 1926. He served as President of the Louisiana Section of the Society in 1927 and 1928, and as Secretary for many years prior to April 25, 1925, when he was elected Vice-President of the Section.

ARTHUR O'BRIEN, M. Am. Soc. C. E.[1]

DIED APRIL 24, 1935

Arthur O'Brien was born in Forestport, N. Y., on January 2, 1870, the son of Jeremiah and Catherine (Hennessy) O'Brien. He attended the local schools and received as good an education as the town then afforded. After leaving school, Mr. O'Brien taught in the district school at Floyd, N. Y. Soon afterward he went into the lumbering business in which his knowledge of the work and his natural aptitude for mathematics secured rapid promotion.

In April, 1894, he entered the Department of the State Engineer and Surveyor of New York State where he served as Chainman, Rodman, Leveler, and Assistant Engineer. In 1896, he was placed in charge of surveys, estimates, etc. Later, he had charge of the construction of a sea-wall and breakwaters, at Geneva, N. Y.; seven miles of the Erie Canal improvement, at Montezuma, N. Y.; dredging the harbor and canal, at Cayuga, N. Y.; building causeways across Otisco Lake, at Otisco, N. Y.; and other canal work.

He also took charge of surveys, plans, and estimates for highway improvement, at Syracuse, N. Y.; the relocation of the boundary line between New York State and Connecticut and Canada; the construction of a lift-bridge, at Utica, N. Y.; and a fixed-span bridge, at Rome, N. Y. These seven years of State work gave Mr. O'Brien not only a wide knowledge of public work, but also an extensive acquaintance with public officials, contractors, and others engaged in the construction industry.

In April, 1902, together with Messrs. Campbell W. Adams, former State Engineer, of Utica, and Herschel Roberts, of Albany, N. Y., Mr. O'Brien sailed for Norway to take charge of the building of a railroad and harbor at Mo, for the Dunderland Iron Ore Company, Limited, of London, England. After the completion of this important piece of work, Mr. O'Brien traveled on the Continent and studied some of the European engineering projects.

Upon returning to the United States, he engaged in private practice in Albany, N. Y., until 1906, when he took the position of General Manager of the Fort Orange Construction Company. In this capacity he had charge of the construction of three great locks on the Barge Canal, at Waterford, N. Y.

In the fall of 1907 Mr. O'Brien was asked to accept the position of City Engineer, of Utica, in his home county. He was the first City Engineer under the second-class cities charter. In 1910 and 1911, he was again engaged in canal work, being employed by the Receiver of the McDermott Construction Company, at Fulton, N. Y.

In January, 1912, Mr. O'Brien was appointed by the Board of Supervisors of Oneida County as County Superintendent of Highways, which position he held continuously until his death, except for one year—August, 1919, to August, 1920. Under his direction more than 500 miles of County roads were constructed, giving employment during the last few years to between 600 and 700 men, at an annual expenditure of about $500 000. He supervised the work done on town roads as well as County roads and organized and supervised the work of snow removal throughout the County. He was known as one who spent public money as conscientiously as his own, saving the County thousands of dollars.

---

[1] Memoir prepared by H. C. Seubert, Esq., Utica, N. Y.

Mr. O'Brien possessed an unusual knowledge of highway law and was considered an authority on the subject. He was known throughout the State as an excellent authority on road construction and maintenance. Throughout his life, he was a constant reader of worth while books. This trait, combined with his excellent memory, gave him a knowledge of the best in literature which few possess.

For many years he was a member of the Fort Orange Club, of Albany, and the City Club, of Utica. He also belonged to the Rome Club and the Republican Club, of Utica. He was never married.

The *Utica Daily Press* of April 27, 1935, contained the following editorial notice of Mr. O'Brien's death:

> "Much regret will be felt over the death of Arthur O'Brien, County Superintendent of Highways, which followed an illness of only a few days. He was a quiet, unassuming man, courteous in his attitude toward his fellow men. There was a reserve about him, however, which gave him personality and strength of character. His demeanor and actions won him the confidence and trust of those with whom he had to deal.
>
> "These qualities, combined with his ability as an engineer, had enabled him to hold the office of County Superintendent of Highways for twenty-two years. Merit, rather than politics, retained him in office. * * *; he served the County faithfully and honestly. Whatever factional differences prevailed in the Board of Supervisors, to which he owed his appointment, they rarely, if ever, involved him. This was because all regarded him as an honest and efficient official, whose services were valuable to the county. He had created a following upon a stronger base than politics. He set a good example for those who are in office, or who may be contemplating entering public life. He had a busy and useful career and by industry and perseverance had won a high rank in his profession as an engineer."

Mr. O'Brien was elected a Member of the American Society of Civil Engineers on July 1, 1909.

SIR FREDERICK PALMER, M. Am. Soc. C. E.[1]

Died April 7, 1934

Frederick Palmer, son of George Palmer, Railway Contractor, was born in South Wales, Great Britain, on January 31, 1862. He was educated at Neath and in 1876 became an articled pupil on the Great Western Railway, serving it as Assistant Engineer after the completion of his four years of pupilage, until 1883.

In that year Mr. Palmer was appointed Assistant Engineer on the East Indian Railway. He was selected for the post by the late Sir Alexander

---

[1] Memoir prepared by Sir Robert Richard Gales, M. Am. Soc. C. E.

Rendel, then Consulting Engineer to the Government of India, who nearly thirty years later, invited him to become his partner.

In India Mr. Palmer soon began to distinguish himself. After experience in charge of the Drafting Room and as personal Assistant to the Chief Engineer, in Calcutta, he was promoted in 1889 to Resident Engineer and placed on the survey of the Grand Chord Line in the Hill Section. In 1893, he became District Engineer, at Allahabad, in charge of maintenance. In 1896, he was appointed Engineer in Charge of the Moghalserai-Gaya Survey and subsequently became District Engineer in charge of the construction of the line which comprised 126 miles of new railway, including a bridge over the Sone River consisting of 93 spans of 100 ft, which incidentally was and still is the longest bridge in India.

On the completion of this work in 1900, Mr. Palmer had spent about seventeen years on railway engineering on the East Indian Railway. He then took up and devoted himself for twelve years exclusively to dock and harbor work.

About this time the trade of Calcutta was outgrowing the accommodation and the Port Commissioners required an experienced engineer to prepare plans for the development of the Port and to carry out the extensions. Mr. Palmer applied for the position and, in 1901, was appointed Chief Engineer. He was soon actively engaged in the construction of additional jetties in the Hooghly, with transit sheds and equipment and new berths in the Kidderpore Docks to meet the most pressing needs. At the same time he prepared a comprehensive report dealing with the increase in traffic and in the size of ships and including proposals and plans for new docks and jetties at Garden Reach, but it was not until after the World War that these projects were undertaken.

Meanwhile in 1909 Mr. Palmer, being then on leave in England, was offered and accepted the appointment of Chief Engineer to the newly constituted Port of London Authority. The problem here was similar to that at the Port of Calcutta but on a larger scale. It was in fact to modernize the existing accommodation and equipment and to provide for the future growth of the largest port in the world. In 1910 he presented a report which included a program of deepening the channel of the River Thames for 47 miles from London Bridge to the Nore Lightship and proposals for improvements in existing docks, consisting of new enlarged entrance locks, installations of impounding pumps, dry docks, enlarged transit sheds and warehouses, and improved equipment and communications by road and railway, together with new docks with larger entrance locks and new dry docks at the Victoria and Albert Dock group and at Tilbury, where also a floating passenger landing-stage was to be provided at which the largest liners using the Port could go alongside at any stage of the tide. Many of the works of improvement had been carried out when in 1913 Mr. Palmer resigned the post of Chief Engineer to become a partner in the firm of Rendel, Palmer and Tritton, Consulting Engineers, of which, on the death of Sir Alexander Rendel in 1918, he became the head. In 1925, however, he was appointed Consulting Engineer to the Port of London Authority to carry out major works at the West India Docks and at Tilbury. The floating passenger landing-stage, the last of these works to be completed, was brought into use in 1930, by which time £20 000 000 had been spent on the improvements and extensions which he had initiated.

During the World War, 1914 to 1918, Mr. Palmer gave his services voluntarily to the Ministry of Munitions, under which he became Director General of Contract Finance and Chairman of the Munitions Works Board, and to the Board of Trade by which he was appointed Chairman of a Committee to consider the future of English railways. The conclusions of this Committee formed the basis of the legislation subsequently adopted on this subject.

After the war, he directed with ability the activities of his firm, as Consulting Engineers to the Government of India, including the State Railways of India, as well as most of the company-owned railways in that country; to a number of Native States; to several Indian Harbor Boards; to the Crown Agents for the Colonies; to the Port of Glasgow, Scotland; to the Tyne Commissioners; to the River Mersey Conservators; to the Mersey Harbor Board; and to other public bodies.

In 1920 Mr. Palmer was elected a member of the Commission Consultative Internationale de Travaux du Canal de Suez, in succession to Sir William Matthews, and continued to serve on that Commission to the time of his death.

In 1919 he was asked to advise on facilities at the Port of Karachi, in India, and in 1920 after two visits to that port he presented a valuable report embodying a plan of extension and improvement marked by his then well-known foresight and good judgment. The plan was accepted and the works have since been largely completed. In 1921 Mr. Palmer represented the Foreign Office on the Shanghai Harbor Committee and in 1923 he reported to the Government of China on Yangtse River improvements. In the same year, he advised the Anglo-Persian Oil Company on the possibility of improving the Shatt-al-Arab between the Anglo-Persian Oil Company's depot at Abadan and the open sea. His recommendations have been carried out and have resulted in the depth of water on the bar about 15 miles from Fao being increased from 10 to 20 ft at low water, thus enabling oil tankers and other large vessels to navigate the river. In this year also, at the request of the Colonial Office, he visited Palestine to advise the Government on the question of a harbor. His recommendations were adopted and the construction of a harbor at Haifa by the Palestine Government, with his firm as Consulting Engineers, was begun in 1929 and completed in 1933.

In 1924, he was asked by the Secretary of State for the Colonies to report on Takoradi Harbor, Gold Coast, and the firm was subsequently appointed Consulting Engineers for the completion of the construction. The harbor was opened in 1928.

In 1926, Mr. Palmer became President of the Institution of Civil Engineers and it was while holding this important office that he was invited by the Canadian Government to advise on the selection of the terminal port for the Hudson Bay Railway, projected to afford a more direct route to England for wheat and other products from Western Canada. His recommendation of Churchill in preference to Nelson was adopted and the Port of

Churchill was opened for traffic in September, 1931, by the loading of the *Farnworth* with 227 000 bushels of wheat for London. In 1927, he advised the Canadian Government on a plan for a £10 000 000 terminal station for the Canadian National Railways, at Montreal, Que.

In 1927 his firm was asked by the Colonial Office to prepare a project for a bridge over the River Zambesi to give uninterrupted rail communication between Nyasaland and the seaport of Beira. The bridge, which is 12 064 ft in length and is believed to be the longest bridge in the world over a river, was constructed in collaboration with the firm of Livesey, Son and Henderson, Consulting Engineers.

In association with Aktiebolaget Vattenbyggnadsbyran, of Stockholm, Sweden, his firm was responsible for the hydro-electric power installation at Chenderoh, on the Perak River, in the Federated Malay States. This was put into commercial operation in 1930.

Mr. Palmer was closely connected with questions concerning the bridges of London. In December, 1924, he reported to the London County Council on the condition of Westminster Bridge. From 1926, he was concerned with the various projects for rebuilding or reconditioning and widening the much discussed Waterloo Bridge, but it was not until after his death, in 1934, that the demolition and rebuilding of the bridge was entrusted to his firm as Consulting Engineers. Following the extraordinary flood which occurred in the Thames on the night of January 6, 1928, he was appointed, with Sir George Humphreys, to report on the future standard of flood prevention works in the County of London. In 1929, he was appointed by the Council as Engineer for the Charing Cross Bridge project. This scheme would have involved an expenditure of £12 500 000, but it was rejected by the Select Committee of the House of Commons in May, 1930. Mr. Palmer was also appointed Engineer, in 1931, for the reconstruction of Chelsea Bridge and, subsequently, in 1933, this work was entrusted to his firm as Consulting Engineers.

In 1929, his firm was appointed Consulting Engineers for the bridge over the River Hooghly, at Calcutta; for the construction of the Victoria Docks Road forming a main artery of communication for this group of Port of London docks; and in collaboration with the firms of Livesey, Son and Henderson and Mott, Hay and Anderson, the firm was appointed by the Ministry of Transport to report on the Channel Tunnel scheme.

Mr. Palmer was appointed a Companion of the Most Eminent Order of the Indian Empire (C.I.E.) in 1907 for his work in India and, in 1930, he received the Honor of Knighthood and was invested with the Insignia of a Knight Commander of the Most Distinguished Order of St. Michael and St. George (K.C.M.G.) for services to the Colonies.

In 1930 and 1931, his firm located a new railway line, about 700 miles long, from Haifa, the port in Palestine, to Baghdad, the capital of Iraq.

Sir Frederick Palmer was a man of outstanding personality, great vitality, broad views, and sound judgment. He was held in high repute for the many large projects with which he was connected, and he was greatly esteemed by all who knew him. At his death, he was honored with a memorial service in Westminster Abbey.

He held the rank of Colonel in the Engineer and Railway Staff Corps and the Efficiency Decoration of the Territorial Army was conferred upon him in December, 1931. He was a Member and Past-President of the Institution of Civil Engineers, and a Fellow of the Royal Geographical Society.

He was married, in 1903, to Florence, only child of the late John Elliott Mason, of San Francisco, Calif., and is survived by Lady Palmer and a son and two daughters.

Sir Frederick was elected a Member of the American Society of Civil Engineers on October 4, 1899.

HARRY de BERKELEY PARSONS, M. Am. Soc. C. E.[1]

Died January 26, 1935

Harry de Berkeley Parsons was born on January 6, 1862, in New York, N. Y., the son of William Barclay Parsons and Eliza Glass (Livingston) Parsons. He was descended from distinguished Colonial stock, long identified with the development of New York City. Among his direct ancestors were Robert Livingston, First Lord of the Manor, who came to this country from Scotland in 1673; Cadwallader Colden, Lieutenant-Governor of the Province of New York in 1760; and Colonel Thomas Barclay, who was appointed the British Consul General for New York, after the American Revolution. A brother who distinguished himself as an engineer and a soldier of the United States was the late William Barclay Parsons, Hon. M. Am. Soc. C. E., at one time a Director of the Society, who was Chief Engineer of the Rapid Transit Railroad Commission during the construction of the first Rapid Transit Subway for New York City, and, later, Colonel of the 11th Engineers, American Expeditionary Forces, which served so notably in France during the World War.[2]

In 1870, Mr. Parsons went to Europe with his family and during the following four years studied under private tutors, while traveling in France, Germany, and Italy. He entered Columbia College, in New York City, in 1878, from which he was graduated with the degree of Bachelor of Science in 1882. He then entered Stevens Institute of Technology, in Hoboken, N. J., from which he was graduated in 1884 with the degree of Mechanical Engineer. In 1926, Stevens conferred on him the Honorary Degree of Doctor of Engineering.

In 1885, Mr. Parsons established an office in New York City as a Consulting Engineer and maintained it there until his death. His field of practice was an unusually diversified one. To recite all the activities of his fifty years of experince as a Consulting Engineer would make too formidable a list to publish herein, but one who has studied them is impressed with their number, and with the versatility of mind of this quiet conscientious man. Among the earlier projects with which he was connected was the construction of the Fort Worth and Rio Grande Railway, in Texas, including the erection of a bridge over the Brazos River, and, in 1889, the completion of the water supply for Stevens Point, Wis. In 1893, he was Consulting Engineer for the Nicaragua Canal Construction Company and some of its related organizations.

---

[1] Memoir prepared by Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E., and Lynne J. Bevan, M. Am. Soc. C. E.

[2] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1485.

From 1892 to 1907, he was Professor of Steam Engineering at Rensselaer Polytechnic Institute, Troy, N. Y., and from the latter date until his death was its Emeritus Professor of Practical Engineering.

In 1898 he was consulted on the adequacy of the foundations for the Protestant Episcopal Cathedral of St. John the Divine in New York City. At a later date, he designed and installed the heating system for the Cathedral, and also had to do with the design of some of the appurtenant structures.

In the period, 1901 to 1903, Mr. Parsons designed the Spiers Falls Dam and Power House, on the Hudson River, at Spiers Falls, N. Y.—1 570 ft long, with a maximum height of 154 ft—and, in the period, 1921 to 1923, the Sherman Island Dam on the same river, near Glens Falls, N. Y., for the International Paper Company. He also acted as Consulting Engineer while these projects were being constructed.

Between 1898 and 1914 he was a member of the New York State Voting Machine Commission, and was Chairman of the Mayor's Committee to Report on Street Cleaning and Waste Disposal, in New York City, in 1906 and 1907. From 1908 to 1914, he served as a member of the Metropolitan Sewerage Commission which prepared a monumental report on the Storm and Sanitary Drainage of New York City; and from 1898 to the time of his death Mr. Parsons was a Consulting Engineer for the New York Zoological Society.

His activities included the designing of water and steam power plants for mills; roof trusses, heating plants, and other features of church buildings; water supply and sewerage projects for cities; many designs for hydro-electric developments, and numerous appraisals of industrial projects, water powers, and railroads in many States. He designed foundations and underpinning for many structures for construction contractors, in connection with the building of the Rapid Transit Subway in New York City; and in 1918 and 1919, as District Appraisal Officer at Detroit, Mich., Mr. Parsons represented the United States Government in the settlement of World War contracts connected with the Air Service and aircraft production. He acted as Consulting Engineer for the Cramp Ship and Engine Building Company on reports and appraisals; for the Pressed Steel Car Company; for The Consolidated Gas Company of New York; numerous paper companies; the Seaboard Air Line; and the New Hampshire Traction Company. He was Consulting Engineer for the Department of Street Cleaning of New York City through five administrations, during which he designed and built two rubbish destructor plants and prepared the design for a third for the building of which the City did not appropriate the necessary funds. For a time, 1905–1906, he was the Consulting Engineer for the Fire Department and for the Department of Docks and Ferries, of New York City, and designed and constructed a number of fire-boats and ferry-boats for these Departments.

For many years Mr. Parsons was the Consulting Engineer for the Corporation of Trinity Church, the Rhinelander Estates, the Corn Exchange Bank, the Mechanics and Metals Bank, and the Bush Terminal, all of New York City. The Delaware and Hudson Company retained him to report on and appraise some of its electric railway properties, the construction cost of which amounted to more than $14 000 000. The City of New York employed him to appraise the damages to the Ulster and Delaware Railroad by the flooding of the Ashokan Reservoir, for the properties taken for the large Chelsea Dock improvement, on the Hudson River front, and for the new County Court House—the condemnation for all of which amounted to many millions of dollars.

He regarded as his most important accomplishments the Spiers Falls and the Sherman Island Dams, the study of tidal flows in the Harbor of New York for the Metropolitan Sewerage Commission, and the appraisals at the end of the World War for the U. S. Army Air Service plants, at Detroit.

Mr. Parsons was a liberal contributor to the publications of the Society, as well as to those of other engineering and scientific bodies, both in original papers and in discussions of those of other authors. He was awarded the Thomas Fitch Rowland Prize by the Society in 1925 for his paper on "Sherman Island Dam and Power-House",[3] and, in 1930, was given the J. James R. Croes Medal for his paper on "Hydrostatic Uplift in Pervious Soils."[4] Mr. Parsons was also the author of "Disposal of Municipal Refuse and Rubbish Incineration"[5]; "Tidal Phenomena of the Harbor of New York"[6]; "Some Soil Pressure Tests",[7] and many other papers, including an original research on the "Displacement Curves of Fish". His book entitled "Steam Boilers, Their Theory and Design" went through five editions (first edition, 1903; fifth edition, 1917).

He was a member of the Delta Psi Fraternity, of the American Society of Mechanical Engineers, the Society of Naval Architects and Marine Engineers, and the American Institute of Consulting Engineers, of which he was the President in 1926. He served as President of the Alumni Association of Stevens Institute in 1895 and 1896, and as Alumnus Trustee from 1896 to 1899. He was Chairman of the Professional Engineers Committee on Unemployment, which represented the four Founder Societies, in 1931 and 1932, and was on its Advisory Board in 1932 and 1933. In addition, Mr. Parsons was active in civic affairs, and was a member of the New York

[7] *Loc. cit.*, Vol. 100 (1935), p. 1.

Zoological Society and of its Board of Trustees, the Chamber of Commerce of the State of New York, the Merchants Association of New York, the Metropolitan Museum of Art, New York, and was a Trustee of the United Hospital of Portchester, N. Y., and Chairman of its Endowment Fund.

He belonged to the Protestant Episcopal Church and was a member of the vestry of the Church of the Incarnation, in New York City, where his funeral services were held, and of Christ Church, at Rye, N. Y., where his beautiful summer home is located. He belonged to the following clubs in New York City: Union, Engineers, New York Yacht, and the Downtown Association, and to the American Yacht Club, and the Apawamis Club, in Rye, N. Y.

Mr. Parsons was a keen yachtsman and as a young man gained much experience at the helms of his own boats and of his father's yacht. He was much interested in this clean sport, and for many years subsequent to 1895 served as Chairman of the Race Committee of the American Yacht Club. From 1904 to 1922, he was also a member of the Race Committee of the New York Yacht Club, being Chairman from 1907 to 1922. The *New York Times* in an article published concerning him on January 27, 1935, quotes this statement of his made in 1917:

> "Yachting has a peculiar charm which is difficult to describe. I fancy it comes from the feeling of freedom and from the intimate companionship which is so pleasant. Men who are fond of the sea are usually fearless, frank and good sportsmen, qualities which make for staunch friendships and the pleasantest associations."

One feels how inadequate is this recital of Mr. Parson's deeds as a measure of what he accomplished during his life. When meeting him, one always felt that one was with a man who, by instinct and training, was a finished engineer. Always courteous, his quiet refinement of manner, his sincerity of purpose, his modesty, and his grounding in the fundamentals of his profession distinctly impressed one. A cultured gentleman possessed of broad knowledge, his life was unusually full and useful. In spite of his modesty time will appraise the real value of his contributions to his profession and the Society. An engineer associate—who was close to him and his activities for many years—writes of Mr. Parsons:

> "As I knew him I came to feel that he had rendered his best services to the profession in his very many contributions of lucid thought to the literature of the Society, and his modest assistance to his fellow engineers. These services have rarely commanded the spotlight, yet in the aggregate they are far more valuable to mankind than the occasional spotlight performance of less modest men."

He was married on December 16, 1890, to Frances Thompson Walker, of New York City, who died in 1917. He is survived by a son, Livingston Parsons, and a daughter, Katherine de B. Parsons, and three grand-children.

Mr. Parsons was elected a Member of the American Society of Civil Engineers on February 3, 1897.

WILLIAM MERIT PENNIMAN, M. Am. Soc. C. E.[1]

DIED AUGUST 26, 1934

William Merit Penniman, the son of Merit Farnum and Lavina (Damon) Penniman, was born at Windsor, Vt., on February 19, 1868. His boyhood was spent on his father's farm, near the banks of the Connecticut River.

He attended the public schools of Windsor and Hartland, Vt., and was graduated from Kimball Union Academy, at Meriden, N. H., in 1888. Mr. Penniman entered Dartmouth College, at Hanover, N. H., in 1889, and was graduated therefrom in 1893, with the degree of Bachelor of Science. In college, he was distinguished for scholastic standing, especially in higher mathematics.

During summer vacations, beginning May 1, 1891, Mr. Penniman entered the service of the United States Government, in the United States Engineer Department, St. Louis, Mo., District, and was engaged on the improvement of the Mississippi River. Shortly after leaving college in 1893, he was re-employed by the St. Louis District, and remained in that service in various grades practically without intermission until his death, his last engagement being as Senior Engineer.

From August, 1907, to June, 1909, he was engaged as Principal Assistant Engineer on the survey of the Mississippi River between St. Louis, and Cairo, Ill., for the Board of Examination and Survey of the Mississippi River (14-ft waterway, Lakes to the Gulf). His review of methods of complete river regulation by bank protection, permeable dikes, and submerged dams, published as Appendix No. 5, to the report of that Board,[2] was so comprehensive that it is still used as a reference.

In later years, a formula for the flow of water in open channels was derived by Mr. Penniman, but was never published. The formula has been widely used in monograph form in the St. Louis Engineer District and in other districts, where the ability and work of the originator are known. Locally, it is known as the "Penniman" formula.

It is difficult to state wherein Mr. Penniman was of greatest value to the Engineer Department. Because of his unusual knowledge and technical skill, he was employed almost constantly during his later years on special investigations and reports. His services were utilized to aid the decisions reached by Boards of Engineers on problems beyond the bounds of the St. Louis District. His training of younger engineers to produce accurate and reliable work has proved to be of major value to the Engineer Department, since many of his former assistants now hold responsible positions in the St. Louis District, and in other Engineer Districts.

Mr. Penniman's entire service was characterized by his loyalty to the Department which he served so well. His open-mindedness and ability to keep informed on current developments in hydraulic and other engineering theories, made him a man whose counsel was frequently sought when important decisions were to be made. Since his death, as a tribute to his high standing, the St. Louis District has renamed a large steam towboat, *Penniman.*

---

[1] Memoir prepared by a Committee of the St. Louis Section, consisting of J. W. Skelly, E. C. Constance, C. M. Daily, and J. B. Dean, Members, Am. Soc. C. E.

[2] H. R. Doc. No. 50, 61st Cong., 1st Session.

His long experience embraced a wide range of phases of open-river improvement, including surveys, hydrography, bank protection, contraction works, and the design and operation of hydraulic dredges, and other floating plant. He was trained under Captain D. M. Currie and the late William Selby Mitchell, M. Am. Soc. C. E., who were engineers and gentlemen of the old school. They lived in a day when Government funds were sparingly granted, and when projects were most critically examined for their engineering and economic merit.

Mr. Penniman loved the outdoor life, and during the first ten years of his service, which was largely spent in the field, he took a keen delight in baseball and hunting. In manner, he was affable, although quiet and reserved, and to a stranger might have even seemed to be taciturn. In his later years, he weathered several attacks of sickness, which however gave no premonition of the malady which brought a useful life to what seems an untimely end. About two years prior to his death he suffered a paralytic stroke from which he partly recovered. On August 23, 1934, he was fatally stricken and three days later passed peacefully away. He was buried in Bellefontaine Cemetery, at St. Louis, on a hillside overlooking the Mississippi River which he loved so well.

He was married on August 6, 1901, to Idell Lombardi, of Galveston, Tex. He is survived by his widow, a daughter, Catherine Lavina (Mrs. T. D. Storie), and a son, Allen Damon. He was a member of the Masonic Fraternity and of the Society of American Military Engineers.

Mr. Penniman was elected a Member of the American Society of Civil Engineers, on May 28, 1923.

EUGENE EVERETT PETTEE, M. Am. Soc. C. E.[1]

DIED MARCH 17, 1935

Eugene Everett Pettee, the son of Captain Lemuel and Mary (Westall) Pettee, was born on January 15, 1870, at Jefferson, Tex., where his father, who had served throughout the Civil War in the Regular Army, was stationed at the time, on guard duty against Indians.

During his boyhood Mr. Pettee lived with his parents in many parts of the United States and his schooling was obtained from the public schools wherever he happened to be located. He was finally fitted for the Massachusetts Institute of Technology in the Whitman (Mass.) High School, and entered the Institute in 1888. For various reasons, he was unable to complete the course, and, in 1891, left school to enter the Drafting Office of the Boston Bridge Works, where his unusual ability was recognized and where he remained for three years.

---

[1] Memoir prepared by J. R. Worcester, M. Am. Soc. C. E., and Thomas Worcester, Esq., Boston, Mass.

In 1894, he accepted a position in the City Engineer's Office, of Newton, Mass., where he was employed until, in 1896, he was called into the office of one of the writers, J. R. Worcester, M. Am. Soc. C. E., to assist in completing the design of the train-shed (since removed) of the South Station of the New York, New Haven and Hartford and the Boston and Albany Railroads.

The association thus begun was to continue throughout Mr. Pettee's life. In 1906, he became a partner in the newly organized firm of J. R. Worcester and Company, and until February, 1934, when he suffered a paralytic stroke, he was actively engaged in the design and supervision of construction of many bridges, buildings, and other structures, and by his frankly honest, yet courteous and genial bearing, won many enduring friendships with other engineers, with architects and contractors, as well as with many public officials. As an expert witness, he was convincing and effective.

Among the projects with which Mr. Pettee was most closely identified were: The elevated structure of the Boston Elevated Railway, including the Charles River Bridge; three bridges over the Connecticut River, at Woodsville, N. H., Bellows Falls, Vt., and Walpole, N. H.; the bridge across Portland Harbor, between Portland and South Portland, Me., to which he gave his personal attention, living in Portland for two years; and, toward the end of his life, the bridge now (1935) under construction over the Saugus River between Revere and Lynn, Mass. For some years he was engaged in examining all the bridges over which the lines of the Boston and Northern and Old Colony Street Railways had tracks.

Among his other gifts Mr. Pettee had a strong artistic sense, rare among engineers, ~~and~~ he found his greatest satisfaction in producing, with the help of architects, structures having real architectural merit. Numerous small bridges and over-passes bear witness to his success in this endeavor. He was an expert photographer and delighted in thus catching and preserving beautiful natural scenery.

He was a member of the Boston Society of Civil Engineers, the Appalachian Mountain Club, the Boston City Club, the New-Church Club, and the Wellesley Country Club.

Descended from two grandfathers who were New-Church (Swedenborgian) ministers, Mr. Pettee was naturally a faithful member of that church, in which he was a prominent layman, and held a number of important official positions.

In 1909, he was married to Margaret Edith Babcock, who survives him. He is also survived by one brother, Charles L. W. Pettee, of Hartford, Conn., and by three nephews and three nieces.

Mr. Pettee was elected an Associate Member of the American Society of Civil Engineers on September 3, 1902, and a Member on March 2, 1909.

AUGUSTUS LYON PHILLIPS, M. Am. Soc. C. E.[1]

Died January 31, 1935

Augustus Lyon Phillips was born in Manchester, England, on October 6, 1860, the son of George Ricketts Phillips and Elizabeth Catherine (Robinson) Phillips. He was educated at the Edinburgh Academy, Edinburgh, Scotland, and studied Civil Engineering at Owens College, Victoria University, Manchester, England, for two years, 1877–1878.

In 1879–80, he was articled to T. B. Farrington, Borough Engineer, Colwyn Bay, North Wales, and was engaged in surveying, the design and construction of streets, water-works, sewerage systems, etc. In 1881, Mr. Phillips was articled to G. L. Waring, Chief Engineer, West Lancashire Railway, in England, as Junior Engineer on location and construction, design of coffer-dams, etc. In 1882, he was Contractor's Engineer, on the replacement of a two-track, with a five-track, plate-girder bridge (under traffic), over the intersection of three streets, at Stockport, England, for the Midland Railway Company, and on the widening of part of the main line (two additional tracks), of the London and North Western Railway; he also designed the falsework to carry traffic during the reconstruction of a bridge over the Mersey River.

From 1883 to June, 1884, he was Assistant Engineer for the British Government on a railroad in Jamaica, for which he had charge of the construction of a 25-mile section, with 5 miles in rough mountain country, two short tunnels, long retaining walls, river diversions, small concrete bridges, etc. These bridges were among the earliest constructed of concrete.

From June, 1884, to March, 1885, Mr. Phillips was Assistant to Samuel McElroy, Consulting Engineer, of New York City, and was engaged in office and field work on the farms of the Insane Asylum for Brooklyn, N. Y.

For nine months in 1885, he was engaged in designing and drafting heating and ventilating layouts, for the Creque Manufacturing Company, of New York City. From January, 1886, to June, 1887, Mr. Phillips was Assistant Engineer (under the Chief Engineer), for the Leroy and Caney Valley Air Line Railroad, on prospecting, surveys, location, and construction; he also designed the Howe truss bridges and timber trestles (one more than 500 ft long and 47 ft high). His work for the Leroy and Caney Valley Air Line Railroad was field work through Kansas and Indian Territory on what became later a part of the Missouri Pacific System. Some of his experiences as an Eastern tenderfoot, but lately out of Europe, in a West which still retained a great deal of the frontier aspect, were very amusing; such as his carefully taking along a revolver and then, after observing some of the local talent pick out the six spots from a six of spades in about 2 sec, deciding that he would be safer unarmed and promptly giving away his revolver. Then there was the local rodman who would cheerfully ford all rivers less than a couple of feet in depth, but when they came to the Arkansas, which at that ford at that season was about 3½ ft, he was panic-stricken, as he had always heard that if he ever got any water on his back, he would take cold and die (Mr. Phillips said his neck bore out his strict faith in this theory), so they could only get him across standing up in the cook wagon. Of course, there was the matter of building lots; promoters were laying out fictitious towns far ahead of the rail-head on what they hoped would be the line, and everybody was speculating in lots, Mr. Phillips included. Anybody could always sell him a lot, and he invariably made the down payment, and then found that the lot was worthless; at one time or another, he must have made down payments on most of the New Jersey coast between Sandy Hook and Cape May (and between the extreme low-water mark and the coast of Spain). So, of course, he bought a block of lots in one of these paper towns, made his down payment and according to rule never did anything more about them. Years later, he discovered the lots were at what later became the business center of Wichita, Kans. One morning in Indian Territory they sighted the last remnant—about thirty head—of the Southern Herd of buffalo, which only a few years before had numbered millions.

---

[1] Memoir prepared by T. Kennard Thomson, M. Am. Soc. C. E., and J. H. H. Muirhead, Esq.

From June, 1887, to September, 1888, he served as Draftsman, for the Union Elevated Railroad Company, in Brooklyn, N. Y., designing and detailing under the Chief Engineer, the late Othniel Foster Nichols, M. Am. Soc. C. E.

From October, 1888, to March, 1902, Mr. Phillips was with the Bridge and Construction Department, of the Pencoyd Iron Works (later, the American Bridge Company), at Pencoyd, Pa., having been given the position by the Chief Engineer, the late Charles Conrad Schneider, Past-President, Am. Soc. C. E., who was familiar with his work in Brooklyn. Mr. Schneider always had the highest opinion of Mr. Phillips. On this work Mr. Phillips was Checker and Squad Boss, on buildings and bridges of all kinds and sizes, subway and elevated work, etc. It has been well said that he was an exceptional Checker, inasmuch as he was extremely accurate and thorough, and, at the same time (and this is very unusual) able to point out the errors and have them corrected, without giving offense to the Draftsmen, many of whom still have the highest admiration and affection for his memory.

From April, 1902, to March, 1908, he was Assistant Engineer, with the Philadelphia Rapid Transit Company, under William S. Twining, M. Am. Soc. C. E., Chief Engineer. Mr. Twining had the highest opinion of Mr. Phillips, who, he states, was no small factor in the design of that work. Mr. Phillips spent 1½ yr on the preliminary investigations and on the design of the subways and elevated structures; 4½ yr in charge of the Engineering Office, designing and detailing for 2½ miles of subway; a four-track bridge over the Schuylkill River; 5½ miles of two-track elevated, etc., the approximate cost being $20 000 000.

From April, 1908, to March, 1909, he was Supervising Engineer for the Interstate Engineering and Supply Company of Philadelphia, Pa., building a large power plant for the Metropolitan Electric Company at Reading, Pa., changing and rebuilding the old power plant (under operation) into substation, etc. (cost, $2 000 000).

From April, 1909, to 1923, Mr. Phillips was in private practice as a Consulting Engineer, in Philadelphia. As such he made investigations, surveys, estimates, layout, and plans for the Philadelphia and Suburban Railroad Company, for 8 miles of two-track subway, and 32 miles of two-track elevated railroad (estimated cost, $43 000 000; not built); he also made the preliminary surveys and layout for a system of docks on the Delaware River, below Philadelphia, for the Hughes Terminal Company (estimated cost, with 4 miles of connecting railroad, $5 000 000); he made surveys, and located and constructed 4½ miles of single-track railroad across the salt meadows for the Wildwood and Delaware Bay Short Line Railroad Company, including three trestle bridges (1 200 ft) and a single-track, single-leaf Scherzer rolling lift bridge over the inland waterway, with concrete piers in 20 ft of water at low tide (cost, $250 000); made surveys and plans for a high-grade land development suburb (100 acres) of Philadelphia, with central heating and domestic service plant, all pipes, wires, etc., in sidewalk conduits, and roads in park effect (estimated cost, $400 000); as well as investigations and reports on several proposed interurban trolley lines and miscellaneous minor work.

Mr. Phillips was one of those forward-looking engineers who are years ahead of their time. He advocated the abandonment of surface trolleys and their replacement by double-deck busses, at a time when the present system of bus transportation was practically unknown in the United States.

He was the originator of the project, and one of the incorporators of a transportation company formed for the purpose of operating arterial north and south subway and elevated lines in Philadelphia, with lateral bus-line feeders, and connecting elevated lines to the principal suburbs. He completed all the preliminary engineering work on this comprehensive system. Financial backing for the project was arranged for, and a charter was obtained from the State of Pennsylvania, but the opposing influences in the City Council proved too powerful to enable the Company to secure the necessary franchise.

However, the wide publicity given these projects, and the consequent strong public demand, practically forced the City Council into the building and the operation of the present city-owned Subway and Elevated Railway System. Mr. Phillips was also an early advocate of two-level streets in the center of the city whereby the vehicular traffic would be carried at the street level and the pedestrian traffic in sub-surface concourses with shop entrances and display windows at both levels for the accommodation of both classes of patrons. This has only been done to a limited extent as yet, but may be realized in the near future.

Among his non-engineering activities was his life-long devotion to vocal music. He was almost constantly engaged as choir master or tenor soloist in some church, the most famous of which was "Old St. Peter's" in Philadelphia.

He always took a great interest in athletics, having been captain of the football team at his college, and an active member of the cricket team, of which his brother was captain. He was one of the organizers and charter members of the Wissahickon Cricket Club of Philadelphia. He was also very expert with boxing gloves, which he frequently enjoyed using—during lunch hour—in the Drafting Room, at Pencoyd. He maintained a keen interest in doing carpenter work and gardening about the house, and was an avid stamp collector.

Besides his connection with the Society (of which he was very proud), Mr. Phillips was a member of the Engineers' Club of Philadelphia, Roxborough Lodge No. 135 F. & A. M., The Society of the Sons of St. George, and the Veteran Athletes' Association of Philadelphia.

Mr. Phillips was much liked by all—even the draftsmen whose numerous mistakes he had to correct. One of them writes, after 46 years, of what a fatherly care Mr. Phillips took of him, a young chap just out from Scotland, and how Mr. Phillips had visited him in the Philadelphia Hospital every Sunday for 25 weeks, while he had typhoid fever. Several others wrote that he was the best friend they ever had. Mr. Twining wrote affectionately of his high character, and sound engineering judgment.

In short, Augustus Lyon Phillips was a man whose absolute integrity, great ability in Engineering, and kind-heartedness, won for him the undying love and admiration of all who knew him. He died of arterio-sclerosis after years of suffering, in the beautiful Lincolndale (Westchester), home of his sister, Miss J. Annette Phillips, where he had received the best of care and loving attention.

He was married to Janet Macpherson Fulton, in Brooklyn, N. Y., on June 23, 1887, who survives him. He is also survived by two sons, George William Macpherson Phillips, and Charles Stuart Phillips, one daughter, Jean Bannerman Phillips, one grandson, Alfred Gordon Phillips, one granddaughter, Janet Fulton Phillips, two brothers, Henry H. S. Phillips, and John R. Phillips, and three sisters, J. Annette Phillips, Margaret I. C. Phillips, and Ellen A. G. Phillips.

Mr. Phillips was elected a Member of the American Society of Civil Engineers on June 23, 1916.

LOUIS HENRY PRELL, M. Am. Soc. C. E.[1]

Died March 18, 1936

Louis Henry Prell was born in Cincinnati, Ohio, on March 28, 1874, the son of Ludwig H. Prell and Maria (Goetze) Prell. He received his preparatory education in the public schools at Cincinnati, and at Mt. Healthy, Ohio.

Mr. Prell began his career in engineering with Frank B. Betts, Civil Engineer, in 1893. During the period, 1893 to 1898, he continued in the service of Mr. Betts, and was engaged in land surveying, sub-division work, and railroad layouts. During this period he was employed in various capacities as Rodman, Chainman, Transitman, and Draftsman. Following his engagement with Mr. Betts, he entered the Ohio Normal University, at Ada, Ohio, in 1899, from which he received the degree of Civil Engineer in 1902.

---

[1] Memoir prepared by H. H. Peters, Esq., U. S. Engr. Office, Cincinnati, Ohio.

In 1901, Mr. Prell was employed as Rodman by the United States Engineer Department, at Cincinnati, Ohio, during his school vacation. On completing his University studies, he re-entered the service of this Department in July, 1902, and from that date until his death, he was continuously employed by the Department, except for short intervals in 1904 and 1905. During this time, his work and accomplishments pertained principally to the canalization of the Ohio River by the construction of a series of locks and dams extending from Pittsburgh, Pa., to Cairo, Ill. In this work, he had a conspicuous part, and rendered capable and valuable service. In the period from July, 1902, to June, 1905, he was engaged in the field, on drafting, and on computations of the original Ohio River survey which established a basis for the present system of locks and dams on the Ohio River.

From July, 1905, to June, 1910, Mr. Prell was Assistant to the Engineer in charge of the design and construction of Lock and Dam No. 37, Ohio River, at Fernbank, Ohio, and from July, 1910, to June, 1913, he was Assistant Engineer in field charge of the completion of that lock and dam, power-house, dwellings, and other features of the reservation. Upon completion of the work at Lock and Dam No. 37, Ohio River, he was assigned as Assistant Engineer in field charge of the construction of Lock and Dam No. 35, Ohio River, which was built under contract. He was engaged on that work during the period from July, 1913, to June, 1916.

In July, 1916, he was transferred to Lock and Dam No. 39, Ohio River, which was under construction by hired labor. He was placed in field charge, and the work was completed under his supervision in December, 1922. In addition to his assignment at Lock and Dam No. 39, Mr. Prell was also the Assistant Engineer in field charge on the construction of Lock and Dam No. 38, Ohio River, during 1921 and 1922.

In February, 1923, he was appointed to the position of Assistant Engineer in charge of the United States Engineer Depot and Repair Yards of the Cincinnati Engineer District, at Fernbank, Ohio. In connection with this project, he completed the construction work on Lock and Dam No. 36, Ohio River, during 1924 and 1925. He was promoted to the position of Senior Engineer on April 4, 1930. The activities of the U. S. Engineer Depot and Repair Yards included the maintenance and repair work on completed Ohio River Locks and Dams Nos. 29 to 39; Kentucky River Locks and Dams Nos. 1 to 14; and the upkeep of steamboats, dredges, and other floating plant of the District. He was engaged on this work at the time of his death.

Through his long and varied experiences on Ohio River lock and dam construction, Mr. Prell acquired special and valuable knowledge of underwater work. He was a useful and respected citizen, a capable engineer, and his passing will be keenly felt by friends and by those who sought his counsel.

Mr. Prell is survived by his widow, Elizabeth Seiter Voris Prell, to whom he was married at Lawrenceburg, Ind., on January 17, 1917, and his step-son, William T. Voris. He is also survived by a sister, Mrs. Emma (Prell) Schroth, and a brother, Frederick Prell.

He was a member of the Masonic Order, McMakin Lodge No. 120, F. and A. M. and Kilwinning Chapter No. 97, R. A. M., at Mt. Healthy, Ohio.

Mr. Prell was elected a Member of the American Society of Civil Engineers on August 31, 1915.

LOUIS E. RITTER, M. Am. Soc. C. E.[1]

DIED JULY 3, 1934

Louis E. Ritter was born on March 14, 1864, at Cleveland, Ohio. After his preparatory schooling he entered the Case School of Applied Science, at Cleveland, from which he was graduated in 1886.

His early experience in engineering was obtained on miscellaneous railroad surveys and construction. This was followed by hydrographic work with the United States Corps of Engineers and the Mississippi River Commission, the rigid training school for so many engineers who later rose to prominence in the profession.

In 1892, Mr. Ritter became associated with the firm of Jennie and Mundie, Architects, of Chicago, Ill., as Structural Engineer. From that time until his death on July 3, 1934, he devoted himself to the problems of building design and construction. The development of the modern skyscraper was taking place during all this period and to Louis E. Ritter, as a pioneer, must be given credit for such development, probably to as great an extent as to any engineer in the United States.

In 1897, he entered private practice as a Consulting Civil Engineer, and, in 1899, became associated with Mr. A. D. Mott under the firm name of Ritter and Mott. Mr. Mott retired in 1917, at which time Mr. Ritter resumed practice under his own name. During the thirty-eight years of his private practice, many of the most important buildings in the United States were designed and constructed under his direction, as Consulting Engineer for practically every prominent architect in the country.

Mr. Ritter possessed a deeply philosophical and analytical mind and was regarded, for many years, as the Dean of the Engineering Profession in the Middle West. He was the unofficial mentor and adviser to the younger men in the profession, who came to him for advice and help on personal as well as on professional matters.

He was a great believer in the necessity of proper organization among engineers to combine for the common good, and was a member of practically all the major professional societies, with which he did yeoman work. The social side of the engineer also received Mr. Ritter's very active encouragement and support. As a prominent member of the Chicago Engineers' Club, his efforts in this direction are lovingly remembered by his many associates.

---

[1] Memoir prepared by I. F. Stern, M. Am. Soc. C. E.

He was married in 1899, and is survived by his widow, Mrs. Mary (Stair) Ritter, and by two children, Louis Stair Ritter, and Frances Hamilton Ritter.

Mr. Ritter was elected a Member of the American Society of Civil Engineers on October 4, 1905.

STEPHEN ALLEN ROAKE, M. Am. Soc. C. E.[1]

Died February 2, 1935

Stephen Allen Roake was born in Peekskill, N. Y., on August 10, 1874, and received his formal education there. He was graduated from the Peekskill High School in June, 1891.

Mr. Roake entered the Engineering Profession in 1892 by way of a job as Rodman for the City and County of New York, continuing in that work until 1895. At that time, October, 1895, he was employed as a Draftsman by the Elmira (N. Y.) Bridge Company, at the Southport Works. This plant later became known as the Elmira Plant of the American Bridge Company and was commonly referred to as the "Old South Works" after the construction of the new plant at Elmira Heights. Between 1895 and 1900 he was engaged in various assignments as a Structural Draftsman, in and out of the Elmira Bridge Company, working for longer or shorter periods with the Union Bridge Company, at Athens, Pa., with Levering and Garrigues, of New York, N. Y., the Pittsburgh Bridge Company, at Pittsburgh, Pa., and the Lehigh Valley Railroad Company.

On April 18, 1901, Mr. Roake was transferred to the Athens, N. Y., Plant of the American Bridge Company, and, on June 30 of the same year, he was sent to the Company's Pencoyd (Pa.) Plant. On January 4, 1904, he was again transferred to the Ambridge (Pa.) Drawing Room of the Company, and on June 4, 1906, he was sent to its Trenton (N. J.) Drawing Room, where he became Squad Boss in charge of all movable bridges assigned to that office.

From this last date (June 4, 1906) to May 15, 1915, although he was normally assigned to the Trenton Plant, Mr. Roake spent several short periods in the New York Designing Office, of the Company. He also received leave of absence for a short period to do special work for Boller, Hodge, and Baird, Consulting Engineers, of New York City. On May 15, 1915, he left the American Bridge Company, severing a connection of fifteen years' standing. He had acquired a thorough knowledge of steel construction, a specialized knowledge of movable bridges, and a wide circle of friends in the steel business.

From 1915 to 1917 Mr. Roake worked for the Celluloid Company, of Newark, N. J., as a Concrete Designer. For a short period in 1917 he was Chief Draftsman at the Bergen Point Iron Works, at Bayonne, N. J. In 1917 he entered the employ of the Southern Pacific Company in the office of the late John Dove Isaacs, M. Am. Soc. C. E., then Consulting Engineer for that Company, in New York City. At first Designer, then Chief Draftsman, he later became Assistant Consulting Engineer, continuing in that capacity until 1925. From 1925 to 1928 Mr. Roake was Office Engineer in the General Office in New York City. After 1928, changes in the organization of the Company resulted in his transfer to San Francisco, Calif., where he acted as Chief Designing Engineer for the Suisun Bay Bridge, built by the Southern Pacific Company to replace car ferries which had long been a "bottle-neck" between San Francisco and the north. Upon the completion of the Suisun Bay Bridge in December, 1931, he entered the office of the San Francisco-Oakland Bay Bridge as a Supervising Design Engineer, in which position he remained until ill health caused him to take a leave of absence in August, 1934.

---

[1] Memoir prepared by J. R. Kelsey, M. Am. Soc. C. E.

"Steve" Roake was christened Stephen Allen Roake, but his friends neither used the long form of his first name, nor realized that he had a second. His structural experience was invaluable to the organization of which he became a part. It was largely through his efforts that the many varied and unprecedented problems which arose in connection with the 1400-ft cantilever structure (one of the largest of such structures in the world), between Yerba Buena Island and Oakland, Calif., were solved. Many of the larger joints of this structure are his designs. In the face of increasing physical disability he prosecuted this work until he was able to feel that the essentials of it were behind him. During this time he worked with the knowledge, imparted by previous illness, that overstrain was dangerous to his health. Throughout his life "Steve" had been handicapped by extremely poor eyesight which rigidly limited his pleasures and which made his measure of success the more remarkable. Those who worked with him marveled at the energy with which he overcame his inability to see properly.

He is survived by his widow, Mrs. Katharine Griffes Roake, and two sons and two daughters.

Mr. Roake was elected an Associate Member of the American Society of Civil Engineers on June 6, 1911, and a Member on March 13, 1917. He was also a member of the American Railway Engineering Association.

JAMES WINGATE ROLLINS, Jr., M. Am. Soc. C. E.[1]

Died November 19, 1935

James Wingate Rollins, Jr., was born in West Roxbury, Mass., on October 17, 1858, the son of James Wingate and Sophia Webb (Hutchings) Rollins. Although born in Massachusetts, Mr. Rollins belonged to the well known New Hampshire family of that name, which traces its lineage to the earliest settlers. James Rawlins, the founder of the family in America, immigrated to this country from England in 1632 and first settled in Ipswich, Mass., but moved shortly afterward to Dover, N. H.

---

[1] Memoir prepared by Clarence Blakeslee, M. Am. Soc. C. E.

Mr. Rollins was in direct descent from the Hon. Ichabod Rollins who held various public offices in Revolutionary days and was a member of the Convention when, in January, 1776, it resolved itself into an independent State Government. He was the first Judge of Probate under the new Government and held the position until 1784. It was in his generation that the spelling of the name was changed from Rawlins to Rollins. Mr. Rollins' father was graduated from Dartmouth College, at Hanover, N. H., and practiced law in Boston, Mass., for many years. His own education was obtained in the public schools, and upon graduation from the High School at West Roxbury, he entered the Massachusetts Institute of Technology, taking the Civil Engineering Course, and was graduated in the Class of 1878. During his school and college years, he was an enthusiastic baseball and football player.

Following his graduation from college he was employed by the Massachusetts Central Railroad Company on survey and construction work. In 1882, he went to Virginia as Chief Engineer for the Atlantic and Danville Railroad Company, which position he held until 1886. After leaving the service of this Company (later part of the Southern Railway System in Virginia), Mr. Rollins entered that of the Union Pacific Railway Company through his acquaintance with the late Charles Francis Adams, then President of the Company, and was in charge of important construction in Kansas. He then was transferred to the Union Pacific Railway in the Northwest, where he was engaged on very difficult location in the Bitter Root Mountains.

Mr. Rollins was next sent to Wyoming, and started construction of a branch line of the Union Pacific from Fort Steele up the North Platte River toward the North Park of Colorado. When this work was suspended, Mr. Rollins was called into Omaha, Nebr., to settle with the contractors. This being accomplished, after a few weeks he organized a locating party and was sent to Wyoming to continue the location of the line up the North Platte River to the North Park of Colorado—a most difficult piece of engineering.

After the completion of this work, he was sent with his party of engineers to the top of the Continental Divide to re-locate the Denver, South Park, and Pacific Railway, a narrow-gauge branch of the Union Pacific. This work started near Leadville, Colo., and continued down Ten-Mile Creek nearly to Breckenridge, Colo. The party was then taken to Omaha and disbanded.

Shortly afterward, Mr. Rollins spent some time making surveys for a projected railroad in the Adirondack Mountains, and then returned to Boston and entered the service of the Old Colony Railroad Company (later a part of the New York, New Haven and Hartford System). During his employment with the Old Colony Railroad Company he prepared plans for the four-track work from the Back Bay Station, in Boston, out through Forest Hills, and, later, was Resident Engineer on this work when it was started. He remained there until he was transferred to take charge of grade-crossing elimination work at Brockton, Mass.

In 1897, Mr. Rollins left the Old Colony Railroad Company to join the organization of Holbrook, Cabot, and Daly; in 1900, he became a partner and the firm name was changed to Holbrook, Cabot, and Rollins. He was President of this Corporation from 1900 until its dissolution in 1928.

In the early days of his contracting career he developed and patented several unique and highly successful pieces of construction equipment, notable among which was a submarine pile-cutting device for pile foundations, which operated in depths as great as to 40 ft, and also buckets for use in placing concrete under water. He had the ability and foresight to surmount the most unusual construction difficulties. He liked to attempt the most perplexing operations and on numerous occasions would be the only bidder on difficult foundations.

From 1900, the firm of Holbrook, Cabot, and Rollins, under Mr. Rollins as President, successfully constructed many large structures in New England and New York State, among the most important being the West Boston Bridge, over the Charles River; the Charles River Dam and Locks at the lower end of the Charles River; the four-track drawbridge at Fort Point Channel, for the New York, New Haven and Hartford Railroad Company; the Neponset Railroad Bridge; the Lechmere Viaduct; the Boston Fish Pier; the Larz Anderson Bridge, near the Harvard Stadium; the Thames River Railroad Bridge, at New London, Conn.; the Portland-South Portland Bridge, in Portland, Me.; and the Boston Dry Dock, the largest dock of its kind on the Atlantic Coast.

To quote from an article on his career that appeared in 1917:

> "If Mr. Rollins has a hobby it is the surmounting of difficulties by the use of resourceful expedients. He uses keen judgment and has inaugurated many improvements in the work under his supervision.
>
> "J. W. Rollins has a slogan: 'Best plant, best work, best results.' An important factor in the success of Mr. Rollins is his principle of profiting by failures or disappointments if they occur, and this fact should be an inspiring example to other contractors, especially the young ones.
>
> "The surest road to success is to do the best piece of work possible and then welcome suggestions for possible improvement. This was characteristically demonstrated on recent construction where it was necessary to re-design and rebuild: Mr. Rollins cheerfully explained the original mistakes and their corrections, satisfied in having done as well as possible at the beginning, yet ready to share with others the knowledge acquired by experience. Among his recent improvements is one that will be standard in future construction, a detachable concrete bottom for floating caissons, materially improving the footings of many submerged bridge piers."

From 1912 until the World War years, many important projects were completed by the firm in New York, N. Y., among them Dry Dock No. 4 at the Brooklyn Navy Yard and an important section of the New York Subway System, at Times Square.

Mr. Rollins' activities during the war years included the construction of the wharf areas of the Boston Army Base and the New Orleans (La.), Army Base; and the Squantum Destroyer Plant, at Quincy, Mass. His firm was also one of the many contracting firms engaged at the famous Hog Island Shipyard, near Philadelphia, Pa.

Following the World War came the foundations for the Memorial Bridge across the Piscataqua River, at Portsmouth, N. H., a most difficult undertaking of sinking two pneumatic caissons in 90 ft of water, with a 5-mile per hr tidal current running in alternate directions.[2] Other work followed, including the outfall end of the Passaic Valley Sewer Tunnel, at Bayonne, N. J., which was the last large contract accepted by the Holbrook, Cabot, and Rollins Corporation before its dissolution.

In 1924, Mr. Rollins became associated with C. W. Blakeslee and Sons, of New Haven, Conn., and the Blakeslee Rollins Corporation was founded. He served as Vice-President and Treasurer of this firm until his death. This Corporation did considerable work under his direction, including the construction of water-front properties for the Bethlehem Shipbuilding Corporation; piers for the Mid-Hudson Bridge, at Poughkeepsie, N. Y.; underpinning of the Boston Public Library; and the construction of piers for the highway and railroad bridges over the Cape Cod Canal.

During the construction of the Mid-Hudson Bridge, one of the cassions weighing about 20 000 tons listed to an angle of 45° and was almost wholly submerged in the waters of the Hudson River. The successful righting of this caisson, conducted under Mr. Rollins' direction, is an epic in construction history. Many engineers said that it could not be done and urged that the caisson be destroyed, but after a year's work and tremendous expense, Mr. Rollins proved his contention, and the bridge now stands on this pier which he was urged to abandon.

He tried to do work quickly and well, and to assure his client, whether it was public or private work, of what he termed a "good job." He did this to the end, even though at great personal loss to himself. He earned that confidence which so few contractors ever gain, in that he never failed to complete a project, nor to give the owner the best possible job.

Mr. Rollins was the author of several papers describing his construction activities, one of which, describing construction of the Mid-Hudson Bridge piers, was awarded the Desmond FitzGerald Medal by the Boston Society of Civil Engineers as being the best of the year. His articles on the "Relationship Between Engineers and Contractors" were widely read and contained much homely philosophy on this subject.

Mr. Rollins was a member of the Boston Society of Civil Engineers, to which organization he was elected in 1895. He was at one time President of the University Club of Boston; Vice-President of the Boston City Club; and President of the Boston Society of Civil Engineers, Technology Alumni Association, and Technology Clubs, Associated. He had twice served as a term member of the Corporation of the Massachusetts Institute of Technology. At the time of his death he was also a member of the Engineers Club of Boston, the Milton Club, and the Hoosic Whisick Club. For many years previously he had belonged to the Brookline Country Club, the Cohasset Golf Club, the Algonquin Club, and the Automobile Club, and had been President of the Crow Point Golf Club, in Hingham, Mass., where he had a summer home, for twenty-seven years. He was a member of the Board of Managers of the

[2] "Difficult Foundation Problems for Piscataqua Bridge at Portsmouth, N. H.", by James Wingate Rollins, Jr., M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 443.

Boston Boys Club, and was also much interested in the civic welfare of his home town, Milton, Mass., where he had served for a great many years as Chairman of the Sewer Commission, and also on the Milton Committee on Employment.

In 1892, Mr. Rollins was married to Clara Boyden Clark, the daughter of the Rev. Nathaniel G. and Elizabeth Sargent Worcester Clark. Mrs. Rollins, their daughter, Elizabeth Sargent Rollins (Mrs. O. H. Saunders), and their son, Wingate Rollins, survive him.

Among Mr. Rollins' outstanding characteristics were his never-failing loyalty, his sense of fair play, his sincerity, and his charity of judgment. He had an inherent belief in the honesty of his fellow men, and was reluctant to believe evil of any one. His devotion to his highest ideals, both in his profession and in his daily living, was unfaltering. His courage was great, and he would fight to the end for a cause he believed to be just. Yet when disappointments came, he always met them bravely, with a gallant spirit that harbored no bitterness. Added to these qualities were his modesty, his natural optimism, his sense of humor, and his sympathetic, genial ways. He was indeed, as one of his friends has said, "not only a builder of works, but a builder of friends", and the same friend also added that,

> "Out of this life of active adventure and strenuous work a character had developed seemingly strangely at variance with the rigorous circumstances of his exacting responsibilities. His innate nature was both delicate and sensitive. His heart responded instinctively to the emotions of pity and sympathy for the distressed and the unfortunate, and he gave fully of his resources to the relief of those in need. He loved the beautiful and admired the finer qualities of others. His spirit remained youthful to the end, and attracted to him a host of friends from every walk of life. It is most significant that those who knew him best loved him most. His passing leaves an aching void in many hearts that will never be completely healed."

Mr. Rollins was elected a Member of the American Society of Civil Engineers on November 7, 1900.

HENRY BEDINGER RUST, M. Am. Soc. C. E.[1]

DIED JANUARY 17, 1936

Henry Bedinger Rust was born on December 13, 1872, at "Rockland", near Leesburg, Va., the family home built by his grandfather, General George Rust, about 1820. He was a son of the late Colonel Armistead T. M. Rust and his wife, Ida Lee, and a descendant of two of the pioneer families of Virginia, both of which had taken an active part in public life.

His grandfather, General Rust, served as a member of the Virginia Legislature from 1819 to 1824, and as Superintendent of the United States

---

[1] Memoir prepared by The Koppers Company, Pittsburgh, Pa.

Arsenal at Harpers Ferry from 1829 to 1837. His father was graduated from the United States Military Academy at West Point, N. Y., in 1842, and served at Fort Gibson, Indian Territory, as a Lieutenant in the First Dragoons. He resigned from the Army about three years later and engaged in farming near Leesburg, but, in 1861, he was commissioned a Colonel in the Confederate Army and served throughout the Civil War. Mr. Rust's mother was a member of the Lee family of Virginia, and a cousin of General Robert E. Lee. Two members of this family, Richard Henry Lee and Francis Lightfoot Lee, were signers of the Declaration of Independence.

Mr. Rust was one of a large family which, like most Virginia families, had suffered serious reverses during the long struggle between the North and the South. With money scarce and educational facilities very limited, he was able to obtain but a meager education in the local country schools, although his private study continued throughout his lifetime.

At the age of 18 he secured a position as Axeman on an Engineer Corps in the employ of the City of Pittsburgh, Pa., which was the start of his long and successful engineering career. While on this work his spare time was devoted to the study of engineering subjects, and he used every opportunity to become familiar with the transit and the level. By private study and close application to work he became, successively, Chainman, Rodman, and Transitman, and, at the age of 21, Assistant City Engineer.

At this time the City of Pittsburgh was starting the development of Schenley Park, a rugged, hilly tract of about 600 acres located in the eastern section of the city. Mr. Rust was in charge of this work, which included the location, grading, and paving of roadways, the erection of steel arch bridges with heavy masonry approaches, and the construction of park buildings and sewers. The design and construction of an ornamental masonry bridge with a single arch of 150-ft span, carrying an 80-ft roadway, was perhaps the outstanding feature of this work.

On completion of the work in Schenley Park, Mr. Rust was transferred to the Bureau of Construction, which had charge of designing and building pavements, sewers, and bridges for the City. One of his duties required a careful study of materials and methods with a view to improving the quality of asphalt streets. Following this, he revised the contract forms and prepared complete specifications and standard designs for sewers, pavements, and other requirements of the City. At various times he was in charge of different sections of the city work, such as the construction of sewers, field work in connection with new bridges, paving of streets, and the completion of Bigelow Boulevard. For a time he had charge of the inspection of materials and workmanship on all construction projects.

In 1901, the Colorado Fuel and Iron Company initiated a program for greatly expanding its works at Pueblo, and Mr. Rust was employed as Superintendent of Construction. The existing plant included three small blast furnaces and auxiliary equipment. The new Superintendent of Construction was charged with the responsibility of removing the old blast furnaces, boiler houses, etc., and of building three new blast furnaces, with the necessary boiler and engine houses; also new rail and Bessemer mills. Many of the new buildings replaced existing structures, and the work presented many difficulties. However, Mr. Rust so organized and co-ordinated construction activities that the improvements were carried out without delay to regular operations.

He returned to Pittsburgh early in the summer of 1903 and succeeded his brother, Edwin G. Rust, as Vice-President and General Manager of the Rust Boiler Company, which the latter had organized early that year with the support of Messrs. H. C. and W. C. Fownes, for the manufacture and sale of the Rust Water Tube Boiler, designed and patented by him. Mr. Rust shared the office of the Messrs. Fownes and began his task of promoting the Rust boiler. He first arranged with the Riter-Conley Manufacturing Company to manufacture this boiler, at its Leetsdale Plant, and then built up an engineering, erection, and sales organization. He did most of the selling himself and as the Rust boiler was especially adapted to utilize blast-furnace gas as a fuel, many steel plants purchased large installations.

The Rust boiler was just becoming established in the trade when a competitor instituted suit for infringement of patents. This suit lasted about two years, but, finally, Mr. Rust won the decision. By this time the business had grown sufficiently in volume to require a plant of its own, and, in 1906, the Company purchased a site at Midland, Pa., and built a large modern boiler shop. The organization and volume of business continued to grow and by 1908 was quite a factor in the boiler industry, so much so that its principal competitor started negotiations for the purchase of the Company. The business was sold late that year to the Babcock and Wilcox Company, with which Company Mr. Rust became associated as Special Representative, with headquarters in Pittsburgh.

In 1914, with Messrs. H. W. Croft and Hamilton Stewart, he developed a plan to acquire the H. Koppers Company, an engineering and contracting company, with headquarters in Chicago, Ill. This Company was engaged in designing and building by-product coke, benzol, and tar-distilling plants under patents of H. Koppers, of Essen, Germany. Mr. Rust saw very clearly the great possibilities for the development of this business, and with the co-operation and backing of Messrs. A. W. and R. B. Mellon, it was taken over the latter part of 1914. Mr. Rust was made President and a few months later the offices were moved to Pittsburgh, bringing a total of 82 men from Chicago. It developed rapidly into the outstanding organization in its particular field, which includes designing and building of by-product coke, gas, tar, and other industrial plants, mining and production of bituminous coal, and the manufacturing and merchandising of coke, tar, gas, and other coal by-products. Later, the corporate name was changed to The Koppers Company and, at the end of 1935, employees of the Company and its subsidiary and affiliated interests numbered more than 28 000.

The business grew to be one of the most successful enterprises of Pittsburgh and one of the great engineering and manufacturing organizations of the United States. The interests of Messrs. Croft and Stewart were acquired by Messrs. C. D. Marshall and H. H. McClintic in 1919. Early in 1929, the Company moved into its new 32-story office building. Mr. Rust continued as President of The Koppers Company until the latter part of 1933, when he was made Chairman of the Board, which position he held at the time of his death.

The by-product coke oven has now practically replaced the old-fashioned bee-hive coke oven, thereby effecting great savings through by-products, such as tar, motor fuel, creosote, benzol, toluol, etc., which were formerly wasted. As many of these products entered directly into the manufacture of explosives and other war materials, the development of this industry under the direction of Mr. Rust and his associates at this particular time was of material help to the United States and the Allies in the World War.

Mr. Rust was a man of vision and great constructive ability. He believed that no industry could succeed except through leadership in its own field, and by leadership he meant not the development of a large organization, but rather the development of the technical aspects of its business. In 1916, he was convinced that The Koppers Company should build and operate plants of its own, and two such plants were built—the Seaboard By-Product Coke Company, at Kearny, N. J., supplying gas to the Public Service Corporation of New Jersey, and the Minnesota By-Product Coke Company, at St. Paul, Minn., supplying gas to the St. Paul Gas Light Company. Similar plants were built later at Montreal, Que., Canada, Boston, Mass., New Haven, Conn., Brooklyn, N. Y., Philadelphia, Pa., Hamilton, Ohio, and Chicago. The coke from these plants was marketed largely for domestic fuel.

In 1920, to assist the Peoples Gas Light and Coke Company to overcome difficulties due to conditions in the gas industry, he organized the Chicago By-Product Coke Company, to finance, build, and operate a large by-product plant in Chicago. This plant was largely instrumental in enabling the Gas Company to meet adequately the rapidly growing demands for its service.

Mr. Rust's progressive spirit was typified by his support of Joseph Becker's design of a new coke oven, since known as the Becker oven. At the time the Koppers oven was at the peak of its popularity, he recognized the merit of the Becker oven and, with his support, this oven was developed.

Soon after the Koppers organization had moved to Pittsburgh, a Fellowship was established at the Mellon Institute of Industrial Research to study coal carbonization and utilization of the by-products. With this Fellowship as a base, a strong research organization was developed, with the necessary laboratory and field forces of men with good training and analytical mental processes. This organization developed processes of marked value, for many of which patents were secured. These processes covered the entire field of liquid purification of gases and resulted in basic patents through which The Koppers Company was recognized as a leader in this field. Fertilizer research and soil and crop production were given careful study, and an experimental farm was placed in operation.

The testing and evaluation of coal for by-product qualities proceeded both at laboratory and plant; methods were developed for making good coke from what had hitherto been regarded as poor coal; studies were made of various coals and their qualities, through which conclusions were reached as to the best coals for a given plant from an economic standpoint. The tar industry was carefully surveyed, new products were introduced, and the manufacture of pitch coke was brought to a high standard of quality. Benzol plants were improved in output and quality of product and, during the World War, a process was developed for the recovery of toluol from water-gas operation that was invaluable to the Nation.

Starting with a small designing and constructing organization, the new business grew, through Mr. Rust's foresight and vision, to a complete and integrated operating unit. In the operation of by-product coke ovens, coke, gas, and various by-products are produced. The coke is marketed for blast furnace use and for domestic heating. To secure the quality of coke needed for these and other specific purposes, certain grades of coal and certain mixtures of high and low volatile coals are required. Mr. Rust realized that to insure an adequate supply of the proper kinds of coal the Company should have its own coal-producing properties. Such properties were acquired from time to time until the Company now ranks second in the United States in the commercial production of bituminous coal.

The gas is sold to distributing companies, but various objectionable substances must first be removed in order to make it suitable for domestic or commercial use. Processes for such purification of gas were developed by The Koppers Company and are now used throughout the gas industry.

Tar obtained in the purification of coke oven gas is refined into many widely used products. The Koppers Products Company purchases the crude tar from Company plants, as well as from many independent plants, refines it into various saleable products and markets them. One of the products is creosote oil, used principally in timber preservation, and another subsidiary, the Wood Preserving Corporation, is the principal user of this creosote oil.

From time to time, as seemed expedient, other businesses were acquired which would fit into the operation as a whole, either as producers of materials required by other units, or as users of products for which a market was needed.

Mr. Rust was outstanding in his character, integrity, and loyalty. He had a remarkable understanding of human nature and was deeply interested in his fellow men and their problems. He gave unstintingly of his time and strength in the interest of any employee or friend who needed help. Perhaps his greatest achievement lay in the confidence which he inspired in others through his ability to understand, to sympathize, and to help.

He was impressed with the importance of placing responsibility on the shoulders of younger men in order to develop them for greater usefulness. In appointing operating heads for subsidiary companies he endeavored to select young men of real capacity to whom practically the entire management of their operations could be entrusted. His relations with employees, and especially with labor, were so eminently fair that practically no labor difficulties arose during the period of his management.

In recognition of Mr. Rust's character and attainments Syracuse University, Syracuse, N. Y., conferred on him the honorary degree of Doctor of Engineering in 1930, and, in 1934, Oglethorpe University, Atlanta, Ga., conferred on him the honorary degree of Doctor of Commercial Science.

In addition to his activities in business and industry, Mr. Rust took a substantial but unassuming part in nearly all movements for the good of his community and his fellow men. He was especially interested in St. Barnabas' Free Home, at Gibsonia, Pa., the National Cathedral, at Washington, D. C., and many other good works. He was a member of Calvary Protestant Episcopal Church, at Pittsburgh, and served on its Vestry for many years. He was also a member of St. James' Church, at Leesburg, Va., and served on its Vestry, as did his father before him. Deeply religious himself, he was a great influence for good, particularly among the younger people whom he met and counted his friends.

Mr. Rust was married to Elizabeth S. Watkins, of New York, N. Y., in 1901. He is survived by his widow and one daughter, Mrs. Stanley N. Brown, of Pittsburgh; three grandsons, Henry B. R., Stanley N., and Fitzhugh Lee Brown; two sisters, Mrs. T. W. Edwards, of Leesburg, Va., and Mrs. John D. Follett, of New York City; and six brothers, Captain Armistead Rust, U. S. Navy (*Retired*), of Boston; George Rust, of Salt Lake City, Utah; William F. Rust, of Leesburg; E. J. Lee Rust, of Birmingham, Ala.; E. Marshall Rust, of Washington, D. C.; and S. Murray Rust, of Pittsburgh.

Services were held at Calvary Church, Pittsburgh, on Sunday, January 19, 1936, Dr. Edwin J. van Etten officiating. Following this service Dr. van Etten accompanied the family to Leesburg, where he again conducted short services at "Rockland", the home of Mr. Rust, and at Union Cemetery. These services were attended by men prominent in the industrial and financial affairs of the country and by many friends and representatives of his business organizations, who came from distant points.

Mr. Rust was elected an Associate Member of the American Society of Civil Engineers on April 6, 1898, and a Member on April 1, 1903.

CHARLES SCHULTZE SAMPLE, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 25, 1935

Charles Schultze Sample, the son of John and Maria (Kraft) Sample, was born at Philo, Ill., on June 1, 1873. His family having moved to Indiana during his boyhood, it was natural that when he determined upon an engineering career, he should choose Purdue University, at Lafayette, Ind. At Purdue he became one of the now famous "Dorm Devils", the membership of which included so many of the University's noted sons. Solving the engineering problems connected with the famous "tank scraps" were not the only difficulties encountered at Purdue, for young Sample played tackle and halfback on the University football team. Those were the days of the flying wedge, mutton chop whiskers, and Mike and Katy Golden, a brother and a sister who came from Ireland to Purdue and whose interest in athletics, particularly football, was outstanding.

---

[1] Memoir prepared by a Committee of the St. Louis Section, consisting of Baxter L. Brown and W. J. Burton, Members, Am. Soc. C. E.

After his graduation from the School of Civil Engineering in 1899, he served for two years as Rodman and Transitman on construction for the Chicago and Northwestern Railway Company.

In 1901, Mr. Sample was employed by the St. Louis Valley Railway Company on the location of its lines from East St. Louis to Thebes, Ill., and, later, as Resident Engineer on the construction of the road. On this work he demonstrated his ability to such extent that upon the purchase of the railway, in 1902, by the Missouri Pacific Railway Company, he was retained by that Company and upon the completion of the work, was transferred to the construction of its Gurdon and Fort Smith Branch, in the semi-mountainous district of Western Arkansas. Later, he was in charge of important terminal construction at Hoisington, Kans., and, in 1913, was placed in charge of the location and construction of the 42-mile line in Eastern Arkansas, known as the Marianna Cut-Off. The construction of this line was especially difficult because of high water in the Mississippi River, and, at one time, before the line was finally completed, it was possible to make a trip over the right of way by steamboat.

For brief intervals in 1908 and 1915, Mr. Sample left the Missouri Pacific Railway Company to engage in railroad construction for the Dalhoff Construction Company and for the Garden City Sugar and Land Company, the latter work being in Western Kansas. Following the latter engagement, Mr. Sample returned to the Missouri Pacific to become Chief Pilot Engineer in connection with the inventory and valuation of the lines being made by the Interstate Commerce Commission.

When an extensive program of improvement work was undertaken by the Missouri Pacific Railway Company in 1921, Mr. Sample was made Construction Engineer. His experience in dealing with contractors, his characteristic ability to secure the loyal support of subordinates, his common sense, good judgment, and fairness, all made him peculiarly fitted for this responsibility. Among the larger projects under his direction as Construction Engineer were the $18 000 000 double-track project between St. Louis and Jefferson City, in Missouri, and the heavy line and grade revision work between Kansas City, Mo., and Pueblo, Colo., which cost more than $5 000 000.

In 1902, Mr. Sample was married to Helen Brewster, of Corydon, Ind. Their two sons, Dr. Charles S. and Robert Brewster, and their daughter, Mrs. Mary Baxter Conrad, survive him. Mrs. Sample died in 1923. In 1926, Mr. Sample was married to Alice Alter, of Kirkwood, Mo., the St. Louis suburb where he made his home, who also survives him. He died on September 25, 1935, and was buried in Oak Hill Cemetery, at Kirkwood.

Mr. Sample was a member of the American Railway Engineering Association and the St. Louis Railway Club. He served as Alderman of Kirkwood for five years, and as a member of the Board of Public Works. He was a Mason (Chester, Ill.), and an active member of the First Presbyterian Church of Kirkwood.

He will be remembered by his many friends and associates for his thoughtful and kindly concern for all with whom he came in contact, and his mindfulness of the teachings found in the Sixth Chapter of the Gospel according to St. Matthew.

Mr. Sample was elected a Member of the American Society of Civil Engineers on December 22, 1930.

WILLIAM LUTHER SIBERT, M. Am. Soc. C. E.[1]

DIED OCTOBER 16, 1935

William Luther Sibert was born at Gadsden, Ala., on October 12, 1860, the son of William J. and Marietta (Ward) Sibert, and was the descendant of three generations of pioneers. His great-grandfather was a South Carolina Revolutionary soldier; his grandfather moved from South Carolina to Alabama with the typical covered wagon of pioneer days; his father was a Confederate soldier; all sturdy stock who obtained their livelihood primarily from the soil.

Young Sibert's boyhood was spent on the farm, and he became accustomed early to physical labor. His education in the country schools was meager, as there were no high school facilities in Gadsden at that time. However, as the advantages of a higher education were desired for the boy, a tutor was engaged, and William Sibert entered the University of Alabama, at University, Ala., in 1878.

After two years at the University of Alabama, he entered the United States Military Academy, at West Point, N. Y., from Alabama, on July 11, 1880. As a Cadet he was studious, reserved, tolerant, and loved by all; he became known affectionately as "Goliah" due to his splendid physique and the fact that he roomed with the late Colonel David Gaillard, U. S. Army (*Retired*): "David and Goliath living together." He was graduated on June 15, 1884, standing seventh in a class of thirty-seven members, and was commissioned a Second Lieutenant in the Corps of Engineers.

On the completion of his graduation leave, in September, 1884, Lieutenant Sibert reported at Willets Point, N. Y., for duty with the Battalion of Engineers, and to pursue the course in the Engineer School of Application from which he was graduated in 1887. He left Willets Point on July 6 of that year, and from this time until the Spanish-American War, was engaged almost exclusively on river and harbor work.

After a period of duty as an Assistant to the Officer in Charge of the District at Louisville, Ky., from July, 1887, to April, 1888, he served in a similar capacity at Cincinnati, Ohio.

On April 7, 1888, he was promoted to the grade of First Lieutenant. The following December, Lieutenant Sibert was placed in local charge of improvement works on the Green and Barren Rivers, near Bowling Green, Ky., where he remained until August, 1892. The next two years were spent at Detroit, Mich., where the "Soo" Locks and channels connecting the Great Lakes were under construction. He was placed in local charge of the construction of the ship channel from the foot of Lake Huron to the head of Lake Erie. In August, 1894, he was transferred to Arkansas and placed in charge of the River and Harbor District at Little Rock, one of the first officers to be placed in charge of a district while in the grade of First Lieutenant. His responsibilities in this position included all improvements on the Arkansas, White, Black, Current, and St. Francis Rivers, in Arkansas, Missouri, and Indian Territory. During this period of duty he was promoted to the grade of Captain on March 31, 1896.

---

[1] Memoir prepared under the direction of Major General E. M. Markham, Chf. of Engrs., U. S. Army, M. Am. Soc. C. E.

In September, 1898, the Army took advantage of the wide experience in practical engineering which had been afforded Captain Sibert in the preceding ten years, and he returned to Willets Point, as an Instructor in Civil Engineering in the School of Application; he was also placed in command of Company B of the Battalion of Engineers. Shortly after the declaration of war against Spain, Captain Sibert officially requested that he be assigned duty at the front with the field forces, but it was not until July 5, 1899, that he left the station at Willets Point for field service. On this date he left the post in command of Company B, Battalion of Engineers, en route to the Philippine Islands for operations against the insurgents.

Much was crowded into the brief period between his departure from Willets Point and May 31, 1900, when he returned to the United States. During this period Captain Sibert participated in several minor actions in the field operations in Luzon and distinguished himself as an engineer soldier, being highly commended by his superior officers not only for his professional work, but for his actions in the firing line. He served in both the First and Second Divisions of the Eighth Army Corps, and from September 2, to November 25, 1899, was Chief Engineer of the Department of the Pacific, in addition to commanding the Engineer Battalion. He was also for some time Chief Engineer of the Eighth Army Corps. He accompanied General Schwan's Brigade against the insurgents in Northern Luzon, from October 7 to 14, 1899; and in his campaign through Cavite, Laguna, Batangas, and Tabayas Provinces, in Southern Luzon, from January 2, to February 5, 1900. In regard to his work, General Schwan in his official report on the latter operations stated: "I cannot commend too highly the work of this officer; his constancy, his tact, his professional skill are worthy of special recognition." At a later date, this same officer in a letter to the Adjutant General, U. S. Army, wrote:

> "I know of no individual officer who contributed more to the success of the movement than did Captain William L. Sibert, Corps of Engineers. Not only as an engineer officer, in the surmounting, removal, and avoidance of road obstacles, were his services brought into requisition: His good work extended to and had the effect of facilitating and expediting every operation that was undertaken in the course of the campaign. To me he proved, as he did on a former expedition, a safe and most valuable prop. I cannot sufficiently empha-

size my appreciation of the services of this accomplished, discreet, and withal modest officer.

"Though my acquaintance with the officers of the Army is quite extensive, I know of none who possesses the qualities requisite in the command of a volunteer regiment in a higher degree than Captain Sibert, or who, by reason of his past service, better merits the appointment of colonel of volunteers. It is hoped that the War Department may see its way clear in the future to recognize in some marked way the excellent work he has rendered in the field and with troops."

From February 10 to April 20, 1900, Captain Sibert was Chief Engineer and General Manager of the Manila and Dagupan Railway, during which period he reconstructed, re-organized, and operated the line until it was transferred back to its owners. He sailed on the transport, *Meade*, for the United States on May 5, 1900.

Following his return to the United States, Captain Sibert was assigned as District Engineer, at Louisville, Ky., and took over his duties in July, 1900. For the next seven years he was to be actively engaged on engineering works. In December, 1901, he was transferred to Pittsburgh, Pa., to become District Engineer of that important District, in which capacity he served until March, 1907. He was largely responsible for the adoption and development of the 9-ft channel on the Ohio River. The proof of his outstanding engineering ability and high character are amply borne out by letters from residents of the District in which he served written to officials of the Government and which are on file in the War Department. While in charge of this District, he was promoted to the grade of Major on April 23, 1904.

During a severe flood of the Allegheny River in January, 1907, Major Sibert's prompt and energetic action in demolishing part of Dam No. 3, at Springdale, Pa., was undoubtedly the means of saving considerable property. The following letter from the President of the Heidenkamp Mirror Company to the Engineer Department is of interest in this connection:

"We desire to express our appreciation of the prompt and strenuous measures used by your department to prevent damage to property by the recent washout around Dam No. 3 in the Allegheny River at Springdale, Pennsylvania. The river had washed out around the north end of the dam and for two days it continued to carve out a new channel, the force of the water steadily growing in power until it seemed as if all property below the dam, between the river and the railroad, for the distance of a mile, must be swept into the river. It also seemed as if the railroad communication between here and the city would be officially cut off.

"We cannot too strongly commend the energy and zeal of Major William L. Sibert during this crisis. His recommendation that the top of the dam be blown off with dynamite in order to divert the current, was most wise and resulted in saving a large amount of valuable property. Our factory seemed to be right in the river's path, and while we have lost considerable land and several of our smaller buildings, yet our main buildings are intact and our factory has continued in operation.

"We feel that words of highest commendation are due to these men who have labored so earnestly and so wisely to keep the river within its proper bounds."

The Chief of Engineers, in referring to this commendation in a communication to the War Department, declared:

> "The Chief of Engineers wishes to add that this commendation of Major Sibert is well deserved, and that in the entire conduct of this difficult and dangerous matter Major Sibert has shown ability and judgment of a high order."

In March, 1907, Major Sibert, selected as one of the three Army engineers to build the Panama Canal, was appointed a member of the Isthmian Canal Commission. This assignment can be considered as a most definite proof of his ability and integrity. He served as a member of this Commission until April 1, 1914, a period of seven years. On September 21, 1909, he was promoted to the grade of Lieutenant Colonel.

As Division Engineer of the Atlantic Division of the Panama Canal he was directly in charge of the construction of the Colon Breakwater, the channel excavation from Gatun to the Atlantic Ocean, the Gatun Dam, and the Gatun Locks. He had a fanatical zeal for his work, appearing daily on the job, and instilled a tremendous spirit of competition in the force operating under his supervision. He took an active interest in the life and welfare of his subordinates of all classes. It is a tribute to Colonel Sibert's ability as an engineer that the Atlantic Sector was the first part completed, particularly as it had been estimated by the Chief Engineer that the construction of the Gatun Locks and Dam would require two years longer than the remainder of the Canal.

In 1914, as the result of a joint resolution of Congress, the Chief of Engineers was called upon to recommend an officer of the Corps of Engineers for appointment as Chairman of a Board of Engineers to assist the Republic of China in making an examination and report on the reclamation of the Huai River for the prevention of floods and resultant famines. With due appreciation of the responsibility of such an assignment, the great difficulties involved in the conduct of the work to be undertaken, and the necessity of appointing an officer of national repute, Colonel Sibert was recommended. His appointment was highly satisfactory to the American Red Cross which was sponsoring and assisting in the work; and he was granted leave of absence to enable him to accept the appointment. This work engaged his attention from June 11 to October 15, 1914, although the outbreak of the World War disrupted the Red Cross plan.

Following his return from China, Colonel Sibert assumed the duties of Division Engineer, Central River and Harbor Division, and District Engineer, 2d Cincinnati District. He was again active in the solution of the problems of the Ohio River and became a member of a Board on the construction or modification of locks and dams on that river, and also a member of a Board on flood conditions in the valley of the Ohio River and in the drainage area of Lake Erie.

On March 4, 1915, Colonel Sibert received the thanks of Congress for having "rendered distinguished service in constructing the Panama Canal", an honor of which he was justly proud. In addition, he was at the same time rewarded by being promoted to the rank of Brigadier-General of the Line. He was then ordered to the Pacific Coast where he assumed command of the Pacific Coast Artillery District, on March 4, 1915. He remained on this duty until shortly after May 15, 1917, when he was promoted to the rank of Major General.

General Sibert's first duties following his relief from assignment on the Pacific Coast were in Washington, D. C., with what later became the Headquarters of the American Expeditionary Force. On June 8, 1917, he assumed command of the First Division and shortly afterward sailed for France with the first American troop units to enter the theater of active operations. He remained in command of the Division through the arduous preliminary training period and brought it to a high state of effectiveness.

He participated in action with the Division in the Luneville Sector, October 21 to November 20, 1917. In the words of his Chief of Staff, Major General Hanson Ely:

"His sterling character was the admiration of all his subordinates. He commanded the division most efficiently, without fear, favor, or affection; while working it to the limit under the circumstances. He tempered justice with mercy and showed such discriminating consideration for his subordinates that all were sorry to see him go. Those who knew his excellent work under the many handicaps of the early training were convinced that the division suffered a great loss in his being called to what may have been considered more important work."

On December 14, 1917, General Sibert released command of the Division to General Bullard and returned to the United States to assume command of the South Eastern Department, with headquarters at Charleston, S. C. He was relieved from this duty on May 16, 1918, and brought to Washington to organize what became the Chemical Warfare Service. This was an entirely new service in the Army, and it is due largely to the energy and administrative ability of General Sibert that an able and efficient service was brought into being. In recognition of this accomplishment he was awarded the Distinguished Service Medal with the citation: "For services in the organization and administration of the Chemical Warfare Service, contributory to the successful prosecution of the war."

On March 1, 1920, he left the Chemical Warfare Service and was assigned command of the Fifth Division and Camp Gordon, Georgia. He retired from active service upon his own request on April 4, 1920, under the provisions of the Panama Canal Act.

Following retirement from active service, General Sibert was intimately connected with and engaged in engineering work until 1932. His native State of Alabama turned to him, as an able engineer and administrator, to act as Chief Engineer and General Manager of the Alabama State Docks Commission which, under a $10 000 000 appropriation, constructed an ocean terminal at Mobile. Consequently, the City of Mobile can now boast of one of the most modern and well-equipped ports of the South. In 1928, he was also appointed Chairman of the Boulder Dam Commission, a Commission of Engineers and Geologists appointed under an Act of Congress to investigate and report on the Boulder Dam project. From 1929 to 1930, he was President of the American Association of Port Authorities.

In 1932, General Sibert retired from active engineering and spent the final years of his life on his farm near Bowling Green, Ky., where he died on October 16, 1935. He was buried with full military honors in Arlington National Cemetery, on October 18, 1935.

General Sibert's active life was devoted to public service, not only during his thirty-six years in the Army Corps of Engineers, but also for twelve years after his retirement. During his life he was many times singularly honored —the thanks of Congress; the Distinguished Service Medal; a Commander in the Legion of Honor of France; the degree of Doctor of Laws from the University of Alabama (1919); the degree of Doctor of Engineering from the University of Nebraska (1919); the many important positions of trust—all bear witness to the worth of his service and the regard of those for whom he devoted his life, his fellow men. Like all men who have done great things, General Sibert knew men and how to use them. Particularly did he understand young men and how best to develop them. The heritage which he left in the hearts and minds of the many young men who served under him and were taught by him is being transmitted by them to other young men and will be continued as long as the Corps of Engineers endures. He was loyal and zealous in his work, efficient without being harsh, loved and respected by all.

He was married to Mary Margaret Cummings, of Brownsville, Tex., in September, 1887, Juliette Roberts, in 1917, and Evelyn C. Bairnsfather, of Edinburgh, Scotland, in June, 1922. He was survived at the time of his death by his widow, Evelyn C. Sibert, and by William, Franklin, Harold, Edwin, Martin, and Mary (Mrs. E. S. Smith) Sibert, children of his first wife.

General Sibert was elected a Member of the American Society of Civil Engineers on June 2, 1897.

EUGENE ADALBERT SILAGI, M. Am. Soc. C. E.[1]

Died April 5, 1935

Eugene Adalbert Silagi was born at Rozsno, Hungary, on August 24, 1876. He was educated at the Joseph Royal Technical University, at Budapest, from which he was graduated in 1898 with the degree of Civil Engineer. For a period of fourteen years following his graduation, he served as Lieutenant and First Lieutenant in the Hungarian Army, teaching mathematics, surveying, and mapping in the Military Academy at Pecs, Hungary, during the last two years of this service.

---

[1] Memoir prepared by the late E. G. Bradbury, M. Am. Soc. C. E.

From 1902 to 1904, Mr. Silagi was engaged as Supervising Engineer on the construction of reinforced concrete stations and roundhouses for the Trans-Siberian Railways, at Tamsk (or Omsk), Siberia. This was followed by a two-year engagement as Designing Engineer for concrete structures of the Chemin de Fer d'Algerique, at Oran and Saida, Alger, North Africa.

In 1907, Mr. Silagi came to the United States and was employed by the Trussed Concrete Steel Company, at Detroit, Mich., his work including the construction of numerous warehouses, bridges, tall buildings, and factories. This connection was continued until 1913, when he became Chief Engineer for the United Engineers, Limited, of Singapore, Straits Settlements, and, for two years, he was engaged in the design and construction of sea walls, retaining walls, wharves, heavy foundations, bridges, and buildings.

During 1915, Mr. Silagi made an investigation for the Trussed Concrete Steel Company of its agencies in Manila, Philippine Islands, Shanghai, China, and Honolulu, Hawaii, making reports and recommendations as to future policies. Late in the same year he returned to America, and became Manager of the Columbus, Ohio, Office of the Truscon Steel Company, directing designs, estimates, and sales, and personally designing a number of warehouses, schools, hotels, and factories. In 1919, while still managing the Truscon Company's Office, he acted as Consulting Engineer in connection with the design of a large refinery for the Ohio Cities' Gas Company, and a number of other projects.

His connection with the Truscon Steel Company was continued until Mr. Silagi's death. In 1920, he left Columbus and until 1922 his headquarters were at the Company's New York Office, but he traveled extensively, his duties taking him to Calcutta and Rangoon, in India, Singapore, Batavia, Dutch East Indies, and Shanghai; from 1923 to 1927, he was the Company's General Manager at Shanghai; in 1928, he went to Manila, as its representative, associated with the Pacific Commercial Company, and remained in this capacity until 1933, when he became Sales Manager for the China United Engineering Corporation, Truscon Agents at Shanghai, holding this position for the remainder of his life. In all these positions he was engaged largely in the design and construction of important buildings and engineering works.

Mr. Silagi was a remarkable linguist, speaking nine languages, namely, English, Hungarian, German, French, Italian, Austrian, Chinese, Japanese, and Hindustani. During the World War he rendered valuable service to the Columbus, Ohio, Chamber of Commerce as interpreter and by addressing, in their own languages, gatherings of the foreign population, ironing out factional differences and possibly averting serious trouble. He also organized, and acted as Captain and Drillmaster of Company A, Columbus Reserve Guard, which was made up of members of the Engineers' Club of Columbus, of which he was an active and valued member. He was a member of the Masonic Order and of the Benevolent and Protective Order of Elks.

He was possessed of a very pleasing personality and of a frank, loyal, and generous character, and was highly regarded by those with whom he had business or social relations. He was an enthusiastic lover of horses and dogs, and sometimes rode his own horses in races in the Far East. He was also fond of hunting.

Mr. Silagi was elected an Associate Member of the American Society of Civil Engineers on June 11, 1917, and a Member on March 9, 1920.

HENRY CLEMENT SMITH, M. Am. Soc. C. E.[1]

DIED JANUARY 11, 1936

Henry Clement Smith was born in Philadelphia, Pa., on February 2, 1860, the elder son of A. Lewis Smith and Rebecca Levis (Wood) Smith. He obtained his college preparation at the Friends Central School, in Philadelphia, and was graduated from the University of Pennsylvania as a Civil Engineer in 1881.

His early engagements were with the Pennsylvania Railroad Company. the Pennsylvania, Schuylkill Valley Railroad Company, and the Philadelphia, Germantown and Chestnut Hill Railroad Company. He served also with the Department of Surveys of Philadelphia, in the capacities of Draftsman, Rodman, and Instrumentman.

In 1885, Mr. Smith was with the Little Rock and Fort Smith Railroad Company, at Little Rock, Ark., as Chief Clerk in the General Manager's Office. He was obliged to resign, however, and return home in the course of a year as the result of a severe illness. Throughout the remainder of his life, he remained in the Philadelphia District.

During the following two years he was in the employ of the Pennsylvania Railroad Company as an Assistant Engineer in charge of shop and warehouse construction, track construction, and a preliminary survey of the Maurice River Railroad, in New Jersey. Mr. Smith then went to the old Philadelphia, Wilmington, and Baltimore Railway Company as an Assistant Engineer. Later, he became the Division Engineer of its Central Division.

He remained with the Pennsylvania Railroad System, until about 1905, when he resigned to become Division Engineer of the Philadelphia Division of the Philadelphia and Reading Railroad, with offices in Philadelphia. During his long service with the Reading System, Mr. Smith, in addition to discharging the onerous duties of a Division Engineer, was often consulted by his associates on matters concerning improvements or the design and erection of important structures needful in the expansion of a great railroad system. In the latter part of his life, he at times shouldered responsibilities incident to the uninterrupted operation of his Division, which severely taxed his strength and undoubtedly enfeebled his retiring years.

In his bearing, Mr. Smith was quiet and dignified, but firm in the discharge of his duties. He was conscientious to a marked degree, well informed in his profession, and had the respect and good will of his men. He was a member of the Engineers Club of Philadelphia.

---

[1] Memoir prepared by William Easby, Jr., M. Am. Soc. C. E.

He was married on October 9, 1889, to Anna P. Cheyney, of Media, Pa., and is survived by his widow and a son, Lewis Cheyney Smith.

Mr. Smith was elected a Member of the American Society of Civil Engineers on October 2, 1901.

JONATHAN PARKER SNOW, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 4, 1933

Jonathan Parker Snow was born in Concord, N. H., on November 19, 1848, the son of Jonathan and Lydia Ann (Parker) Snow. His paternal ancestors were sea-faring men, of Cape Cod, Mass., and his maternal ancestors, English immigrants prominent in the early settlement of the Massachusetts Bay Colony. His early education was obtained at a private academy at Contoocook, N. H., and he was graduated from the Thayer School of Civil Engineering, Dartmouth College, at Hanover, N. H., in 1875, with the degree of Civil Engineer.

At that time schools or colleges for teaching Civil Engineering were few, and most of them were privately endowed. State universities of repute could be counted on the fingers of one hand; high schools were rare; engineering text-books were few and inadequate; recourse was had to English and French treatises; and, consequently, American practice conformed in many respects to that abroad. In spite of handicaps, however, by zealous application Mr. Snow obtained a thorough knowledge of the science of engineering, and a retentive memory enabled him to make full use of his education.

At the time of his graduation, Mr. Snow was in his twenty-seventh year, but more mature than is usual at that age. His first employment was as Principal Assistant to the City Engineer of Fitchburg, Mass.; and then, on the Manchester and Keene Railroad, in New Hampshire, as Transitman and as Assistant Engineer in charge of location, and as Division Engineer in charge of construction. He also fulfilled some engagements in North Carolina and Pennsylvania. Recalled to the Thayer School as an Instructor during one year, he conducted field work and prepared useful notes on carpentry, explosives, rock-drills, and quarrying, which served temporarily until suitable textbooks appeared. His next engagement was as a Surveyor on map work at Prince Edward Island. Entering the Boston Bridge Works, in November, 1879, he served for four and one-half years as First Assistant to the late David Herbert Andrews, M. Am. Soc. C. E., the Proprietor, in charge of designs and estimates, at a time when it was customary for railroad companies, municipalities, and architects to depend upon contractors for engineering designs. In 1884, he entered the office of the late John Waldo Ellis, M. Am. Soc. C. E., at

---

[1] Memoir prepared by the late Robert Fletcher, M. Am. Soc. C. E., and J. R. Worcester, M. Am. Soc. C. E.

Woonsocket, R. I. In addition to a large private practice, Mr. Ellis served as Engineer of the Providence and Worcester Railroad Company, and Mr. Snow had charge of the Bridge Department for four years. In July, 1888, he was apointed Bridge Engineer of the Boston and Maine Railroad Company, which office he held until, twenty-one years later, he was promoted to be Chief Engineer. After two years as Chief Engineer, a re-organization brought in a controlling influence of the New York, New Haven, and Hartford Railroad Company, and he was released from the office. Thereafter, he carried on a consulting practice, with an office in Boston.

In this connection with the railroads, Mr. Snow devoted himself to the service with whole-hearted zeal and the knowledge gained by years of previous experience. His notebooks indicated the condition of every bridge on main lines and branches, not only in general, but by computed strength of each member. On occasions, he conducted small groups of students on a tour for bridge inspection. The bridges with which he had to deal included practically all types of construction, among the most unique of which were several "jack-knife" draw-bridges, such as those over the Charles River, in front of the Boston Terminal. In this construction the track stringers were hinged at the fixed ends, while the outer ends were suspended from a rigid frame. In operation, the stringers while remaining parallel to each other, were swung around by a side-haul so as to shut together like a jack-knife, leaving a clear passageway.

The majority of the bridges for which he was responsible were built with timber, chiefly the lattice and Howe truss types, with or without timber arches. Mr. Snow advocated conserving these bridges as long as they could be made assuredly safe under the loads then allowed. He held strongly to the conviction that, in the development of types of timber trusses and combination trusses, the merits of the Towne lattice with built-in timber arch were not fully appreciated. He pointed to the facts that they required no elaborate framing, used only timber in less bulky shapes, were more easily erected, had greater lateral stability, and that experience of thirty years in designing and maintaining such structures had shown that they continued to carry—without over-strain—loads far heavier than those for which they were designed. In a paper entitled "Wooden Bridge Construction on the Boston and Maine Railroad",[3] he described such a truss with drawings in detail and convincing arguments.

It was a time of experimentation with various types of wrought-iron trusses or those in which timber and wrought iron were combined. Steel had not then been adopted in bridge construction. The Bollman, Fink, and Post trusses, etc., bore the names of their inventors, while others were named from the bridge shops which produced them. Those were the days of controversy between American engineers who designed pin-connected trusses to gain the utmost economy of material, and English engineers who preferred riveted types with less concern for the greater weight of metal used. Mr. Snow's preference was for the riveted type, particularly to gain more rigidity, and in this preference he was forestalling the trend of more recent times.

---

[3] *Journal*, Assoc. of Eng. Societies, Vol. XV, 1895, p. 31.

Mr. Snow was a faithful member of the Society and contributed liberally to its publications. Previous to 1895, he had furnished discussions on subjects, such as the life of iron bridges, railway bridge design, thin floors for bridges, tests of bridge members, wind-bracing on high buildings, etc. His final contribution to the *Transactions* was as co-author of a paper entitled "A History of the Development of Wooden Bridges"[3], prepared during the years 1931–33. Of this paper a distinguished member of the Society wrote: "It is not only a history of wooden bridges; it is practically a treatise on the design of wooden bridges of the more recent types." Its authoritative and practical value as a treatise is due to a large extent to Mr. Snow. He died within two weeks after the issue of the complete reprint.

Mr. Snow was a member of the American Railway Engineering Association from the time of its organization, and, for many years, a regular attendant at its Annual Conventions, where he took part in the discussions. He was Chairman of the Committee on Iron and Steel Structures during the time that this Committee was formulating its first Specification for Steel Railway Bridges. He was adverse to the law under which the Interstate Commerce Commission made the valuation of the railroads, claiming that the cost of rails, roadbed, buildings, and rolling stock had little significance if the financial return was inadequate; and that the proper basis is revenue received. He was a member of the Special Committee of the Society which made the Final Report to Formulate Principles and Methods for the Valuation of Railroad and Other Public Utilities.[4]

He was also a member of the American Association of Superintendents of Bridges and Buildings, the American Society for Testing Materials, the Boston Society of Civil Engineers, and the Thayer Society of Engineers, as well as the following clubs: New England Railway, Engineers, and New Hampshire Club, of Somerville, Mass.

In 1880, Mr. Snow was married, in Boston, to Mrs. Marietta B. Eaton, of Wilton, N. H., who died in June, 1928. In June, 1929, he was married to Mrs. Delia Hardy Osgood, who died in September, 1932. During the later years his sister, Josephine E. Snow, kept house for him at his home in Somerville, Mass. He was a Republican in politics, and a Universalist in faith.

Mr. Snow was an original thinker, not bound by precedent; he could visualize the result of his work, and his object was to attain the result without wasting time or expense in the process. While he had a proper respect for beauty, he did not consider it to be his job to produce it; he seemed to feel that in engineering structures an evident suitability for the use was all that appearance demanded. His practical experience with shop and field work made him ever watchful of the practicability of constructing and erecting whatever he designed. His open-mindedness is evidenced by a brief talk to members of a graduating class, in which he cautioned them to "restrain their knowledge until it was needed," and assured them that they would find much to be learned from the workmen on the job. Also, that the safe policy was to say little and, in the meantime, to make full use of their eyes and ears.

---

[3] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 314.

[4] *Loc. cit.*, Vol. LXXXI (1917), p. 1311.

In his contacts with men he was blunt, frank, and outspoken, taking a seeming pleasure in the use of colloquial expressions, but he was never discourteous. He was always open to argument and free to listen to his opponent. As a result, he was respected and beloved by those who were privileged to have dealings with him. He was too modest to set a proper value on his own opinions, and gave freely of advice that to others was priceless.

The impression which Mr. Snow's personality made on his associates is happily expressed by one of his colleagues, a prominent member of the Society, who writes as follows:

> "We were all very fond of Mr. Snow, and had great respect for his ability as an engineer and his character as a man. I feel that * * * his sound judgment, common sense, and practical attitude toward all * * * problems made him one of the most valuable counsellors * * *.

Mr. Snow was elected a Member of the American Society of Civil Engineers on June 3, 1885. He served as a Director of the Society from 1911 to 1913.

EARL EUGENE SPERRY, M. Am. Soc. C. E.[1]

DIED AUGUST 17, 1935

Earl Eugene Sperry, the son of John Eugene and Julia (Paul) Sperry, was born in West Monroe, N. Y., on May 27, 1883. His preliminary education was obtained at Manlius Military Academy, at Manlius, N. Y., from which he was graduated in 1900 at the head of his Class. In 1904, he was graduated from the Rensselaer Polytechnic Institute, at Troy, N. Y., with the degree of Civil Engineer. During his course at college he demonstrated that exceptional ability which proved such an asset during his business career and, on graduation, received the much coveted insignia of Sigma Xi, representative of the highest type of scholarship. He was a member of the Delta Kappa Epsilon Fraternity.

Following his graduation from Rensselaer, Mr. Sperry, in July, 1904, entered the Engineering Department of the Solvay Process Company, in Syracuse, N. Y. In 1907, he was promoted to the position of Assistant Civil Engineer and, in 1921, he was given the position of Chief Civil Engineer which he held until his resignation in 1924.

Much could be recorded regarding his varied and intricate engineering work during his years with the Solvay Company. Among his activities were included the design, construction, and operation of immense quarry and rock-crushing plants, water and sewerage systems, brine wells, steam power plants, water, air, and brine pipe lines, and plant railroads for the Company's plants at Syracuse, Detroit, Mich., and Kansas City, Mo. His most notable professional work consisted of a unique development of deep-well pumping which revolutionized the methods then in use.

---

[1] Memoir prepared by William P. Creager, M. Am. Soc. C. E.

In 1924, he entered into private business as a Retail Coal Merchant and a Concrete Products Manufacturer, with an office and works at Oneida, N. Y., which business he conducted until his death on August 17, 1935.

Mr. Sperry endeared himself to all with whom he came in contact, not only because of his engaging personality, but also for his exceptionally high standard of sportsmanship. His business associates admired him not only for his great ability as an engineer, but for his friendly spirit and wonderful cheerfulness and fortitude under extreme stress. Had he continued within the technical branch of his profession, he undoubtedly would have attained the highest pinnacle in the field of industrial engineering.

During his late years, he successfully hid from even his closest associates the continued agony of the heart affliction which not only handicapped him in every way, but ultimately was the cause of his death. He was a member of the Congregational Church, of Munnsville, N. Y.

He was married to Elizabeth Burns, of Troy, N. Y., on October 3, 1904, who, with his daughter, Margarete Elaine, one brother, and two sisters, survives him.

Mr. Sperry was elected a Member of the American Society of Civil Engineers on December 15, 1924.

OSCAR VAN PELT STOUT, M. Am. Soc. C. E.[1]

Died August 4, 1935

An awkward, overgrown country lad once enrolled in the Civil Engineering Department of the University of Nebraska, at Lincoln, Nebr. Early in his second year he presented himself at the Dean's office one day after class. A year at college had added but little to his urbanity. His movements were still gawky, his hands and feet were too large, and he could not find any place to put his hat.

He finally explained, hesitatingly, that his folks had told him he had better have a talk with the "perfesser" to see whether there was any use in his taking any more engineering. He said he liked the study and the surveying all right, but "did the 'prof' think he could ever be an engineer?" Dean Stout's reply was brief and pertinent: "If I were you I'd try to join a 'frat', mix a little, and learn something about life."

What a diviner of things human! Such an one becomes infinitely more than a mere teacher—he becomes an institution, a human guide-post!

Dr. Stout began his career in railroad work during college and subsequent to his graduation from the University of Nebraska in 1888. He left the "Burlington" early in 1890, to accept an appointment as City Engineer of Beatrice, Nebr., but was called back to his Alma Mater in the fall of 1891 as Instructor in the Civil Engineering Department. Within two years he was placed in charge of the Department and, in 1912, was made Dean of the Engineering College which position he held until he resigned in 1920.

---

[1] Memoir prepared by J. C. Stevens, M. Am. Soc. C. E., and C. H. Purcell, Assoc. M. Am. Soc. C. E.

As his students finished their Freshman and Sophomore years and learned about railroads from his experience (in the early days railroading was about the only engineering experience available for civil engineers), the stern professor relaxed, particularly toward those who were following engineering in the summer during their vacations. They were called in and afforded those intimate contacts which, even more than the technical training, everlastingly endeared him to them.

He had a most subtle way of pointing out the human elements in engineering—lessons not found in books, but of which he was a past master. One of his epigrams has become famous—"the engineer is a resourceful man."

Those who were graduated under him carried with them the conviction that engineering was an office of trust and a profession of honor—a conviction so firmly instilled that it could never be forgotten in the practice of their profession.

At the time of receiving his Bachelor's degree he was awarded the scholastic honor of membership in Phi Beta Kappa. He was also a Charter Member of the Nebraska Chapter of Sigma XI, organized in 1897. The professional degree of Civil Engineer was conferred upon him in 1897, and that of Doctor of Engineering in 1932, both by the University of Nebraska. His college fraternity was Beta Theta Pi. He was made an honorary member of Sigma Tau at the founding of that engineering honorary fraternity at the University of Nebraska in 1904.

In honor of Cyrus Hall McCormick a Gold Medal Award was created in the American Society of Agricultural Engineers to be given each year "for exceptional and meritorious engineering achievement in agriculture." Dr. Stout was chosen almost without competition as the first recipient of that award which was made at Columbus, Ohio, in 1932, at the Annual Convention of the Society.

During the period of teaching he was also engaged in the general practice of engineering. He did considerable work for the Water Resources Branch of the United States Geological Survey, and for what is now the Bureau of Agricultural Engineering of the Department of Agriculture. Some of his private engagements included work for the Ingold Placer Mining Company, of Colorado, Tristate Land Company, of Scottsbluff, Nebr., and Costillo Estates Development Company, in the San Luis Valley, Colorado. His professional advice was frequently sought in matters of reclamation, drainage, and other fields of hydraulic engineering. He had a most happy faculty of combining thorough theoretical knowledge with simple and practical ways of doing things. One of his pungent remarks long remembered is, "You should never place your entire organization on an experimental basis."

In connection with his water supply work for the Government he devised a simple and effective method of determining the daily discharges from a limited number of measurements on erratic streams, such as those with unstable beds, or those affected by growth of aquatic plants. This method is still used by hydrographers and is known as "Stout's Method for Shifting Stream Beds."

As soon as the United States entered the World War, Dean Stout volunteered for service, secured a leave of absence from the University, and received a commission as Major of Engineers in the Reserve Corps, United States Army. He spent two months in a training camp, four months with the Construction Division, and seven months as Battalion Commander. To most of his contemporaries he is still lovingly referred to as "Major Stout."

In the midst of the war excitement of 1917 and 1918, an old Nebraska engineering graduate alighted one evening at a hotel in Washington, D. C., and looking across the lobby saw Dean Stout dressed in the uniform of a Major of Engineers. In answer to the "grad's" question as to what he was doing, he very modestly deprecated the very important service he was then rendering, but showed himself as restless as any 21-yr old recruit to get over to France. To one who had been out of school for fifteen years, and who as a student had looked upon the Dean as a man of mature age, it was amazing and most refreshing to find him so full of vigor and "champing at the bit" to get into action.

In 1919 he resumed work at the University of Nebraska, but resigned within a year to engage in private practice. Land reclamation projects which looked promising at the time "went on the rocks", and he turned to irrigation work for the Government in which service he continued until his death. His last work was in the Division of Irrigation of the Bureau of Agricultural Engineering, with headquarters at Berkeley, Calif. It consisted of special research work carried on in connection with the California Agricultural Experiment Station and in co-operation with the California State Department of Public Works.

At the time of his death he was engaged in a special study of the Platte River in Nebraska for the United States Bureau of Reclamation. He was taken ill on duty and died in Denver, Colo., after only a few days' sickness.

Late one hot summer afternoon in 1932, a Nebraska engineering graduate driving in the Sacramento Valley, stopped beside a car parked in the shade of a tree, only to find Dean Stout in the midst of one of his numerous investigations, sitting in his car making notes. Pleasantries were exchanged and the former student learned that the Dean expected to travel about ninety miles yet to reach home that night, and even then was planning what he was going to do early the next morning—and the Dean had been thought of as elderly by his students, thirty years before!

His knowledge of human nature was most cogently demonstrated as an expert witness in an important water-right case affecting very valuable properties in Southern California. The case, which was being tried before a jury of farmers, had been hopelessly muddled by a metropolitan attorney and the witnesses he had produced up to that time. The Dean's frank and clear statements were an education to that farmer jury, to which they responded graciously in their verdict which prevented the public from suffering the loss of many thousands of dollars on a purely trumped-up claim. After the verdict every member of the jury insisted on shaking hands with the Dean and lingering longer to talk with him.

Dr. Stout was born in Jerseyville, Ill., on November 14, 1865. He was married to Edith Forbes, at Beatrice, Nebr., in 1890. To them were born six children—Richard Forbes, Donald John, Oscar Charles, Marian Edith, Harris Pinkerton, and Burt Elihu. A granddaughter lived for a number of years at his home in Oakland, Calif. At the age of seven, one day her rejoinder to something a playmate had said was overheard, "Aw, grandfathers don't get cross at yu!"

Dr. Stout had a burning interest in every young man that passed through his institution. He never tired of meeting "his boys." He knew the names of most of them and could tell with astonishing detail the career of each since leaving college. Probably one of the proudest moments in his life was the occasion of his escorting Charles H. Purcell, Assoc. M. Am. Soc. C. E., one of "his boys", to the platform to receive a degree of Doctor of Engineering at the Commencement of 1935, after the Dean had been away from the University for seventeen years.

A bit of advice he often gave to young engineers was, "Any engineer who ever expects to amount to anything should join the American Society of Civil Engineers and do it before some one gets it in for him." It is well known that he held the Society in great reverence, but for some reason never applied for membership until he resigned as Dean. In 1922, he had his application papers made out and was just on the verge of sending them in when his reclamation "bubble" burst, and the application was never filed.

On November 5, 1926 a special dinner meeting was called of the University of Nebraska Alumni at San Francisco, Calif., and about two hundred sat down to the banquet at the Stewart Hotel. Fred M. Hunter, now Chancellor of Higher Education in Oregon, was Toastmaster. Dean and Mrs. Stout and available members of his family were present. The Dean was presented with a handsomely bound and suitably inscribed volume of letters that had been gathered from "his boys" from all corners of the world—about 160 of them had written a message of affection and cheer. They had also made up a fund and presented to the Dean the grade of Member in the American Society of Civil Engineers[2], with all fees and dues paid. A small balance remained in that fund at the time of his death, which was immediately turned over to Mrs. Stout.

Dean Stout was elected a Member of the American Society of Civil Engineers on April 18, 1927.

CHARLES FREDERICK SWIGERT, M. Am. Soc. C. E.[1]

DIED JUNE 23, 1935

Charles Frederick Swigert, one of the best known Engineer-Executives of the Pacific Coast, was born at Swanton Village, Ohio, on December 1, 1862.

---

[2] The story of this episode is contained in *Civil Engineering*, September, 1935, p. 603.

[1] Memoir prepared by James H. Polhemus, M. Am. Soc. C. E.

He was the son of Charles Frederick Swigert and Elizabeth (Gorrill) Swigert, and was the only boy in a family of four children. His father died when Mr. Swigert was quite young, and he went with his three sisters to live with his grandparents. He received his education in the public grade and high schools.

Mr. Swigert's career identifying him with engineering, construction, and operation of various types on the Pacific Coast began in June, 1881, with the Pacific Bridge Company of San Francisco, Calif. In 1888, he moved to Portland, Ore., to establish a branch of the Pacific Bridge Company and his first major undertaking was the building of the original Morrison Street Bridge which was the first to span the Willamette River, at Portland.

He was still identified with the Pacific Bridge Company at the time of his death, although in the interim of 54 yr, he had been actively concerned, mostly in an executive or proprietary capacity, with many activities. These included extensive construction works as well as in giving the benefit of his abilities in unremunerative public service.

Among his earlier activities in addition to his work with the Pacific Bridge Company, he was Consulting Engineer for the Albina Light and Water Company from 1892 to 1898; between 1892 and 1905, he acted as Consulting Engineer, then as Chief Engineer, for the City and Suburban Railway Company and, later, became Vice-President and Manager of that Company. When that Company's interests were sold to a new company which absorbed three electric railway companies and the power and light company serving Portland, Mr. Swigert retired from active management, but became a Director of the consolidated company, then known as the Portland Railway, Light and Power Company. When Mr. Swigert relinquished the active management of the Street Railway Company mentioned, he devoted the greater part of the year, 1906, to travel in various parts of the world, viewing on this trip not only ancient and modern engineering works of the European countries and on the borders of the Mediterranean, but acquiring a comprehensive understanding of the world's economic relations.

Mr. Swigert's service in a public capacity was as a member of The Port of Portland Commission from 1901 to 1911, except for a part of 1905 and 1906, while he was traveling in foreign countries. Shortly after his appointment to The Port Commission he was elected President of the Commission and continued to be its leader during his tenure. This Commission is a body created by the Legislature for the purpose of establishing and maintaining a channel in the Willamette and Columbia Rivers between Portland and the sea, capable of accommodating ocean commerce. The Commissioners serve entirely without remuneration and the leadership in this endeavor was well suited to the creative talents and executive abilities of Mr. Swigert. At the time he entered upon these public duties river and harbor appropriations by the Federal Government for the improvement of the Columbia River channel were not large. The channel in the Columbia and Willamette Rivers for a distance of about 100 miles, stretching between the sea and Portland, was inadequate in depth and width for the increasing commerce of the Port, and its maintenance against annual sedimentation due to freshets was uncertain. Even adequate equipment was lacking. Mr. Swigert was largely instrumental in formulating and carrying out a program by which definite results were obtained.

In large construction work, Mr. Swigert's activities increased with his years. He was already in his seventies when he and his associates in the Pacific Bridge Company undertook and carried out, before his death, the construction of the foundation piers of the Golden Gate Bridge, as well as participating in similar construction on the San Francisco Bay Bridge. Bridge foundation work was a specialty with Mr. Swigert. Among the other comparatively recent bridge foundation structures placed by the Company of which he was President, are the Interstate Bridge, over the Columbia River, at Vancouver, Wash.; the Lake Union Bridge, at Seattle, Wash.; the Longview Bridge, over the Columbia River; the Burnside and Ross Island Bridges, over the Willamette River, at Portland Harbor; and the St. Johns Suspension Bridge over the Willamette River. In past years the Company did the pier work on practically all the bridges at Portland and its vicinity and, at times, carried out similar work in other parts of the United States.

The Pacific Bridge Company was one of the original members of the six companies which built the Boulder Dam and which were awarded the contract for the Parker Dam on the Colorado River. The Company is also associated with the General-Shea Company which was awarded the contract for the Bonneville Power House.

Among the industrial activities in which Mr. Swigert engaged at various times during his career, some of which were still receiving his attention at the time of his death, were manufacturing in such lines as iron and steel products, wood products, paints, and wood preservatives. The best known institutions in this line are the Electric Steel Foundry of Portland, and the Willamette Hyster Company. To list in detail the various companies with which Mr. Swigert was connected either as an active executive, or in a consulting or advisory capacity, would take much space.

To mention so many varied activities encompassing works of such extraordinary size tends to give the impression of a man in whom what are called the human or homely characteristics might be expected to be crowded out. This was emphatically not the case with Charles F. Swigert. He numbered personal friends and acquaintances by thousands and his life was as filled with friendly human contacts as it was with business activities. He was never the distant impersonal executive but, to the limits of human capacity, he had a personal knowledge of and interest in the personnel of the organizations with which he was connected, not overlooking the humblest employee.

He passed away unexpectedly in San Francisco, Calif., on June 23, 1935, having died during his sleep, in his seventy-second year. He is survived by his widow, Rena G. Swigert and three sons, Charles Frederick, Jr., Earnest Goodnough, and William Gorrill Swigert.

Mr. Swigert was elected a Member of the American Society of Civil Engineers on June 4, 1928.

CHARLES VOETSCH, M. Am. Soc. C. E.[1]

DIED FEBRUARY 7, 1935

Charles Voetsch, the son of Jacob and Anna (Huonker) Voetsch, was born at Waldenbuch, Germany, on August 8, 1877. His early education was obtained in that city where his father was a Public Attorney. His technical education was extensive, covering both Mechanical and Electrical Engineering. He received his degree of Mechanical Engineer from the Technical University of Stuttgart, Germany, and, later, his degree of Electrical Engineer from the Technical University of Darmstadt, Germany. As part of the requirements for these degrees, Mr. Voetsch on his first work obtained considerable shop experience as a machinist.

Upon coming to America in 1904, Mr. Voetsch was employed by the I. P. Morris Company, of Philadelphia, Pa., as Designer of hydraulic turbines. While with this Company he designed the 10 500-hp runners for the Shawinigan Water Power Company, of Quebec, Que., Canada. His next work was with the Allis-Chalmers Manufacturing Company, at Milwaukee, Wis., where he was employed from November, 1904, to September, 1906. During this period he designed the 13 500-hp turbines for the Great Northern Power Company, and the 10 000-hp turbines for the California Gas and Electric Company.

From September, 1906 to October, 1907, Mr. Voetsch was associated with Sellers and Rippey, Consulting Engineers, of Philadelphia, engaged on the design of hydro-electric power developments. He was next with the Bidwell Electric Company, of Chicago Heights, Ill., until October, 1908, as Chief Engineer in charge of design of electric motors, dynamos, and carbonic acid ice machines, and Superintendent in charge of the Company's shops.

From April, 1909, to October, 1910, he was employed by the Indiana Steel Company, in Chicago, as Designing Engineer. His next work, continuing to October, 1911, was with the Falkenau Electric Construction Company, of Chicago, on the design of the hydro-electric power plant for the Davis and Weber County Canal Company, of Ogden, Utah, and sub-stations and steam-generating stations at Ogden, and at Salt Lake City, Utah, including also the electric installations on these projects. Thereafter, until February, 1913, he was Chief Engineer in charge of designs and shops for the Camden Hydraulic Turbine Corporation, of Camden, N. Y.

Mr. Voetsch served as Electrical, Hydraulic, and Mechanical Engineer for the Utica Gas and Electric Company, of Utica, N. Y., from April, 1913, to August, 1922, in charge of reconstruction of steam and hydro-electric plants, and planning and designing power-plant extensions, sub-stations, transmission lines, and new power developments. While with this Company, he prepared designs for the Trenton Falls Plant, consisting of three 9 000-hp turbines operating under a 265-ft head. In the latter part of this period, he was temporarily transferred to the staff of the Hooven-Owens-Rentschler Company, to re-design and build two 10 000-hp turbines for the Utica Gas and Electric Company and the Cohoes (N.Y.) Power and Light Company.

---

[1] Memoir prepared by J. L. Savage, M. Am. Soc. C. E., assisted by Henry J. Tebow, Jun. Am. Soc. C. E., and M. H. Fresen, Esq., all of the U. S. Bureau of Reclamation, Denver, Colo.

From August, 1922, to June, 1924, Mr. Voetsch was with the Adirondack Power and Light Company, of Schenectady, N. Y., in charge of the design and installation of a 9 000-hp unit and of a 114 000-volt outdoor sub-station at Spier Falls, N. Y., on the Hudson River.

In 1925, he was in Hamburg, Germany, where he supervised the designs of a pulverized fuel boiler plant for the Vickers-Spearing Boiler Company, of London, England. From July, 1925, to April, 1927, he was engaged in a consulting engineering practice particularly on the design of special machinery, with offices in Cleveland, Ohio.

Mr. Voetsch entered the Government service in April, 1927, and from then until June 5, 1928, he was employed in the United States Engineer Office, at Chattanooga, Tenn., as Hydro-Electric Engineer on the power surveys of the Tennessee River and its tributaries.[3] This survey included a comprehensive study of the hydro-electric possibilities of the Tennessee River Basin, involving the investigation of about 150 proposed storage projects, run-of-river plants, and auxiliary steam plants. In connection with this work, Mr. Voetsch developed new and more direct methods for determining the combined power of this complicated system with the most economical use of water for maximum firm power development. In connection with this survey, furthermore, he made preliminary layouts and designs for the Cove Creek Project, on the Clinch River, which later became the Norris Dam Project of the Tennessee Valley Authority. Subsequently he was transferred to the United States Engineer Office, at Nashville, Tenn., where on November 1, 1929, he was advanced to the position of Senior Hydro-Electric Engineer and assigned to a power survey of the Cumberland River and its tributaries.

On November 23, 1929, he was transferred to the Madden Dam Project of the Panama Canal Zone where he prepared preliminary designs and estimates for the Madden Dam and Power Plant. He also prepared the final designs for the 66-kv transmission line, from Madden Dam to Summit. In February, 1931, Mr. Voetsch was transferred to the United States Bureau of Reclamation at Denver, Colo., to assist in the preparation of final designs for the Madden Dam and Power Plant. After the completion of these designs, he was engaged on hydraulic designs for the Boulder Canyon, Grand Coulee, and Seminoe Power Plants, of the Bureau of Reclamation, and also for the Norris and Wheeler Power Plants of the Tennessee Valley Authority.

Those who are familiar with Mr. Voetsch's professional work attribute his successful and useful career to certain distinctive qualifications. He was an indefatigable student and worker. He had a keen mind, devoted much time to reading technical literature, and was able to converse in four different languages, English, German, French, and Spanish, which gave him an unusual ability to study technical problems. His early technical training, together with his broad experience and sound engineering judgment, made him unusually well qualified to handle important design work.

---

[3] H. R. Doc. 828, 71st Cong., 1st Session.

He was exceptionally well informed in precedents and standard practice in the design, construction, and operation of American and European hydroelectric developments, and resourceful in the adaptation of these practices to the problems at hand. Mr. Voetsch contributed generously to the store of American engineering knowledge by translating articles on engineering and research work done in Europe. He was the author of several papers on hydroelectric design and construction.

He was a member of the American Society of Military Engineers, the Masonic and Shrine fraternities, and the Benevolent and Protective Order of Elks; and he was a Licensed Engineer and Land Surveyor of the State of New York.

Mr. Voetsch was modest, unassuming, and friendly. He always dealt with people with courtesy and with instinctive consideration for their feelings. He was highly respected by his associates who prized his sincere and unaffected friendship. He was thoughtful of those working under him and was always ready to assist and encourage his associates. Notwithstanding his extensive technical knowledge, he was open-minded and considered carefully the suggestions and opinions of others.

His principal hobby, aside from study, was the collection of curios, specimens, pictures, and especially engineering data. He was a skilled violinist and occasionally delighted his friends by playing classical music.

The following are quotations from letters that have been received from some of Mr. Voetsch's friends and associates:

Lt.-Col. Lewis H. Watkins, General Staff, U. S. Army, formerly District Engineer, U. S. Engineer Offices, Chattanooga and Nashville, Tenn., writes:

"Mr. Charles Voetsch was employed by me from 1927 to 1929, on the surveys of the Tennessee River and its Tributaries and the Cumberland River and its Tributaries for their combined development for navigation, power, flood control, irrigation, prevention of soil erosion, and other useful purposes.

"These were the first comprehensive surveys covering the complete economic development of a large river and its tributaries ever made by the Federal Government. They involved a large amount of mapping, research work, developments of principles governing the best and most economic methods of developing the river and its tributaries for the combined purposes, and the preparation of general plans and estimates of cost for many engineering projects.

"As a result of these surveys a project for the combined development of the Tennessee River and its Tributaries was adopted by Congress in 1929. The construction of the project is being carried out by the Tennessee Valley Authority.

"In these surveys, Mr. Charles Voetsch rendered valuable assistance in research work, in the development of principles governing the combined development of the river and its tributaries, and in the preparation of general plans and estimates of cost. He soon became my leading man on those phases of the survey. Whenever information or data was desired on any engineering subject, Mr. Voetsch either had it on hand in his personal library or soon acquired it. He showed great initiative and excellent judgment in the development of principles governing the combined development of the river and its tributaries. He was untiring in the preparation of plans and in the computation of the great mass of data required for the survey.

"In all this work Mr. Voetsch proved himself to be a man and an engineer of the highest type and a patriot, serving his Government untiringly, loyally and to the best of his ability, often working overtime at night, regardless of his own personal affairs.

"On account of his excellent work on the survey of the Tennessee and Cumberland rivers, Mr. Voetsch was recommended for and assigned to duty on the construction of the Madden Dam in Panama.

"I consider his death a great loss to the engineering profession and to the Federal Government."

C. M. Hackett, Senior Engineer, U. S. Engineer Office, Nashville, writes:

"The death of Mr. Voetsch has elicited many expressions of sincere regret and sorrow from those associated with him in the Chattanooga and Nashville United States Engineer Offices, at the loss of one whom they regarded as a friend. They remember him as one who was genial and ever willing to co-operate and assist in the solving of any problem that might develop, whether it related to them personally or to their work."

Byron E. White, M. Am. Soc. C. E., of the Syracuse (N. Y.) Lighting Company, Incorporated, formerly with the Utica (N. Y.) Gas and Electric Company, writes:

"We who worked with him daily for nine years knew him as Carl. I must say that the news of his death came as a distinct shock to those in our organization who had long been associated with him.

"Mr. Voetsch personified the traits of patience, accuracy, extreme thoroughness, common sense, tenacity and the rearing of every structure and every conception upon solid foundations, building up block by block, testing each by the square of the fundamental truths, resulting in a finished, workmanlike structure. His was the mind of a scientist rather than of an executive; of a designer rather than of the master of men, materials, and circumstances, who rides roughshod over all difficulties in the rough and tumble of construction and operation.

"He was modest and unassuming, yet his convictions were strong and tenaciously held against all opposition. Like a true scientist, he was honest with himself and others and he appeared to take a peculiar pleasure in imparting knowledge to others or assisting them in a solution of their problems."

George A. Orrok, M. Am. Soc. C. E., Consulting Engineer, New York, N. Y., writes:

"I am most sorry to hear of the death of Mr. Charles Voetsch, whom I knew very well in the past.

"I first became acquainted with Mr. Voetsch * * * when he was employed by a turbine company near Watertown, N. Y. He made for me a number of good wheels which we used at the Dolgeville Plant of the Utica Company. Shortly after, he came in to the Utica Company and was regularly employed there until I believe 1922. During this time, he did a quantity of very good work for the Utica Company for which I was Consulting Engineer, both in the hydraulic line and in mechanical and structural work covering the building of several hydro plants, a steam station, sub-station and much other work.

"Mr. Voetsch was very careful and conscientious and thoroughly competent, was always able to take his end of an argument and present the facts in logical order. I knew of his work with the Government where a designer of his capacity would be appreciated."

E. S. Randolph, M. Am. Soc. C. E., Construction Engineer, Madden Dam, Panama Canal, Balboa Heights, Canal Zone, writes:

"It was a shock to hear of Mr. Voetsch's death. I had grown so well acquainted with him down here and also his wife and children that his passing was very regrettable to me. Personally, Mr. Voetsch impressed me as a very bright and attractive personality, an extremely clever engineer, a congenial friend, and a fond parent to his children."

In 1919, Mr. Voetsch was married, in Brooklyn, N. Y., to Aletha Johnson, of Utica, N. Y. Mrs. Voetsch died in Denver, in February, 1932. He died on February 7, 1935, at St. Anthony's Hospital, in Denver, as a result of septicæmia following rheumatic arthritis and influenza. Two children, Ruth, and Robert Otto, to whom he was very devoted, survive him. He is also survived by a brother, Otto Voetsch, living at Friedrichshafen, Germany.

Mr. Voetsch was elected a Member of the American Society of Civil Engineers on November 27, 1917.

GEORGE CLINTON WARD, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 11, 1933

George Clinton Ward was born at White Plains, N. Y., on January 9, 1863, the son of James and Elizabeth (Ennis) Ward. At an early age he removed to Boonville, in Oneida County, New York. He attended the public school of that town, and when only seventeen, taught in a rural school to help defray his expenses at Phillips Academy, at Andover, Mass., where he studied engineering for two years, graduating in the Class of 1882. His first position, in the summer of 1882, was with the Mohawk Division of the West Shore Railroad, later a part of the New York Central System.

During the three years following, Mr. Ward was engaged in the construction of iron bridges in the northern part of the State, among which was the lift bridge, at Utica, N. Y., the first known of its kind.

In 1886, he was made Assistant Engineer of Location and Construction of the Carthage and Adirondack Railroad. He filled the office of Supervisor of Oneida County for two terms—in 1886 and 1887. During the latter year, he was Assistant Engineer on the Susquehanna Division of the Erie Railroad, and in the succeeding years he conducted the preliminary surveys on various roads, all later incorporated in the New York Central Lines.

From 1890 until 1892, Mr. Ward was engaged in the construction of the Mohawk and Malone Railway, and from 1895 to 1897 served as Superintendent of the Black River Canal. In 1897, he became Assistant Engineer for the New York State Canals, resigning therefrom to accept a position with the Furnaceville Iron Company, and took up his residence at Utica, where he lived until 1902. In 1898, occurred the final construction of the Mohawk and

---

[1] Memoir prepared by H. W. Dennis, M. Am. Soc. C. E.

Malone Railway through the Adirondack Mountains to Racquette Lake. Of this road Mr. Ward had complete control until the death of Collis Potter Huntington, F. Am. Soc. C. E., in August, 1899, when it was leased to the New York Central Railroad Company.

During the years following, Mr. Ward constructed the Glenfield and Western Railroad, in New York State, and, in 1902, went to Washington Court House, Ohio, at the instigation of Henry Edwards Huntington, the nephew of the late Collis P. Huntington. Mr. Huntington owned the water supply system at Washington Court House which up to the time of Mr. Ward's association with it had never produced a sufficient supply of water to serve the needs of the community. He developed new wells and left the plant in a much improved condition when he came to California in the spring of 1905, at the request of Mr. Huntington.

In Los Angeles, he was associated with the Huntington interests for many years, first as Assistant General Manager, later as General Manager of the Huntington Land and Improvement Company and the various subsidiary companies, developing water properties, and laying out subdivisions, in addition to his managerial duties.

One of the most ambitious of Mr. Huntington's ventures was the Pacific Light and Power Corporation, of which Mr. Ward was elected Vice-President in 1911. It was this Company which made the original hydro-electric development in the Big Creek Region northeast of Fresno, Calif. In 1917, the Pacific Light and Power Corporation and the Southern California Edison Company were consolidated, bringing the partly completed Big Creek project into the new ownership and also bringing to the staff Mr. Ward and many of his associates. This great engineering project carried on over a period of years was finally completed in 1928, and attracted widespread attention everywhere in the United States because of its magnificent proportions and completeness of development. During the construction of the Big Creek project, 56 miles of railroad were built through the mountains about 70 miles northeast of Fresno, for the purpose of hauling construction material and men, and huge camps were operated for the thousands of employees. Dams, tunnels, power houses, and transmission lines were built. Something in excess of 500 000 hp was thus developed for use in Central and Southern California.

During this period Mr. Ward was Vice-President in Charge of Engineering and Construction of the Southern California Edison Company and this great project was carried to completion by him. In the fall of 1931, he became Senior Vice-President of the Company, and upon the death of Mr. Russell H. Ballard in August, 1932, he became its President, in which capacity he served until his death.

To provide a supplementary source of power to meet possible emergencies caused by adverse weather conditions, the Edison Company carried on the program of steam-plant construction under Mr. Ward's direction. The site of these supplementary plants is near Long Beach, Calif., where there is an abundance of cooling water, ready access of fuels, and a short transmission distance to the principal areas where electricity is sold. This steam-plant program culminated with the erection of two highly efficient units with a combined capacity of 268 095 hp. Mr. Ward's insistence upon the highest known type of construction in these plants was justified by their performance during the earthquake of March, 1933, when they maintained their service with only a slight interruption.

Mr. Ward's work was recognized by the Western Division of the United States Chamber of Commerce at its meeting in Seattle, Wash., on December 7, 1925. At that time in commemorating the completion of the Florence Lake Tunnel, the Chamber of Commerce presented him with a large bronze medallion mounted on a granite block taken from the excavation of that tunnel. In making the presentation Vice-President Shoup of the Chamber of Commerce paid tribute to the engineering genius of Mr. Ward and his associates and declared that their achievement was a distinct contribution to the welfare and prosperity of the nation. The medallion is centered with a bas-relief of Mr. Ward with this significant phrase, "By their works ye shall know them."

Mr. Ward received the Honorary Degree of Doctor of Engineering from the University of Southern California, at Los Angeles, on June 4, 1927, "in recognition of distinguished achievement in the field of applied science."[3]

Dr. Ward had conferred on him the further Honorary Degree of Doctor of Science by Oberlin College, Oberlin, Ohio, in 1928. In presenting Dr. Ward at the ceremonies Dr. L. W. Taylor, of Oberlin, said of him:

> "He is responsible for the engineering aspects of what has been termed the greatest conservation project in history. The construction of huge water reservoirs at an altitude of more than a mile; the installation of a great system of dams, conduits, tunnels, and power stations; the provision of irrigation facilities for hundreds of square miles, and a power supply for millions of population; the design and development of the most economical system of power distribution known to the engineering world; such accomplishments require scholarly attainment in technical fields, combined with wise and farseeing administration."

Posthumously, Dr. Ward has been further honored. The Southern California Edison Company, Limited, caused his name to be used as a permanent designation of the tunnel between two of its major reservoirs. This tunnel connects Florence Lake Reservoir with Huntington Lake Reservoir as a part of the Big Creek project. It is 13 miles in length, at an altitude of 7 000 ft, and was constructed through the granite of the Sierras at a cost of $17 000 000. During construction days it was called the Florence Tunnel, but now is officially known as the Ward Tunnel, a name which has been confirmed by the Division of Geographic Names of the United States Department of the Interior. Looking down upon the intake of the Ward Tunnel at the Florence Lake Reservoir is a massive pile which appears upon the maps as an unnamed mountain. It includes three peaks at altitudes of 10 395, 10 500, and 10 800 ft, respectively, above sea level. This mountain has been named Ward Mountain, also by action of the Division of Geographic Names.

---

[3] From the minute book in the office of the President of the University of Southern California.

Dr. Ward was married in 1886 to Katherine L. Schweinsberg, of Boonville, N. Y. Mrs. Ward and their daughter, Mrs. Louise (Ward) Watkins, survive him.

He had many interesting hobbies, among them the collection of rare books and manuscripts and of relics of the Indians of the Southwest. He was a member of several organizations, including the California, the Jonathan, the Sunset, and the Zamorana Clubs; and was a Knight Templar and a Thirty-Second Degree Mason. He was an Associate Member of the Board of Trustees of the California Institute of Technology, and a contributor to the philanthropic and civic organizations of Southern California.

Dr. Ward was elected a Member of the American Society of Civil Engineers, on February 10, 1930.

CHARLES ALFRED WILSON, M. Am. Soc. C. E.[1]

Died June 3, 1935

Charles Alfred Wilson was born in Conowingo, Md., on April 4, 1855, the son of John Howard and Anna Catherine (Cheyney) Wilson.

Charles Alfred Wilson entered railway service in 1869 at the age of 14 and during his entire professional career was engaged in railroad engineering. A High School education, at West Chester, Pa., supplemented by technical training obtained while working with his father, who was a practising surveyor and civil engineer, fitted him for his early start as a Flagman with the Engineer Corps of the Philadelphia and Reading Railroad Company.

In those early days, railroad engineering meant mostly railroad construction, and positions as Rodman on construction, with the Pennsylvania and Delaware Railroad Company, and the Atlantic and Great Western Railway Company, and as Resident Engineer, with the South Mountain and Boston Railroad Company, brought him up to February, 1875.

From that time until 1878, Mr. Wilson served as Engineer and Roadmaster, with the Philadelphia, Newtown, and New York Railroad Company, and as Engineer of Surveys, with the Atlantic and Lake Erie Railroad Company. Also, within that period, in 1876, he served on the Bureau of Awards, for the United States Centennial Commission, at Philadelphia, Pa.

During 1879 and 1880 he was Resident Engineer on the construction of the Ohio and West Virginia Railway, which was the Ohio River Division of the Columbus, Hocking Valley, and Toledo Railway, later a part of the Chesapeake and Ohio Railway.

Mr. Wilson's long service with the Wheeling and Lake Erie Railway Company began in 1881 with the duties of Principal Assistant Engineer on Construction. In 1883, he was made Chief Engineer, at the age of 28, and continued in that position until January 1, 1896. In addition, he held the title of General Superintendent from March, 1893, to September, 1895.

---

[1] Memoir prepared by O. E. Selby, Jun. Am. Soc. C. E.

On January 1, 1896, Mr. Wilson entered the service of the Cincinnati, Hamilton, and Dayton Railway Company as Chief Engineer and Assistant to the President. The latter title was dropped eight years later, but he continued as Chief Engineer until displaced by reason of a change in management in 1909.

In 1909, Mr. Wilson opened an office in Cincinnati, Ohio, as a Consulting Engineer and Railway Expert. He accepted retainers as Special Consulting Engineer for the Erie Railroad Company and the Chesapeake and Ohio Railway Company, and conducted investigations and made reports on the valuation and other features of properties for a number of Eastern railroad companies. His principal activities, however, beginning in 1912, were in studies for the improvement of passenger and freight terminal facilities in Cincinnati, resulting in the completion, in 1933, of the magnificent passenger station and other facilities of the Cincinnati Union Terminal Company. Until the formation of that Company for the purpose of building the new terminal in 1927, Mr. Wilson was employed as Consulting Engineer for various Committees of Engineers of the seven railroads entering Cincinnati, engaged in making studies of the various aspects of the terminal problem as related to both passenger and freight service.

The Board of Directors of the Cincinnati Union Terminal Company appointed him Consulting Engineer to the Chief Engineer on November 23, 1927. He continued in that capacity during the construction period, until May, 1933, after which he retained a nominal connection as Consulting Engineer, until his death.

At this point it seems fitting to describe briefly Mr. Wilson's technical society activities. He was a frequent attendant at the Annual Meetings and Annual Conventions of the Society, was an active member of the Local Section, at Cincinnati, Ohio, and, in other ways, showed his interest in the Society and its affairs.

He was one of the promoters and a Charter Member of the American Railway Engineering Association. He was proud of his record of having attended every Annual Convention of that Association. At the meeting in March, 1935, he was cited for that record and for his part in the inception of what has come to be one of the outstanding organizations of railway men.

In his remarks in response to that citation, Mr. Wilson disclosed the history of the formation of the Association and the reasons that actuated him in promoting it. He said that in his relations with the officers of the Motive Power and Car Departments of the railroad companies on which he represented the Engineering and Maintenance-of-Way Department, he found himself at a disadvantage because those men belonged to their respective associations of master mechanics and master car builders, and those organizations had standards and rules of practice, whereas there was nothing like that for maintenance-of-way engineers.

This state of affairs led him to discuss with others the formation of an association of engineers engaged in railway maintenance. A meeting at Chicago, Ill., was called for that purpose in 1898, at which Mr. Wilson nominated the Chairman. The outcome was the formation, in 1899, of what is now the American Railway Engineering Association.

A man of sociable habits and free conversational traits, Mr. Wilson nevertheless was modest to the point of shyness with respect to himself. He discussed men and things and policies, but not his personal affairs. Several of his friends who were in close business relations with him for years have been able to recall for the writer of this memoir only a few incidents or anecdotes relating to his personal life.

He was a man of sterling character and simple habits, with the highest ideals of duty to his employers and to society. Holding strong convictions on many subjects, he discussed them freely, but never was known to show vindictiveness toward any one who held other views. He resided for many years in Wyoming, a suburb of Cincinnati, where he was active in social and civic affairs and formed many friendly relations. In addition to his technical society memberships previously described, he was a member of the Wyoming Golf Club and the Cincinnati Torch Club.

He was married to Carree Ione Stevens on November 21, 1883. Two sons, Cheyney Stevens and Hamilton, were born of this union. Mrs. Wilson died on October 21, 1919. He is survived by Mrs. Edna Sutherland Wilson, whom he married on September 20, 1929, and his two sons.

Mr. Wilson was elected a Member of the American Society of Civil Engineers on April 1, 1891.

HENRY FELIX WILSON, M. Am. Soc. C. E.[1]

DIED MARCH 2, 1935

Henry Felix Wilson was born in Mobile, Ala., on October 31, 1867, the son of Henry Felix Wilson, Sr., and Virginia (Clark) Wilson. He received his preparatory education in private schools, and then entered the University of Alabama, at Tuscaloosa, Ala., from which he was graduated in 1886 with the degree of Bachelor in Engineering.

Immediately after his graduation from college, Mr. Wilson was employed from July, 1886, to March, 1888, as Assistant Engineer and Draftsman with the late Arthur Owen Wilson, M. Am. Soc. C. E., at Birmingham, Ala. As such, he was engaged in general engineering practice, on the location and construction of railroads, municipal engineering, land and topographical surveys, foundations, etc.

Mr. Wilson then entered the railroad field as Assistant Engineer and Draftsman with the Georgia Pacific Railroad Company (later, a part of the Southern Railway System). From May to December, 1888, he served as Assistant Engineer on the construction of the Yazoo River Crossing in Mississippi, which bridge consisted of one 300-ft draw-span, two 100-ft approach spans, about 1 000 lin ft of pile trestle approaches and also 5 miles of grading. On the completion of the bridge, Mr. Wilson was transferred to the Superintendent's Office, in Greenville, Miss.

---

[1] Memoir prepared from information supplied by the family and on file at the Headquarters of the Society.

From January to March, 1889, he was Assistant Engineer in charge of heavy construction on the Huntsville and Monte Sano Railway; and from April to December of the same year, he was Assistant Engineer and Draftsman on the construction of the Briarfield, Blocton, and Birmingham Railroad (later, part of the Southern Railway System). In this position, Mr. Wilson made designs and drawings for wooden Howe trusses, checked estimates, etc.

As Engineer for the Montevallo Coal and Transportation Company from January to April, 1890, he made surveys and mapped the Company's lands, located coal seams, etc. He then returned to the Briarfield, Blocton, and Birmingham Railroad Company and was engaged in making trial right-of-way maps, etc., in the Chief Engineer's Office, in Birmingham. From October to December of that year, Mr. Wilson served as Engineer for the Woodward Iron Company, with headquarters at Woodward, Ala. In this capacity he surveyed and mapped the Company's property, and also did some railroad location and construction.

In January, 1891, Mr. Wilson opened an office in Birmingham and engaged in private practice there until April, 1892, in general engineering. From May, 1892, to September, 1896, he served with J. W. Worthington and Company, of Birmingham. This firm was the largest contractors of iron ores and limestone for furnace fluxing in the District, and Mr. Wilson was engaged in construction, such as railroads, hydraulic pumps, etc.

He then returned to railroad work and from October to December, 1896, he served as Resident Engineer on heavy construction for the Mobile, Jackson, and Kansas City Railroad Company in Mobile County, Alabama, with headquarters in Mobile. In 1897, Mr. Wilson went to the Southwest and was engaged as Chief Engineer of the Raton Coal and Coke Company, at Raton, N. Mex. In this capacity, he designed and constructed railroads, coke ovens, power houses, etc., as well as opening mines and equipping them with electricity.

Still in the Southwest, Mr. Wilson spent the year 1898 as Draftsman and Computer with the International (Water) Boundary Commission between the United States and Mexico. He made large maps of surveys of the Rio Grande, checked the notes of the surveys preparatory to platting, etc. Leaving the Government service, he was employed from January to May, 1899, as Assistant Engineer on the construction of the El Paso and Northeastern Railroad, with headquarters at Alamogordo, N. Mex. He also was engaged in the construction of a mountain timber road.

Returning to Birmingham, Ala., Mr. Wilson was employed from June to September, 1899, as Assistant Engineer and Draftsman with the Southern Bridge Company. He also had charge of all contract lettings for the Company in the South from Virginia to Texas.

In October, 1899, he again entered private practice, with an office in Birmingham, until December, 1908. During this time he was engaged in railroad location and construction; coal and iron ore mining; timber and concrete construction; tests and reports; served on boards of arbitration, as expert witness in Courts in railroad cases, etc. Mr. Wilson represented the Pittsburgh Testing Laboratory, of Pittsburgh, Pa., in the Birmingham District for several years; he also made tests of creosoted timber for the New York State Barge Canal, etc.

In 1909, he closed his office in Birmingham, and went to Goldfield, Nev., during the gold strike there. In 1910, however, he returned to Alabama and was employed as Assistant Engineer in charge of timber railroad construction in Middle Alabama for the Louisville and Nashville Railroad Company. During 1911, and the first three months of 1912, the South was in the grip of an industrial depression, and Mr. Wilson was employed for only three months as Engineer in charge of railroad location from Memphis, Tenn., toward Pensacola, Fla.

In April, 1912, he went to Cuba and until June of that year served as Assistant Engineer with the Guantanamo and Western Railroad Company, with headquarters at Guantanamo. He had been engaged to superintend the reconstruction of the entire road, but the Revolution of 1912 stopped all work and the engineering force was laid off.

Mr. Wilson was employed as Assistant Engineer with the Cuban Central Railways, Limited, at Sagua la Grande, Cuba, from July, 1912, to June 1914. He had charge of the location and construction of various lines, deep-water harbor improvements at Nuevitas, Cuba, including docks, terminals, water-works, etc.

He then returned to the United States and again entered the service of the Southern Railway Company. Among other works, he had charge of the construction of the Freight Terminal, in Mobile. In 1917 and 1918, he was again in Cuba, for eight months, as Engineer of Bridges and Buildings of the Cuban Central Railways Company, Limited, and from June to October, 1918, on special surveys with the Spanish-American Iron Company, at Felton, Cuba.

From November, 1918, to December, 1919, Mr. Wilson was employed on design and construction for the Pratt Consolidated Coal Company of Birmingham. He then entered the service of the Alabama State Highway Department and for six months in 1920 he was engaged on field surveys and in charge of the Drafting Office.

In April, 1921, went to Central America and served on construction and operation with the Cuyamel Fruit Company, in Spanish Honduras. In 1922, he again returned to Birmingham and entered the employ of Martin J. Lide, Consulting Engineer. He retained this position until September of that year, and was engaged in drafting, designing, and construction work. From October, 1922, to July, 1923, Mr. Wilson was with the engineering firm of Black, McKinney, and Stewart, of Washington, D. C., as Chief Draftsman and Chief Engineer of Construction.

In 1924, he entered the employ of the Tennessee Coal and Iron Company, as Draftsman, and remained with this Company until 1933. From that time until his death he was an Engineer for the Federal Government on work for the Civil Works Administration and the Federal Emergency Relief Administration.

He was a member of the Birmingham Engineers Club, the Kappa Alpha Fraternity, and the Presbyterian Church.

On December 23, 1890, Mr. Wilson was married to Corinné Estelle Harris and is survived by his widow, and a son, Harry F. Wilson, of Little Rock, Ark.

Addressing the Editor of *The News,* Mr. E. C. Crow, of Birmingham, Ala., a college classmate, fraternity brother, and long-time neighbor, writes of Mr. Wilson, as follows:

"In the death of Henry F. Wilson recently, Birmingham has lost another of its pioneer builders."

* * * * * * *

"I am confident that Mr. Wilson's business associates and other college friends would join me in testifying to his professional integrity, and his conscientious and efficient services for his city and country."

Mr. Wilson was elected an Associate Member of the American Society of Civil Engineers on April 2, 1902, and a Member on May 2, 1905.

JACKSON FRANKLIN WITT, M. Am. Soc. C. E.[1]

DIED APRIL 2, 1935

Jackson Franklin Witt was born at Dallas, Tex., on November 5, 1869, the son of John T. and Nannie (Johnson) Witt. His early education was received in the grade schools of East Dallas.

Through necessity, Mr. Witt left school when he was twelve years of age and began work as a Chainman with a railroad location party. After this first job, he spent three years at home attending the public schools. When he was sixteen years old he was employed as a Chainman on Federal Government work.

In 1886, Mr. Witt was with the Gulf, Colorado, and Santa Fé Railroad Company, as Rodman and then as Levelman. He was with the St. Louis and Southwestern Railroad Company as a Transitman in 1887, and, in 1888, he served as Transitman on a railroad location from Lampasas, to Llano, Tex. In 1889, he was Transitman on a location survey for the Dallas and Northwestern Railway.

After completing the survey for the Dallas and Northwestern Railway, in 1889, Mr. Witt was employed as City Engineer for East Dallas, Tex. Late in 1890, when he was 21 years of age, he opened an office, and engaged in engineering and surveying. He maintained this office until 1905, when he became Assistant to the County Engineer of Dallas County Texas. During the time he was Assistant County Engineer Mr. Witt assisted in the first program of constructing hard-surfaced roads in Dallas County. This was one of the first programs of its kind in Texas.

---

[1] Memoir prepared by A. P. Rollins, M. Am. Soc. C. E.

In 1907, he was appointed County Engineer of Dallas County, which position he held until 1919. It was while he was County Engineer, in 1911 and 1912, that the old Oak Cliff Viaduct was designed and constructed. This viaduct, one mile long, composed of 80-ft concrete arches, on pile foundations, and with a clear roadway of 44 ft, was outstanding at that time. Several other large bridges were constructed, and many miles of surfaced roads were built. As County Engineer, Mr. Witt was a pioneer in introducing asphalt surfacing for highways in Texas.

During the World War, he served the Government as a member of the Highway Transport Board, at $1 per yr. In 1919, Mr. Witt became a member of the Nagle, Witt, Rollins Engineering Company, which Company operated from 1919 to 1928. During this time he managed the affairs of the Company and had personal supervision of construction amounting in value to more than $10 000 000.

From 1928, until his death, Mr. Witt remained active in private practice in the engineering and construction field. His experience as a Consulting Engineer was broad, including such projects as toll bridges across the Rio Grande and the Red River; a highway program for Hopkins County, Texas; laying out and supervising the construction of a highway plan for Dallas County, Texas; and highway plans for Potter and Stephens Counties, Texas.

His life, as indicated by this record, was a continuous struggle, the opportunity for training having been denied him. His success as an engineer was due to his courage and indomitable will.

Mr. Witt's ability to make new friends and to retain his old ones, his constant desire to serve these friends and his willingness to participate unselfishly in civic affairs brought him wide recognition as a friend and a citizen. He was a member of the Presbyterian Church.

He was married on December 4, 1889, to Lucia Matella Lagow. He is survived by Mrs. Witt and a daughter, Mrs. Elsie Eria Clark.

Mr. Witt was elected an Associate Member of the American Society of Civil Engineers on October 31, 1911, and a Member on September 21, 1915. During his active engineering career, he served for a number of years as Secretary and Treasurer of the Texas Section of the Society.

GEORGE STEVENSON YATES, M. Am. Soc. C. E.[1]

Died November 1, 1935

George Stevenson Yates, the son of James and Elizabeth (Stevenson) Yates, was born in Leith, Scotland, on November 11, 1875. After his preparatory education, he entered Edinburgh University, in 1894, where he studied engineering for three years, and was Assistant Demonstrator in the Engineering Laboratory for two years.

---

[1] Memoir prepared by William Stewart, Esq., London, England.

His first important appointment was with the Caledonian Railway Company, at Glasgow, Scotland (later a part of the London, Midland, and Scottish Railway Company). Under the late Sir Donald Mathieson—then Chief Engineer but afterward General Manager of the Company—Mr. Yates took part in the rebuilding of the Central Station, at Glasgow.

In 1903, he transferred to the Engineering Staff of Dorman, Long and Company, Limited, at Middlesbrough, England, as a Designer and Estimator. After serving with this firm for four years Mr. Yates received an appointment as Chief Engineer and Draftsman at the works of Redpath, Brown and Company, at Greenwich, England. Late in 1918, he opened a Branch Office for the firm in Brussels to take part in the reconstruction of the war areas in Belgium. From Brussels, he was transferred, in 1920, to the works of the Skinningrove Iron Company, Limited, in Yorkshire, in which Redpath, Brown and Company had acquired a financial interest. At Skinningrove, Mr. Yates was in charge of the Materials Yard and had control of the distribution of materials to the various branches of Redpath, Brown and Company throughout Great Britain. On the termination of the arrangement with the Skinningrove Iron Company, Redpath, Brown and Company entered into a financial arrangement with Bolckow, Vaughan and Company, Limited, at Middlesbrough. Here, again, Mr. Yates had control of the Materials Yard and the distribution of materials to all the branches of Redpath, Brown, and Company, as well as of a small construction plant.

His next move, in 1930, was back to the Greenwich Works of Redpath, Brown and Company where, following an amalgamation between Dorman, Long and Company, Limited, and Redpath, Brown and Company, Limited, he had charge of a new Department in which the purchase and control of tools and equipment for all branches of Redpath, Brown and Company and Dorman, Long and Company, in Great Britain, were centered.

At the time of his death, Mr. Yates was a member of the Mechanical Industry Committee of the British Engineering Standards Institution, dealing with derrick cranes.

During the course of his career, he was responsible for the design and erection of many important bridges, factories, office buildings, and clubs, one of his latest designs being for the twelve-span floating bridge, at Mombasa, Kenya Colony, British East Africa. He was a fine mathematician, and had an extensive knowledge of French and English literature.

Of a generous and genial disposition, Mr. Yates had hosts of friends, particularly in London and on the Northeast Coast of England, and was highly esteemed by all who knew him. His death was due to angina pectoris, to which he succumbed after a short illness.

He was married on December 26, 1902, to Margaret Stewart, at Glasgow, Scotland, and is survived by his widow, a daughter, and two sons.

Mr. Yates was elected a Member of the American Society of Civil Engineers on May 12, 1919.

GEORGE WASHINGTON ARMITAGE, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 24, 1935

George Washington Armitage was born in Chicago, Ill., on February 22, 1876, the son of William and Delia Armitage. He received his education in the public schools of his native city, after which, in 1896, he removed to New York, N. Y., where he was employed as a Draftsman in the Construction Division of the Board of Education.

Two years later Mr. Armitage went to the Yukon on a prospecting expedition, and a few months after his return, in 1899, obtained a position under the late General William M. Black, U. S. Army (*Retired*), M. Am. Soc. C. E., as a Civil Engineer in Cuba during the First American Intervention. He remained there until the end of the intervention (May 20, 1902), and during that time took an active part in many construction projects. Upon his return to the United States, he obtained a position as a Civil Engineer and Superintendent of Construction in the Quartermaster Corps of the United States Army. He served in that capacity in Chickamauga Park, Georgia, Fort Lincoln, North Dakota, and other posts.

In 1907, at the beginning of the Second American Intervention in Cuba, his services were especially requested by the Cuban Government. Accordingly, he was granted a leave of absence by the War Department and became Chief of the Department of Civil Construction in Cuba. He remained in that post throughout the Second Intervention and at its close, in 1908, returned to the United States and resumed his duties with the War Department.

In 1909 Mr. Armitage was one of the engineers charged with supervising the construction of the Army piers at Fort Mason, San Francisco, Calif. In the latter part of 1912, he was ordered to Schofield Barracks, Hawaiian Islands, as Superintendent in Charge of Construction. He also planned and supervised the construction of Fort Kamehameha.

After war was declared by the United States against Germany, he accepted, in October, 1917, a commission as Captain in the Quartermaster Corps of the National Army, and in the spring of 1918 was ordered to the Port of Embarkation, at Hoboken, N. J. During that year he was promoted to the rank of Major. In 1920, he was commissioned a Captain in the Regular Army. From 1920 to 1924, he was Construction Officer for the Second Corps Area, with headquarters on Governor's Island, New York. His next station was Washington, D. C., where he remained until 1927. During part of his tour of duty there he was a member of the General Staff and did valuable work in connection with the Housing Program of the Army.

In 1928 Captain Armitage was again sent to the Hawaiian Islands and, after a brief tour of duty as Utility Officer at Fort Armstrong, was appointed

---

[1] **Memoir prepared by George Armitage, Esq., San Francisco, Calif.**

Constructing Quartermaster for the Hawaiian Department. While serving in that capacity, his principal work was planning and supervising the construction of Wheeler Field. That project was dear to him, and the barracks and quarters there are considered models throughout the Army.

In 1933, he became Constructing Quartermaster for the Ninth Corps Area, with headquarters at the Presidio of San Francisco. In addition to his regular duties in connection with construction, repair, and alteration in the Area, Captain Armitage planned and supervised the erection of about 600 camps for the Civil Conservation Corps.

On April 24, 1935, he passed away at the Letterman General Hospital, Presidio of San Francisco, following an operation. He was buried at Arlington National Cemetery, in Virginia, with full military honors.

Captain Armitage leaves his widow, Marie Edna Smith, to whom he was married in New York City, in 1902, and a son, George. He is also survived by three sisters and a brother: M. Theresa Armitage, Mrs. S. H. Richman, Mrs. Dom F. Zito, and William Armitage.

Through his long and eventful career with the War Department, Captain Armitage earned the reputation of being extremely able in his profession. He had the faculty of getting things done despite all obstacles, and his determination was one of his outstanding characteristics. He was regarded as an engineer of marked ability and his loss to the Service will indeed be felt. He leaves many monuments to his memory throughout the United States, including many Army Posts, the two most notable of which are Schofield Barracks and Wheeler Field, in the Hawaiian Islands.

Captain Armitage was elected an Associate Member of the American Society of Civil Engineers on April 2, 1902.

FRANK KARR ASHWORTH, Assoc. M. Am. Soc. C. E.[1]

Died July 24, 1935

Frank Karr Ashworth was born on September 11, 1885, at Osceola, Iowa, the son of Robert H. and Ada (Chapman) Ashworth. On his mother's side he was a descendant of Peter Bulkeley, famous in early Colonial history, and also of the Chapman family, well known throughout New England. His paternal grandmother was a member of the Murray family prominent in the establishment of the Universalist Church in the United States. His father was a Civil Engineer, a graduate of the University of Ohio, at Athens, Ohio.

In 1890, the family moved to Colorado Springs, Colo., where for many years the father was City Engineer. In this enviroment Frank Ashworth early took on interest in engineering work and when old enough spent his vacations learning the rudiments of the profession. He went through the grades and High School in Colorado Springs and distinguished himself in mathematics. At this time, also, he became intensely interested in music and determined to perfect himself in his chosen instrument, the piano. To that end he went to the Bush Temple Conservatory of Music, in Chicago, Ill., in the autumn of 1904. His work there was outstanding and he won a scholarship. However, in 1906, when he was obliged to choose between music and engineering as his life work, the latter won although the former remained a source of great pleasure and inspiration throughout his life.

---

[1] Memoir compiled from information on file at the Headquarters of the Society.

Since a university or technical school training was not possible, Mr. Ashworth early formed the habit of studying by himself, a habit which remained with him and which resulted in his becoming a highly educated and exceptionally well-read man.

At the beginning of 1906, Mr. Ashworth entered the office of the City Engineer in Colorado Springs as Transitman and by 1908 was in charge of the design and construction of many municipal improvements. He remained in Colorado Springs, gaining broad and valuable experience, until late in 1911, when he went to San Diego, Calif., to join the Staff of the San Diego County Highway Commission and, later, the San Diego Securities Company, in charge of general sub-division improvements.

In the early spring of 1913, Mr. Ashworth went to Florida to join his father who had gone there to take charge of the development of a large project, and they opened an office for private practice in the City of Miami. This partnership continued until the death of the father in 1916, after which Mr. Ashworth continued the business alone. In the rapidly growing community of which Miami was the center, he built up a large practice, interesting and diversified, including the design and construction of drainage systems, roads, sea-walls, and various types of municipal improvements. This general practice was interrupted in January, 1917, when he became Chief Engineer for the Chevalier Corporation and spent his entire time in planning the development of its holdings in Southern Florida, amounting to several thousands of acres. He planned a drainage system and a railroad to tap the Great Cypress Swamp.

This project was interrupted by the World War. On September 1, 1918, Mr. Ashworth went to Camp A. A. Humphreys, in Virginia, where he was commissioned a First Lieutenant of Engineers. On his return to civil life in December, 1918, he resumed his private practice in Miami and specialized in sub-division design and supervision. In that community this included drainage, sea-walls, and dredging, in addition to the usual municipal improvements. During the years of Florida's most rapid development, he designed and supervised the work on many of the most beautiful sub-divisions of Miami, including the famous Miami Shores, the plans for which included the expenditure of more than $5 000 000.

In 1930, Mr. Ashworth decided to return to the West and went to Los Angeles, Calif. He did some special work for that City in the Park Department, and then became interested in valuation engineering. He was employed by the Southern California Gas Company, the City of San Diego, and, later, the State Board of Equalization, in this capacity. In April, 1935, he was offered a position with the State Highway Commission, and was stationed at Redding, Calif. A serious attack of bronchial pneumonia in January had gravely affected his heart, however, and on July 24, 1935, he passed away in his sleep. He is survived by his widow, formerly Myrtle English, to whom he was married on March 24, 1915, and by one brother, Raymond C. Ashworth, Assoc. M. Am. Soc. C. E., Valuation Engineer for the Los Angeles Railway Company.

Mr. Ashworth was a Mason, and while in Florida was a member of the Florida Engineering Society, the Florida Natural History Society, the Civitan Club, Miami City Club, and the Miami Section of the Society.

Although quiet and somewhat shy in manner, Mr. Ashworth made many close friends, and he had established an enviable reputation for absolute integrity and loyalty in both personal and business associations. His mental equipment was far beyond the average, and his fine spirit never faltered in the face of adversities, both material and physical, which would have conquered a less courageous soul.

Mr. Ashworth was elected an Associate Member of the American Society of Civil Engineers on June 18, 1919.

THERON McCABE BROWN, Assoc. M. Am. Soc. C. E.[1]

Died March 3, 1935

Theron McCabe Brown was born at Winfield, Kans., on February 19, 1897, the son of Lewis and Orlena L. (Walrath) Brown. His elementary education was obtained in the public schools of Winfield and Hutchinson, Kans., after which he studied at Lombard College, Galesburg, Ill., where he specialized in mathematics. In 1917 he enrolled at the University of Cincinnati, Cincinnati, Ohio, where he was a student of engineering until September, 1918, when he entered the Army Training Corps at the University. Like many college men of this period, his studies were seriously interrupted by the war in Europe, but he was able eventually to complete his technical training through extension courses with the University of Wisconsin, Madison, Wis.

After the World War Mr. Brown was employed as Rodman and Instrumentman on highway and drainage surveys under County Engineer W. B. Harris, at Hutchinson. He then became Secretary-Treasurer of the Southwestern Engineering Company, of Hutchinson, organized to engage in highway and bridge engineering. In December, 1920, Mr. Brown accepted the position of Assistant Engineer to O. N. Powell, County Engineer, at Corpus Christi, Tex., where he was engaged on the design of the Corpus Christi Causeway until the early part of 1921. On the completion of this work he returned to private practice at Hutchinson for about a year. In April, 1922, he was employed as Designer and Construction Engineer in the office of Horner and Wyatt, Consulting Engineers, Kansas City, on industrial development and reclamation projects, where he remained until March, 1924.

---

[1] Memoir prepared by C. L. Williford, M. Am. Soc. C. E.

From April, 1924, to November, 1927, Mr. Brown was Designer and Office Engineer for Nagle and Thompson, Consulting Engineers to the City of Dallas, Tex., on the design and construction of the Garza Reservoir, a $5 000 000 water-supply project, and one of the largest municipal undertakings in the Southwest, which positions he filled with high credit. On the completion of this project, he became Designing Engineer in the Department of Water Supply of the City of Dallas, of which John B. Winder is Superintendent and Chief Engineer. In this position, Mr. Brown was engaged, until April, 1930, in the design and construction of new municipal pumping plants, costing approximately $800 000.

On the completion of his work with the City of Dallas, Mr. Brown became associated with the Frank Parrott Construction Company, of Dallas, as Engineer and Construction Superintendent. This Company was then engaged in the construction of a large viaduct across the Trinity River, in Dallas, and several important grade separation structures in Dallas County. Mr. Brown handled the field operations on these structures to successful completion, and they stand as monuments to his industry.

From April, 1932, to November, 1933, Mr. Brown was connected with the Engineering Staff of the State Highway Department at Dallas, on special designs and construction of important highway bridges. At this time he also inaugurated preliminary studies for the Department and the City of Dallas on the proposed Elm-Main-Commerce Street grade separation at the Union Terminal Railway which is now under construction at a total cost of nearly $1 000 000. He, no doubt, would have been placed in responsible charge of this notable project, but while these studies were in progress he was drafted by the Director of Public Works in Texas, of the National Administration, to supervise all Public Works Administration construction work in the Dallas Area. It was while engaged on this work that he suffered severe injuries in an automobile accident which caused his death a week later, on March 3, 1935. Mr. Brown's untimely death at his prime was a severe shock to his many friends and associates, and most of all to his family.

He was married on June 14, 1920, to Pauline A. Lockhart, of Dallas, who, with their daughter, Marie Adell, and a son, Lewis, survives him. He is also survived by his father and mother, and two sisters, Ruth Evelyn Brown, of Hutchinson Kans., and Rhoda A. Brown, of Los Angeles, Calif.

He was a Mason and a Shriner, and for many years had been an active member of the Episcopal Church, in Dallas. In his home, he was a true husband and father. By those who knew him, he was most highly esteemed as an upright citizen, a Christian gentleman, and a thorough and competent engineer. He was laid to rest among the scenes of his boyhood at Hutchinson, Kans.

Mr. Brown was elected an Associate Member of the American Society of Civil Engineers on November 12, 1928.

GEORGE BUTLER, Assoc. M. Am. Soc. C. E.[1]

Died April 16, 1935

George Butler was born on February 6, 1864, at Boston, Mass., the son of Major George Butler, United States Marine Corps, and Alice (Kierulff) Butler. He was educated in the public and private schools of the region, and at St. Johnsborough Academy, in Vermont. In early youth he suffered a severe accident which interrupted his schooling, and the major part of his engineering education was obtained by constant home study and reading.

In 1887, Mr. Butler moved to Colorado Springs, Colo., where he entered the City Engineer's Office as Draftsman and Instrumentman, later transferring to the County Surveyor's Office of El Paso County, Colorado. In 1888, he entered the employ of the Hartford Loan and Trust Company as Computer and Draftsman on irrigation projects and, in 1889, became Assistant to the Chief Engineer of this Company.

In 1890, Mr. Butler entered into private engineering practice in and around Denver, Colo. In 1891, he joined the United States Indian Bureau, Department of the Interior, under the late Walter Haden Graves, M. Am. Soc. C. E., as Draftsman for the Superintendent of Irrigation and Special Disbursing Agent. In 1892, Mr. Butler was made Principal Assistant to the Superintendent and placed in charge of the design of wooden and masonry irrigation structures, the location of canals, and in immediate charge of the construction of irrigation works in the Crowe and Navajo Indian Reservations. In 1895, he was placed in charge of this work as Superintendent of Irrigation and Special Disbursing Agent.

In 1899, Mr. Butler was appointed General Superintendent of Irrigation with the Indian Bureau in charge of examining, reporting upon, designing, and constructing irrigation, water supply, sanitary, and other engineering works. This work took him to the various Indian reservations in Arizona, New Mexico, Colorado, Wyoming, Nevada, and California.

In 1907, he resigned from the Indian Bureau to enter private engineering practice in and around the City of San Diego, Calif., and, in this same year, he was appointed to the office of County Surveyor of the County of San Diego.

It was during this period that his ability for re-organization and foresightedness stood him in good stead. The use of the automobile for transportation developed rapidly during these years, and the necessity of designing and constructing roads to meet this new method of transportation became apparent, roads had to be relocated and widened, sharp curves and grades eliminated, and drainage facilities provided. This necessitated the mapping of a comprehensive plan of road development and the re-organization of the office to meet these demands. This general use of automobile transportation also brought with it the subdivision of many outlying tracts of land for sale, and Mr. Butler at once realized that some regulations would have to be placed upon the promiscuous sale of lots to the public; it was due in a large part to his efforts that County ordinances and State laws were passed requiring the subdivider to meet certain regulations before his map could be filed and he was allowed to sell the property. This regulation of subdivisions in later years led to the formation of a County Planning Commission. In assuming the functions of County Highway Engineer and Planning Commissioner the once obscure office of County Surveyor became one of the most important departments of the County and was handled very ably by Mr. Butler.

---

[1] Memoir prepared by Paul R. Watson, M. Am. Soc. C. E.

In 1923, he again entered into private engineering practice, specializing in the legal aspects of land surveying, and he was considered an authority on boundary disputes.

As a hobby, Mr. Butler took up photography and his pictures of some of the rugged scenery of Arizona compare favorably with any professional work of this nature. He also took a great interest in the rites, ceremonies, and customs of the American Indian with whom his work with the Indian Bureau brought him in close contact, and he possessed a valuable collection of Indian relics and handicraft.

Mr. Butler was a member of the Masonic Order. He was the first President of the San Diego Section of the Society, and it was during his régime that the licensing of practicing engineers first came to the front in California. It was not until 1929, however, that a law was enacted by the State of California licensing the practice of Civil Engineering in the State.

He was married in 1893 to Bessie F. Wilstack, who survives him. He was a detail man, working from early boyhood under a great physical handicap, patiently and well. The one who knew him best states that whatever the game, however the stress, he always played fair and tried to help the other fellow.

Mr. Butler was elected an Associate Member of the American Society of Civil Engineers on September 6, 1910.

LEVI OSCAR COLEMAN, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 9, 1935

Levi Oscar Coleman was born at Paradise, Ky., on March 19, 1887, the son of P. S. and Arvilla Coleman. After passing the usual Grammar and High School courses, he entered the College of Engineering of the University of Kentucky, at Lexington, from which he received the degree of Bachelor of Civil Engineering in 1914.

During the summer of 1912, he began his engineering career as a Rodman and Levelman for Mr. John B. Wilson, of Hartford, Ky. His 1913 summer vacation was spent as Resident Engineer on five miles of sanitary sewer constructed by the City of Madisonville, Ky.

---

[1] Memoir prepared by A. H. Riney, Assoc. M. Am. Soc. C. E.

After receiving his degree in 1914, young Coleman went with the Delaware, Lackawanna, and Western Railway Company, as Rodman and Inspector on the construction of its Buffalo, N. Y., Terminal. However, the salary offered by the Railroad Company was not sufficient to hold the young engineer, and when in August of the same year a better offer was received from the Interstate Commerce Commission, it was promptly accepted, and from that time until the entry of the United States into the World War, Mr. Coleman worked out of Chattanooga, Tenn., on railroad valuation surveys. Starting as a Tapeman, he had progressed through the grades of Chainman and Rodman to that of Junior Engineer when war was declared.

At the outbreak of the World War Mr. Coleman enlisted, and, of course, was assigned to the Engineers. From May to August, 1917, he was in training—first at Fort Benjamin Harrison, Indiana, and then at Fort Leavenworth, Kansas; and, in August, he was commissioned Second Lieutenant of the 23d Engineers, and stationed at Camp Meade, Maryland, where he was engaged in training engineer troops. In February, 1918, he sailed for France, and during the remainder of the war—a period of sixteen months—he served as Roads Service Officer, building and repairing roads in the zone of the armies of the American Expeditionary Forces. Most of the roads were of water-bound macadam, and Lieutenant Coleman's work included the supervision of the operation of several quarries and stone crushers, about fifty trucks, several rollers, and from 100 to 350 men, including soldiers, labor troops, and prisoners of war. The commission of First Lieutenant was received in September, 1918. He took part in the St. Mihiel Offensive, the Meuse-Argonne Offensive, and the activities in the Toul Sector.

Lieutenant Coleman returned to the United States in July, 1919, and after receiving his honorable discharge in August, went with the Illinois Division of Highways, and was stationed in District 4, with headquarters at Peoria. Starting as a Resident Engineer, his summers were spent in supervising grading and drainage projects, concrete paving, and railroad grade-crossing construction, and during the winters he conducted surveys, made field and office locations, and designed reinforced concrete culverts.

After a time as a Resident Engineer, Mr. Coleman was made Construction Engineer of District 4, which called for the supervision of the various Resident Engineers. During one season, he had more than 100 miles of concrete pavement under construction. One of the most interesting jobs that he supervised was the building of 1½ miles of "sea wall" to protect pavements from being flooded by the Illinois River. The winter months during this period were spent in supervising the location parties operating in the twelve counties of the District.

While with the Illinois Division of Highways, Mr. Coleman began taking a series of Highway Short Courses for graduate engineers at the University of Illinois, at Urbana, Ill., covering Highway Administration, Finance, and Economics. These courses were taken in 1920, and in each of the years from 1922 to 1926.

His final position with the Illinois Division of Highways was as District Maintenance Engineer of the Peoria District, directing the maintenance and all force account construction for additions and betterments of several hundred miles of all types of highways.

In April, 1923, he accepted an offer from the L. S. Kuhn Construction Company, of Bloomington, Ill., and for the next eighteen months he was Construction Superintendent for that firm, in charge of grading, drainage, concrete pavement, and bridge construction projects, using an industrial railway outfit for hauling the aggregate, tractor-drawn elevating graders, and pile-driving outfits. His duties included not only the supervision of construction, but the making of bidding estimates, designing of plant layouts, and the keeping of cost-account records.

This cost-accounting experience was put to profitable use in August, 1924, when it became necessary to leave the Construction Company due to its failure to obtain additional contracts, and he accepted the position of Assistant Highway Engineer in charge of the office of the Illinois Division of Highways, at Springfield. In this capacity, Mr. Coleman supervised about twenty employees, paying bills, and keeping cost-account data on all maintenance and force account construction in the State. Costs and methods in the various Districts were compared in order to promote uniformity of methods and reduction of costs. While in charge of this office, he installed the cost-accounting system now used, and designed many of the devices employed in collecting maintenance cost data. He also collaborated in the design and installation of the maintenance cost-accounting system that was adopted later by most of the States of the Mississippi Valley Highway Association.

When he was offered a higher salary with the State Highway Department of Kentucky, in April, 1926, Mr. Coleman left Illinois to return to his native State as Assistant District Engineer, at Louisville. Here, he was in direct charge of all work done by contract in the District, which, during the three years he held the position, amounted to about $6 000 000. The work included heavy grade and drainage projects, paving, and other types of surfacing, and many concrete structures. Mr. Coleman's duties included also the supervision of surveys, the making of contractors' payment estimates, and the preparation of estimates preliminary to requesting bids. While in this position, he supervised the construction of 3½ miles of napped, stone base, water-bound, macadam road by force account.

In January, 1929, Mr. Coleman left the Highway Department of Kentucky to accept a more remunerative position as Vice-President, and Stockholder, of the Southeastern Construction Company, of Eminence, Ky. Acting as General Field Superintendent, his duties included the making of bidding estimates, the purchase of materials, and the superintendence of cost accounting. In 1929 and 1930, the Company constructed about $1 000 000 of projects, consisting of 75 miles of heavy grade and drainage work, together with bridges. Four steam shovels, ten caterpillar tractors, four scraper outfits, steam pile-driving equipment, and one hundred horses and mules were utilized.

Feeling that the equipment sales business had more possibilities than construction supervision, his interest in the Southeastern Construction Company was sold in April, 1931, and Mr. Coleman went with the Roy C. Wayne Supply Company, of Louisville, selling contractors' equipment in Kentucky. However, the depression caused such a severe curtailment in contractors' equipment purchases that commissions soon dropped below running expenses and shortly after the first of 1932, the sales position was abandoned.

In July, 1932, Mr. Coleman returned to the Kentucky Highway Department, as Superintendent of force account construction, in charge of the building of oiled roads and the construction of heavy grade and drainage projects. He remained with the Highway Department until April, 1935, when he left road building to return to the life that he had loved—that of the Army. He had received the commission of Captain in the Reserve Corps of Engineers on April 12, 1929, and in April, 1935, he was offered the opportunity of going into active service in charge of a camp of the Civilian Conservation Corps which he accepted. He was sent to Fort Knox for preliminary training, preparatory to taking charge of a camp, and then to Camp Benton, Kentucky. He was there until June 3, 1935, when he received an order of discharge because of a physical disability. He underwent an operation and was well on his way to recovery in the Jewish Hospital, at Louisville, when, on July 9, he died suddenly of a blood clot in the heart.

Captain Coleman had a high reputation in his profession, being known not only as a very careful, but also as a successful, engineer. He was especially proficient on work requiring high fills and one of his last jobs was the supervision of the construction of a section of concrete road on the Dixie Highway entering Louisville from the south, which was especially difficult because of the great fill. He never avoided responsibility and was well liked by his associates, having a very pleasing personality.

He was deeply interested in Army affairs from the time of his war service, and was very active in the Reserve Corps, of which he was a Captain in the 380th Engineer General Service Regiment. He often drove many miles to attend the Training School of the Regiment.

He was married at Owensboro, Ky., on May 29, 1920, to Eddith Duke. He is survived by Mrs. Coleman, a son, Bruce Sutton Coleman, a daughter, Anne Coleman, three brothers, and three sisters. He was buried at Owensboro, Ky.

Captain Coleman was elected an Associate Member of the American Society of Civil Engineers on October 15, 1923.

HENRY LEO CONNELL, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 25, 1935

Henry Leo Connell was born in New York, N. Y., on December 18, 1879, the son of Hugh G. and Ellen (Spence) Connell, and throughout his lifetime was identified with New York City. He was educated in its schools, and obtained his scientific education in that efficient school—Cooper Union.

---

[1] Memoir prepared by Lazarus White, M. Am. Soc. C. E.

Mr. Connell entered the service of New York City in 1900 which service continued until his death, except for a period when he was in business for himself as a Contractor.

Entering the City service as Axeman, Mr. Connell served as Axeman, Rodman, Leveler, Transitman, and Section Engineer on subway construction for the Rapid Transit Commission and with the Bridge Department. When the Board of Water Supply undertook the task of bringing Catskill water to New York City in 1905, Mr. Connell was placed in charge of the surveying of the Esopus and Rondout water-sheds, for which work he was well fitted by experience and physique, having been a notable oarsman in his youth. Later, he was in charge of the construction of part of the Ashokan Dam and also a part of the Catskill Aqueduct in New York City.

Ambitious to have an independent business, Mr. Connell, in 1917, organized a contracting firm under the name of The Tunnel Construction Corporation. This Corporation was active for fifteen years and constructed many important works, among which were foundations for the great "Skyway" across the New Jersey meadows, sewage treatment works for the Cities of Lynn, Mass.; and Lakewood, Ridgefield, and Teaneck, N. J. He was President of the Corporation to within a few years of his death.

In 1923, Mayor Hylan, anxious to secure an engineer whose integrity could not be questioned, induced Mr. Connell to accept the appointment as Engineer Member of the Board of Standards and Appeals. This Mr. Connell accepted as a public duty, although it took a great deal of time from his own business. The Board of Standards and Appeals was a most important body, having the power of review of decisions of the Building Superintendents, interpretations of the Zoning Laws, Building Code, etc. As this was a period of intense building activity, great pressure for favorable decisions was brought to bear upon the members of the Board. Mr. Connell manfully accepted his responsibility and mastered the complicated provisions of the Building Code and practices of New York City. When at length charges were brought against the Board—which were never legally substantiated—no suspicions were directed toward Mr. Connell, and he was made Acting Chairman of the Board, serving in this difficult position and in the difficult time of 1930 to 1932, with honor. In spite of his ill-health, Mr. Connell was active to the end of his life.

He was married to Geneveve M. Martinez, on October 18, 1915, who, with two sisters, M. Katherine Connell and Louise H. Connell, and one brother, Jasper Spence Connell, M. Am. Soc. C. E., survives him.

Leo Connell well typified in his life's work a large number of engineers who devote a lifetime to the service of great cities, bearing their burdens, expecting little reward except the satisfaction of service well done.

Mr. Connell was elected an Associate Member of the American Society of Civil Engineers on January 4, 1910.

ERNEST HARRY CORNELIUS, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 8, 1934

Ernest Harry Cornelius, the son of Harry B. and Georgia P. Cornelius, was born at Hastings, Nebr., on October 28, 1890. He attended the public schools of his native town and was graduated from the High School in 1907. He then entered Northwestern University, at Evanston, Ill., but due to an injury received as the result of a fall during his Junior year, he was obliged to leave school. After a residence of approximately eighteen months in California, in order to regain his health, Mr. Cornelius returned to his home in Nebraska and entered the State University, at Lincoln, from which he was graduated in 1913, with the degree of Bachelor of Science.

From September, 1913, to January, 1914, Mr. Cornelius acted as Salesman and Representative of the Jacques Steel Company, in Northern Texas. In January, 1914, he went to Kansas City, Mo., where he had charge of the appraisal of the building of the Kansas Light and Power Company made for the Armour Interests of Chicago, Ill.

On the completion of this work in May, 1914, Mr. Cornelius entered the employ of the Metropolitan Street Railway Company, of Kansas City, as Inspecting Engineer. As such, he was engaged on the construction of new trackage, building and car designs, etc., until April, 1916. From that time until November of the same year he served as Assistant to the Bridge Engineer of the Kansas City Southern Railway Company.

In November, 1916, Mr. Cornelius removed to Tulsa, Okla., where he became associated with the Oklahoma Structural Steel Company, first as Contracting Engineer in charge of sales, etc., and, later, as Chief Engineer and Sales Manager. In January, 1918, he entered private practice as a Consulting Engineer, with headquarters at Tulsa. He was engaged chiefly on the construction of steel buildings in the oil fields, incorporating in 1919, as the Industrial Construction Company.

In 1921, Mr. Cornelius founded the Oklahoma Steel Castings Company which, however, did not become active until 1922. Although Mr. Cornelius had many other interests, he devoted his time and energies as President to this Company. Due to his untiring efforts the Oklahoma Steel Castings Company is now classed as one of the important foundries of its kind, covering practically all trade in steel castings in the southwestern part of the United States; it is also nationally known.

Mr. Cornelius was active in the various Masonic bodies of his city and State, a Past-President of the Rotary Club of Tulsa, and a member, and Chairman of the Financial Committee, of the Boston Avenue Methodist Episcopal Church. He was also a member of the Board of Trustees of Tulsa University.

---

[1] Memoir prepared from information supplied by Burtner Fleeger, Pres., Oklahoma Steel Castings Co., Tulsa, Okla., and from data on file at the Headquarters of the Society.

He was greatly interested in civic affairs and the development of industry within Oklahoma. He was a Past-President and also a Director for years of the Associated Industries of Oklahoma; a Director of the Chamber of Commerce; and was always active in the Tulsa Community Fund, and other charitable organizations of the city. Previous to his last illness, Mr. Cornelius had been appointed to the National Code Commission for the Steel Castings Industry.

His social clubs included the Tulsa Club, the Tulsa Country Club, and the Sigma Nu Fraternity. He was also a member of the American Society of Mechanical Engineers.

Mr. Cornelius was greatly interested in aviation and, in addition to his many activities, found time to take up flying first as a hobby and, later, as a means of business transportation.

He was an ardent lover of Nature and of his fellow men, and no one ever came to him for aid and was turned away. His associates in business and his employees knew him as the kindest and most considerate of employers, always ready to listen to their troubles, advise them, and help in every manner possible. During the depression although he could have saved considerable money by closing down his plant, he kept it in operation, with the characteristic statement, "because of the hundred families dependent on us for a living. * * * We cannot forget our responsibility to those who are less fortunate."

Mr. Cornelius died in Cleveland, Ohio, on May 8, 1934, from complications following an operation, and was buried at Rose Hill Cemetery, in Tulsa.

He was married on October 17, 1914, to Virginia Moseley, of Lincoln, Nebr. Mrs. Cornelius died in 1923. He is survived by three children, Virginia, Marjorie Ann, and Ernest Cornelius, Jr.

Mr. Cornelius was elected an Associate Member of the American Society of Civil Engineers on July 11, 1921.

CHARLES WESLEY ERISMAN, Assoc. M. Am. Soc. C. E.[1]

Died June 15, 1934

Charles Wesley Erisman was born in Lancaster, Pa., on October 31, 1887, a son of Clement S. and Salome (Kleckner) Erisman. His father was a successful contractor and builder in the vicinity of Lancaster for many years.

Mr. Erisman received his education in the public schools of Lancaster and was graduated from the High School. His engineering knowledge he acquired in home study and through association and experience with engineers and engineering construction, having worked his way up from the position of Rodman to stations of responsibility in engineering and business fields.

---

[1] Memoir prepared by Ralph L. Kell, Assoc. M. Am. Soc. C. E.

His first engineering experience was obtained in 1905 in the office of F. H. Shaw, a special engineer engaged by the City of Lancaster to design and supervise the construction of certain water-works and sewerage improvements. In this position Mr. Erisman performed the duties of Rodman, Chainman, and Draftsman. After completing his engagement with Mr. Shaw in 1906, he secured employment with the Pennsylvania Railroad Company with which he served for a period of six months as Rodman, Chainman, and Instrumentman.

In March, 1907, Mr. Erisman made an engineering connection with the Pennsylvania Department of Highways in which field he was destined to direct his energies for the remainder of his life. For a period of nine years he was identified with the Bureau of Township Highways, serving in the capacities of Rodman, Chainman, Instrumentman, Chief of Party, Draftsman, Inspector, and Assistant Engineer. His service as Assistant Engineer covered a period of more than two years, during which time his activities were directed toward the betterment of rural roads that were under the care of Township Road Supervisors. He had under his charge the supervision of the construction of roads and bridges by Township Supervisors over the entire State of Pennsylvania, and was instrumental in organizing Township Boards into County Units, after which Schools of Instruction were formed in the various counties, with sessions held annually or semi-annually. These schools were the means of bringing the construction of rural roads under a uniform standard, resulting in great improvement in appearance and general utility.

In 1916, Mr. Erisman was promoted to the position of District Engineer in the Pennsylvania Department of Highways, in which capacity he had charge of the construction and maintenance of State highways in several districts of the departmental organization, the types of roads involved being water-bound macadam, bituminous macadam, brick, and concrete.

During Mr. Erisman's connection with the Pennsylvania Department of Highways the organization grew from a small unit at the beginning of the automobile era to the vast proportions now found in various Commonwealths of the Union. He was thus brought into close contact with the pioneering and experimental work required in building up a system of highways from the early dirt roads and turnpikes to the present type of road designed for high-speed and heavy traffic, and thereby acquired a first-hand knowledge of road engineering and materials which was a valuable asset in his later work.

In 1921 he severed his connection with the Pennsylvania Department of Highways to engage in the private practice of Highway Engineering and the distribution of road machinery and bituminous and tar road materials, with headquarters in Lancaster. His engineering service took the form of surveys, plans, and designs for roads, streets, and bridges, together with a consulting service for individuals and road-building authorities. He was the local distributor for "Ugite" road tars, his territory embracing several counties in Southeastern Pennsylvania. In 1925, he built an office and warehouse in Lancaster to improve his facilities for handling his business. In 1931, he added a bulk storage plant with a capacity of 50 000 gal which enabled him to develop an extensive business in the distribution of oils and tars. Increasing demands required him to enlarge his storage facilities by 10 000 gal in 1933, at which time he also constructed a mixing plant for the manufacture of bituminous cold-patch material used in repairing macadam roads.

Mr. Erisman was not able to reap the full benefit from the expansion of his business facilities, as failing health necessitated the curtailment of his activities. Although he was still in the prime of life, being only 48 yr of age, he was unable to check the decline in his physical condition, and death followed at his home in Lancaster, on June 15, 1934. The community in which he lived had learned to love and respect him. He was a man of sterling character, such as the world cannot afford to lose. Through his straightforward business dealings and honorable practices, he had built up a large circle of social and business friends who mourn his untimely death. He took an active interest in community affairs and was affiliated with the Masonic Fraternity, the Royal Arcanum, the Lancaster Monarch Club, and the Lancaster Chamber of Commerce.

On November 23, 1909, Mr. Erisman was married to Barbara M. Rogers, a daughter of Augustus and Mary (Young) Rogers, of Intercourse, Lancaster County, Pa., who survives him. Surviving also is a daughter, Lucretia M. (Mrs. Walter C. McMinn, Jr.), and one son, Charles A. Erisman.

Mr. Erisman was elected an Associate Member of the American Society of Civil Engineers, on August 28, 1922.

RALPH DANIEL HAYES, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 20, 1935.

Ralph Daniel Hayes was born in Hawkinsville, N. Y., on June 24, 1881, the son of Oscar Willis Hayes and Emma (Jones) Hayes. On his mother's side he was a direct descendant of Ethan Allen, who assisted eminently in establishing American independence. His father was born in Hawkinsville in 1853, and his great-grandfather was a pioneer in that section. His mother, who died there a few weeks after her son's death, was also a native of Hawkinsville, with which her family had long been prominently identified.

Mr. Hayes' early life was spent in Hawkinsville, but he was educated in the public schools of Boonville, N. Y. In 1900, he entered Clarkson College, at Potsdam, N. Y., from which institution he was graduated in 1904 with the degree of Bachelor of Science in Civil Engineering. During his college years, he worked with the United States Lake Survey, on topographic and hydrographic surveys of the St. Lawrence River. In this work—his first engineering assignment—he served under F. C. Shenehon, M. Am. Soc. C. E.

After his graduation from Clarkson College, Mr. Hayes was employed for a short time with the United States Geological Survey in the Adirondack Mountains, and then joined the staff of the then New York State Engineer,

---

[1] Memoir prepared by Frank C. Boes, M. Am. Soc. C. E.

Henry A. Van Alstyne, M. Am. Soc. C. E.; thereafter, he was engaged in highway work from 1904 to 1907.

In 1908 he transferred to the New York State Barge Canal Department, where he was importantly engaged in the construction of that system of waterways, remaining on this work until 1923, when he was transferred to the Operating and Maintenance Division in the Albany District of the Department of Public Works.

For the next four years he remained in Albany continuously, being actively engaged in various branches of this great waterway, and thus familiarizing himself with every detail of its operation. In 1927, he was appointed Deputy Commissioner, and Engineer Assistant to the Commissioner, Division of Canals, Major Thomas F. Farrell. During his long experience in the construction, operation, and maintenance of the Barge Canal, Mr. Hayes acquired a knowledge concerning this Department that was invaluable to the State of New York. This knowledge, and his ability to inspire full confidence, co-operation, and respect in his assistants and in the public with whom he came in contact, were recognized by his superiors and by the Hon. Franklin D. Roosevelt, then Governor of the State of New York, and, on February 1, 1930, although he had never engaged in politics, Mr. Hayes was appointed Commissioner of Canals and Waterways in the Department of Public Works, to succeed Major Farrell, who was made Chief Engineer of the Department of Public Works at that time. Mr. Hayes served in this position with distinction, looking after every detail of this 500-mile system of canals until his death. He had faithfully served his State for thirty years.

All his appointments and promotions were under the New York State Civil Service. He was the first man to be promoted step by step through the Civil Service from the grade of Leveler to the high post of Commissioner of Canals and Waterways.

Frederick Stuart Greene, M. Am. Soc. C. E., Superintendent of Public Works of New York State, remarked that in all the thirty years' service that he gave to the State, not one hour or one minute of that time did Mr. Hayes swerve from his duty. He so impressed both Governor Roosevelt, and Governor Lehman, that on several occasions they saw fit to show publicly their deep regard for him.

In his college days Mr. Hayes was an earnest student and an honor man, with a full realization of his duty to his parents to make the most of his opportunities and thus show to them his appreciation of their efforts to fit him for an important position in life. At that early age, he possessed unusual dignity, sympathy, and kindliness, and these characteristics were outstanding with him throughout his life. He showed courtesy and thoughtfulness toward others to an unusual degree. His quiet sense of humor was delightful and drew to him many friends who held him in deep affection.

His ethical standards were above question and he was always alert to the responsibilities of his position and his profession. At his death Mrs. Hayes received hundreds of messages of sympathy and condolence from his many friends. Flags along the entire route of the Barge Canal flew at half-mast.

Governor Lehman, with Mrs. Lehman, attended the funeral, as well as many others prominent in the Engineering Profession and in public life.

Governor Lehman issued this statement concerning Mr. Hayes:

"I regarded him as one of the finest and most valuable men in the State service. He was untiring in his work and uncompromising in his devotion to duty. He gained public good-will because he impressed people with his fairness and integrity. I mourn the loss of a loyal, efficient, and devoted public servant."

The *Knickerbocker Press*, of Albany, N. Y., of February 20, 1935, published the following editorial:

"To say that Ralph D. Hayes was an excellent public official does not give him his full meed of merited praise. He was more than an official. As Commissioner of Canals and Waterways, he went far beyond mere duty. To him, office was a public trust. He was modest and he felt himself a servant of the people and he joyed in giving more than mere service.

"Probably few men were held in such high personal regard as was he. To know him was to know a man to whom honesty and fairness was a creed and duty a religion. Throughout the State he served is a feeling of real loss in his death, loss of a man with high ideals of citizenship, a man with an unusual sense of honor and obligation. Ralph Hayes was an exemplary man and official, whose whole life was an inspiration to others."

It goes without saying that such spontaneous and sincere tributes from great and small, showed that here was a most unusual man. They indicate Mr. Hayes' real character and worth far more clearly than volumes of technical accounts of his achievements. His death was a shocking loss to hundreds of friends who will never cease to honor his memory. The writer himself, treasuring many memories of Mr. Hayes from boyhood together, cannot conceive how any one could have come in contact with him without having been made better by the experience.

Mr. Hayes died in the Post Graduate Hospital, in New York, N. Y., as the result of an operation from which he had almost fully recovered, but from which he unexpectedly suffered a relapse. He was buried at Hawkinsville, N. Y., in the family plot, in a cemetery established for the use of his community by his great-grandfather.

In September, 1908, he was married to Genevieve Deneen, of Fort Covington, N. Y., who survives him.

Mr. Hayes was elected a Junior of the American Society of Civil Engineers, on June 4, 1907, and an Associate Member on August 31, 1909. He was also a member of the Albany Society of Civil Engineers.

CHARLES JAY HOGUE, Assoc. M. Am. Soc. C. E.[1]

Died May 28, 1935

Charles Jay Hogue, the son of Dan C. and Rebecca (Starr) Hogue, was born at Watsontown, Pa., on July 12, 1870. After graduation from the Watsontown High School he pursued special studies at Lehigh University, at Bethlehem, Pa., and, in 1890, entered the field of railroad engineering as Draftsman for the Central Railroad Company of Pennsylvania, subsequently removing to Wheeling, W. Va., where he held a similar position with the Wheeling and Citizens Street Railway Company.

---

[1] Memoir prepared by William P. Starr, Esq., Hyattsville, Md.

In May, 1892, Mr. Hogue entered the service of the Short Line Improvement Company as Transitman and Draftsman on the location of a line of railroad from Berwick, to Williamsport, Pa. From May to November of the following year, he was employed as Draftsman and Assistant on Track Work with the Cleveland, Cincinnati, Chicago, and St. Louis Railroad Company. In November, 1893, he entered the service of the Central Pennsylvania and Western Railroad Company as Instrumentman and Chief of Party, engaged on location surveys from Berwick to Stroudsburg, Pa. During 1895, Mr. Hogue was employed as Instrumentman on the Montauk Extension of the Long Island Railroad, from Bridgehampton to Fort Pond Bay, Long Island, under the direction of Frederic Molitor, M. Am. Soc. C. E., Engineer in Charge; he later served as Chief of Party on extensive topographical surveys of Montauk Point.

From 1896 to 1902, Mr. Hogue was again attached to the corps of Mr. Molitor, then Chief Engineer of the Choctaw, Oklahoma and Gulf Railroad. During this time he located the 50-mile extension, from El Reno to Weatherford, Okla., also a part of the 130 miles from Howe, Okla., to Little Rock, Ark. As Division Engineer, he had charge of the rehabilitation of the Choctaw and Memphis Railroad (formerly the Little Rock and Memphis Railroad). This work involved the raising of grades to conform with the St. Francis Levees along the Mississippi River, in Arkansas; relaying 132 miles of heavier steel; moving buildings; laying out yards; designing shore protection, sewer, and water lines; and supervising the erection of shop buildings.

In 1903, Mr. Hogue became Engineer of Maintenance of Way for the Rock Island System, leaving that Company in 1904 to assume charge of a party on the location of the Midland Valley Railroad from Muskogee to Tulsa, Okla. In the following year, he went to New York, N. Y., and was attached for a short time to the office of the Designing Engineer of the New York Central and Hudson River Railroad Company.

In 1906 Mr. Hogue entered the service of the Philippine Railroad Company, acting in the capacity of Principal Assistant Engineer, on the location and construction of approximately 120 miles of railroad on the Islands of Panay and Cebu, Philippine Islands. In 1909, he returned to the United States where he was engaged for a short time in private work.

Returning again to the Philippine Islands, he entered the service of the Manila Railroad Company as Engineer in Charge of Construction (1911–13). Most of this time was spent on a 37-km extension from Aringay to Baguio, Luzon Island, where the mountain route was very difficult. For 11 km, 12% grades were used, and in places the curves were as sharp as 115-m radius. The total rise above sea level was 1 450 m. Four tunnels and one hundred and twenty bridges were required. Owing to the difficulty of this mountain route, the use of rack rail and special locomotives was contemplated.

Upon his return to the United States, Mr. Hogue was employed by the Cumberland and Pennsylvania Railroad Company to make surveys and prepare maps required by orders of the Interstate Commerce Commission, Bureau of Valuation. In the spring of 1915, he purchased an interest in the firm of Brownworth and Company, engaged in the design and manufacture of light structural steel work. He was elected President of that Company, which position he held until the time of his death.

Mr. Hogue was an engineer of resourcefulness and ability. He was a tireless worker, energetic and thorough in everything which he undertook; no assignment was too small to receive his most careful consideration. Although the earlier years of his life were spent in various phases of railroad work, he had an exceptionally keen eye for country and its topography, and his most important service was in the field of railroad location.

By his kindly and genial manner he won and held the friendship of his associates, by whom he was highly esteemed for his integrity and fine personal qualities. Mr. Hogue, although unmarried, enjoyed the quiet simplicity of home life, and welcomed the opportunity which, in 1915, was afforded him to enter business in Philadelphia, Pa., where he resided until on May 28, 1935; he passed away after an illness of six months. His passing has been felt with a distinct sense of loss by his many friends and associates.

Mr. Hogue was elected an Associate Member of the American Society of Civil Engineers, on December 7, 1898.

EDWARD LOUIS KOCH, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 29, 1935

Edward Louis Koch was born at Huntingdon, Pa., on August 17, 1883. He was the son of the late Ferdinand B. and Sue (McHugh) Koch. His father was a prominent business man in Altoona, Pa., having served as Manager for the Standard Supply and Equipment Company at that place.

The Koch family originally came to the United States from Germany in the early years of the Nineteenth Century, and the name is now well known in that part of Huntingdon County, Pennsylvania, where they first settled.

Edward Louis Koch was educated in the public schools of Altoona and was graduated from the local High School in 1902. Unfortunate enough not to be able to take a course at one of the larger universities in his favorite subject of engineering, he made up for this deficiency by night school work, and this resulted, later, in his becoming a qualified Civil Engineer.

After his graduation from High School, he worked for a short time with the State Highway Department of Pennsylvania, but having been brought up in a railroad town, where interest in the Pennsylvania Railroad was paramount, his ambition was to enter railroad work with that Company.

---

[1] Memoir prepared by J. M. Fox, Div. Engr., P. R. R., Baltimore, Md.

From October, 1902, to July, 1904, Mr. Koch was employed as Chainman by the Pennsylvania Railroad Company on construction work.

In November, 1904, he was transferred to the Maintenance-of-Way Department where his particular interest lay. By gradual stages he advanced from Chainman, to Rodman, to Transitman, and, in April, 1910, received his first official appointment as Assistant Track Supervisor on the old Cresson Division, with headquarters at Cresson, Pa. This Division has since been absorbed as a part of the Pittsburgh Division.

Two years later (1912) Mr. Koch was transferred to the Conemaugh Division with headquarters at Pittsburgh, Pa., and, in June, 1913, he was advanced to a job on the Main Line at Pittsburgh in the same capacity.

In 1917, a real chance came to show his knowledge of practical track work, when he was first made Supervisor of Track on the Maryland Division, at Media, Pa. Later in the same year, he was advanced to the West Jersey and Seashore Railroad, at Camden, N. J., and, in 1920, he returned to the Maryland Division as Supervisor on a Sub-Division of the Main Line between New York, N. Y., and Washington, D. C.

In this last capacity Mr. Koch had outstanding success in winning the much sought after prizes offered by the Pennsylvania Railroad Company for excellence in line and surface. For two consecutive years he was awarded the Improvement Prize given to the Supervisor of the Eastern Region whose Division showed the most marked improvement in riding and general condition of track, a feat which had not been equalled prior to this time. Other prizes seemed to be awarded continually to him, indicating a complete mastery of practical track work.

In August, 1929, Mr. Koch was made Assistant to the Division Engineer on the Baltimore Division, with headquarters at Baltimore. During 1934 and 1935, his work in Baltimore necessitated active participation in the improvement program in connection with electrification, and his knowledge of track work, together with his engineering ability, made Mr. Koch invaluable to his Company.

He was married to Mary Price, of Altoona, on November 9, 1907, and is survived by his widow and seven children, two girls and five boys.

Mr. Koch was elected an Associate Member of the American Society of Civil Engineers on November 26, 1918.

FRANKLIN EDWARD LELAND, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 8, 1935

Franklin Edward Leland was born at Ashfield, Mass., on June 29, 1889, the son of George Edward and Mary (Smith) Leland. He was educated in the public schools of Ashfield and at Sanderson Academy. Later, he continued his studies by taking various evening courses along engineering and general business lines.

---

[1] Memoir prepared by Waldo F. Pike, Esq., Boston, Mass.

For several months, in 1909, Mr. Leland was employed as Rodman with C. E. Brown, Civil Engineer, in Greenfield, Mass., following this with a year as Draftsman for Wells Brothers Company, also of Greenfield, and a year with the Chase Turbine Manufacturing Company, at Orange, Mass.

From September, 1911, to November, 1912, he was employed by K. S. Putnam, of Northampton, Mass., on architectural detailing, and followed this by a period of seven months of similar work with the firm of Kilham and Hopkins, of Boston, Mass., and two and one-half years with Allen and Collens, of Boston, on architectural drafting and some structural design.

In 1915, Mr. Leland was employed by the Boston and Albany Railroad Company, at Boston, on the valuation of structures as required under the Federal Valuation Act. From 1915 to 1918, he served as Checker, Designer, and Assistant Squad Chief with the Stone and Webster Corporation, in Boston, and was responsible for detail design of various types of industrial structures, chiefly steam power plants.

During the World War, Mr. Leland was engaged as a Designer by the firm of Fay, Spofford, and Thorndike, of Boston, and was responsible for a considerable part of the design of the superstructure of the Boston Army Supply Base. At the termination of the war, he became Assistant Designing Engineer with the Aberthaw Construction Company, of Boston, returning, later, to Fay, Spofford, and Thorndike with which firm he remained until 1922, as Designer and Resident Engineer on construction.

In 1922, Mr. Leland began an independent practice in engineering design and management, and maintained an office for the following nine years. During this time he handled successfully a number of large projects, principally industrial. He designed and supervised all the work done at the Boston Airport, in 1929, aggregating in value approximately $500 000.

In 1933, he was employed by the firm of Metcalf and Eddy, of Boston, where he assisted in the design of a large sewage disposal project and several water treatment plants. He was in the employ of this firm at the time of his death.

For two or three years prior to his death, Mr. Leland was engaged, as a member of the Committee, in the preparation of the draft of the new Building Code for the City of Boston. He was also a Trustee of the Kendall Square Building, in Cambridge, Mass., and, at one time, had served as a member of the Chamber of Commerce, of Cambridge. He was a member of the Boston Society of Civil Engineers.

Mr. Leland was a capable engineer, a clear thinker, accurate and thorough in his work, and he was highly respected by those with whom he came in contact. He had a high sense of honor and upheld the ethics of his profession, and he took great pride in his work.

He was married to Flora Paramenter Ash, of Orange, Mass., who, with a daughter, Elizabeth Foxwell Leland, survives him. He also leaves a sister, Edith Leland, and two brothers, Archie V. Leland and Harold A. Leland.

Mr. Leland was elected an Associate Member of the American Society of Civil Engineers on June 6, 1921.

HARRY CLIFFORD McCLURE, Assoc. M. Am. Soc. C. E.[1]

DIED NOVEMBER 9, 1935

Harry Clifford McClure was born in Mansfield, Ohio, on August 15, 1884, but he grew to manhood in Cawker City, Kans., where his parents moved when he was between one and two years of age. His father, Robert McClure, was of Scotch ancestry, while his mother, Sarah (Hudson) McClure, was a direct descendant of Henry Hudson, the English navigator and explorer.

He received his formal training for the Engineering Profession at the University of Kansas, at Lawrence, Kans., where he was enrolled as a student in the School of Engineering from 1905 to 1909 and during the year 1913–1914, and at the University of Michigan, at Ann Arbor, Mich., where he did graduate work in 1914–1915. His professional degrees were Bachelor of Science (in Civil Engineering) and Civil Engineer from the University of Kansas in 1909 and 1914, and Civil Engineer from the University of Michigan in 1915.

Mr. McClure's first actual engineering job after his graduation from the University of Kansas was with the Riggs and Sherman Company, of Toledo, Ohio, a noteworthy engineering firm of that time and place which, in addition to distributing regular salary checks, gave effective if somewhat informal post-graduate training in practical engineering to a hand-picked group of young men fresh from the blackboard and testing laboratory. The two fruitful years (June, 1909, to October, 1911) spent with this firm were occupied chiefly by a wide variety of office duties and, later, by work in the field as Engineer-Inspector on a concrete dry dock for the Toledo Shipbuilding Company. His next engagement (November, 1911, to December, 1915) was with the Toledo Board of Education, first as Staff Engineer in the Department of Architecture, but later as Chief Engineer in charge of structural design and construction. This was during a period of active school building in Toledo in which several large ward and High Schools of thoroughly modern type were built and equipped.

He left the service of the Board of Education of Toledo in January, 1916, to become Commissioner of Engineering and Construction in the Department of Public Works of the City of Toledo, under the Hon. David Goodwillie, Director of Public Service. This position was held until February, 1921, when Mr. McClure became Works Manager and Superintendent of New Construction with the Toledo Scale Company. The position with the City of Toledo extended over a period of intense activity in city planning and improvement, covering general plans for the removal of sewage and industrial wastes from Ten-Mile Creek, Swan Creek, and the Maumee River (both sides); the extension and straightening of Summit Street; the reclamation of land for industrial areas; and various water-front and harbor improvements.

Mr. McClure's engagement as Commissioner of Engineering of Toledo was interrupted by a year's leave of absence in 1918 when, commissioned

---

[1] Memoir prepared by W. C. Hoad, M. Am. Soc. C. E.

Captain in the Ordnance Department of the United States Army, he was assigned to duty investigating sites for nitrate plants, and, later, was put in charge of the construction of roads, water supply, and sewers. Afterward he served as Intelligence Officer and Assistant Director of Operations, at U. S. Nitrate Plant No. 4, near Cincinnati, Ohio. This plant had not been finished at the close of hostilities, but Captain McClure was held for a time at this station to assist in closing up the affairs of the plant.

From the Toledo Scale Company, Mr. McClure was called in April, 1923, to be City Engineer and, later, Director of Public Works, of Flint, Mich. As City Engineer he had charge of the design and construction of pavements, sewers, sidewalks, bridges, buildings, and miscellaneous structures (not including water-works), together with the maintenance and repair of such services and structures; he was also in charge of the system of sewage disposal, and managed the collection and disposal of the city's garbage and other city wastes. While Director of Public Works he was also in supervisory charge of the Water-Works Division of Flint. During this period the City's construction work, under Mr. McClure's direct supervision, amounted to approximately $15 000 000, practically all of which was done by force contract. The number of men employed in the Public Works Department varied from about 250 during the routine winter maintenance and snow-removal operations to as many as 1 200 during construction seasons. This was a period of active building in the city to keep pace with the continued expansion of its industries and the rapid growth in its population, a period of consolidating earlier gains, and of welding all improvements together into a smoothly functioning whole. In many ways, it was the period of transition of Flint from the condition of a large town to the status of a well-organized city, and in this transition Mr. McClure bore a notable part. His northwest corner office on the second floor of the City Hall was the recognized center for constructive planning and a never-failing source of forward-looking ideas.

Because of a rapidly developing political opposition, Mr. McClure resigned the position of Director of Public Works of Flint in April, 1931, leaving in May. The following month, he became a member of the State Public Utilities Commission of Michigan, by appointment of Governor Wilbur M. Brucker. He remained in this service until March, 1934, when he, along with other members of the Commission, was removed from office by Governor William A. Comstock.

Mr. McClure's work on the Utilities Commission was about what should normally be expected of a high-minded engineer, mature in years and in constructive thinking, and well-seasoned in experience. He tried to get at all the significant facts of a situation before making a final decision. While he held to a pronounced view of the obligations of the public utilities to the public which they served, he likewise had an unusually clear understanding of the difficulties by which the utility companies themselves were beset. He was known as an official who was always alert and vigorous in the public interest, but always fair. At a time when an enormously expanded State Highway System was stimulating trucking and bus services, when changes in economic conditions were forcing a multitude of rate changes, and when the rapid discovery and exploitation of the gas and oil resources of the State were creating new problems of broad public concern, Commissioner McClure's knowledge of engineering as well as his sound views of public responsibility were of outstanding value to the State.

Mr. McClure was married, in 1912, to Hazel Carter, of Toledo, while he was with the Board of Education of that City. Mrs. McClure and their two daughters, Suzanne and Sallie, survive him.

The beginning of the malady to which Mr. McClure finally succumbed undoubtedly dates back a number of years, but this trouble became more pronounced in the early summer of 1934 and, following a partial recovery, still more severe in 1935. He died suddenly at East Lansing on November 9, 1935, of a heart attack. The funeral services were held November 12, 1935, interment being in Deepdale Cemetery, at Lansing. To one so accustomed to constant and vigorous action, the rest periods prescribed by the physician seemed tedious and difficult to bear and even the light work permitted during his apparent recovery in 1934 fell far short of satisfying his energetic nature; but with his family his buoyancy of spirit and his irrepressible good humor never flagged and much of his time during this period of partial health was happily spent in studying and contriving for their best interests.

He was a member of the Michigan Engineering Society; a member of Sigma Xi and of Tau Beta Pi; he was a Rotarian; a Shriner; a Republican; and a member of the Methodist Episcopal Church. He was also a member of a number of local clubs and civic associations.

Mr. McClure was elected a Junior of the American Society of Civil Engineers on March 1, 1910, and an Associate Member on September 3, 1913.

OSCAR WILLIAM MELIN, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 29, 1935

Oscar William Melin, the son of August Melin and Christine (Sundell) Melin, was born in Moline, Ill., on April 22, 1888.

After attendance at the local schools of his birthplace, he went to the University of Wisconsin, Madison, Wis., from which he was graduated in the Class of 1910, with the degree of Bachelor of Science in Civil Engineering His first duties were the typical tasks of the young engineer seeking to perfect himself in his field: Instrumentman for the United States Reclamation Service, the Illinois Central Railroad Company, and the Madison Street (Chicago, Ill.) Railway Company; a year in the field on concrete construction; and two years as Instructor in Civil Engineering at the University of Kansas, Lawrence, Kans.

---

[1] Memoir prepared by O. C. Spurling, M. Am. Soc. C. E.

In 1914, Mr. Melin entered the Engineering Offices of the Illinois Central Railroad Company and during the ensuing four years worked as Draftsman, Chief Draftsman, and Group Chief in various Departments of the Company. Following a brief engagement in 1918 as an Inspector for the Government on power plant construction, he returned for a short time to railroad work with the Baltimore and Ohio Railroad Company, Western Lines, as Assistant Engineer of Building.

Meanwhile, the chief opportunity he was to enjoy to use his abilities in his too brief career had been slowly taking form at the Hawthorne (Ill.) Works of the Western Electric Company, faced with heavy requirements for new manufacturing facilities brought about by the increasing demands of the nation for telephones.

Mr. Melin joined the Western Electric Company in 1919 as Structural Engineer in the office of the Engineer of Plant. His work was soon regarded favorably, and he was placed in charge of the structural design of a warehouse more than 100 000 sq ft in area. Following this in rapid succession came both single and multi-story buildings, including the complex structural design of large rod and wire-drawing mills with their accompanying heavy machine loads.

Mr. Melin had a keen intelligence and his work was marked primarily by drive and initiative but, always pushing himself harder than he did any of his men, he was a popular leader. In 1923, when the Western Electric Company chose the site for its Kearny (N. J.) works, Mr. Melin was transferred to New York, N. Y., to assume charge of the structural design of the buildings required there. Here, he had charge of the taking of bids and preparation of construction contracts, and from 1924 to 1929 he supervised the structural design and handled the contractual relations of building projects comprising about 900 000 sq ft of floor space.

Fundamentally honest with himself and all those with whom he came into contact, he was satisfied only with the most careful analysis of a problem and demanded of himself and others painstaking and sound engineering practice in its execution. He drew men to him more by their own recognition of his character and ability than by any conscious effort on his part to win them.

Recognizing the need of a "yardstick" to measure building construction performance by the Engineer of Plant, he developed in 1927 from a quantity survey of typical Western Electric buildings, a Building Construction Cost Index which is still in use by the Company. It is only one example of the natural ability and intense application by which Mr. Melin is best remembered by his many friends in the profession.

Mr. Melin was married to Florence Roach on November 27, 1915, at Fennimore, Wis. He is survived by his widow and one daughter, Marjorie Jane Melin, of Pasadena, Calif. He is also survived by three sisters, Emma and Hilma Melin, of Moline, Ill., and Ethel Melin of Pueblo, Colo.

Mr. Melin was elected an Associate Member of the American Society of Civil Engineers on October 14, 1919.

FRANK HURD PICKETT, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 4, 1935

Frank Hurd Pickett was born in Toledo, Ohio, on July 13, 1888, the son of Edward and Mary (Watkins) Pickett. He attended school in Toledo until 1905, at which time he entered the University of Colorado, at Boulder, majoring in Civil Engineering. Subsequently, he was a student at Purdue University, La Fayette, Ind., where for one year he received training as a Cadet, and was made a member of Theta XI Fraternity. His education was complete in every detail, because of his eagerness always to acquaint himself with every new method in the constant problematical and progressive field of engineering.

In 1915, Mr. Pickett attended the Brooklyn (N. Y.) Evening Technical School for special work; and, again, in the fall of 1920, he entered the American Rolling Mills School, at Middletown, Ohio, for a six weeks' term. He next took a short course given by the California Corrugated Culvert Pipe Company, at Berkeley, Calif., during the months of January and February, 1935. The completion of this course preceded his last illness and death, by only one month.

Mr. Pickett's practical experience began in 1908, on various irrigation projects in Colorado, as Chainman, Levelman, Transitman, etc. From 1908 to 1910, he served as Assistant Engineer for the Colorado Irrigation Construction Company, at Denver, Colo. This work consisted of preliminary and final location surveys, plane-table topography, and estimates of cost of water duty on a 60 000-acre project near Denver. Afterward, he was appointed Assistant Engineer for the Rock Creek Conservation Company, Rock River, Wyo., on the location and construction of an irrigation system of a 100 000-acre project.

In 1911 and 1912, Mr. Pickett took a position with the F. W. Dodge Company, of New York, N. Y., his work being entirely in the Construction Reports Department. From 1912 to 1913, he was associated with W. H. Gahagan, Incorporated, of Brooklyn, N. Y., for which Corporation he was in charge of the construction of a power plant and of brick and concrete mine buildings, for the Delaware, Lackawanna, and Western Railroad Company, at Nanticoke, Pa. From 1913 to 1916 he was employed as Engineer for J. and F. Kelly, Dock-Building Contractors, of Brooklyn, N. Y. This detailed work consisted of estimates, designs, and the construction of piers, bulkheads, jetties, and foundations.

Mr. Pickett then accepted a position with the American Graphaphone Company with which he remained during 1916 and 1917, as Assistant Construction Plant Engineer. As such, he had general supervision of the building of the New Record Plant, consisting of brick and steel factories and power plants. For several months prior to the entrance of the United States into the World War, he served as Assistant Construction Engineer for the

---

[1] Memoir prepared by Morris D. Simpson, Esq., New York, N. Y.

Remington Arms Union Metallic Cartridge Company, in charge of the general maintenance and construction of dry kilns.

From 1917 to 1919, Mr. Pickett served in the United States Army as First Lieutenant of Engineers. On August 7, 1918, he received his commission as Captain of Engineers, and held that rank in the Reserve Officers Corps until his death. While in active Army service, he was in charge of troops and Military Trade Schools, and was stationed at Camp Lee in Virginia, Washington Barracks, in the District of Columbia, Fort Benjamin Harrison, in Indiana, Camp Dodge, in Iowa, and Camp Humphreys, in Virginia. He was granted an honorable discharge from the Army at Fort D. A. Russell, in Wyoming, on September 5, 1919.

After his discharge from the Army, Mr. Pickett renewed his engineering career and business interests by accepting a position as Engineer for J. A. Whiting, of Cheyenne, Wyo., on the construction of a sewerage system for the City of Cheyenne, and the Hawks Springs Reservoir Dam. In 1920 he joined the Engineering Corps of the Hardesty Manufacturing Company of Denver, Colo., with which he remained until 1932. He was made Sales and Consulting Engineer. This Company manufactured the Armco iron culverts, flumes, head-gates, meter-measuring devices, etc. In 1932, The California Corrugated Culvert Company purchased the Idaho, Utah, and Colorado territories from the Hardesty Manufacturing Company, thus bringing eleven Western States, and New Mexico, into one Company group. Mr. Pickett maintained supervision of the State of Idaho. Owing to his various contacts with highway officials, contractors, boards of directors of road construction, county commissioners, city councils, etc., his business was made very interesting.

Mr. Pickett was widely known for his "Irish wit" intermingled with a deep and sincere kindness. Especially did he take great pride in scattering sunshine and kindness to those who were less fortunate than himself. He was honest, honorable, and dependable in all great matters, as well as in matters of lesser importance. His keen appreciation of music and literature also added zest to his wonderful and honorable character. The great loss of such a splendid man will be felt by all who knew him.

On June 10, 1921, he was married to Muriel Elizabeth Simpson, who survives him. He is also survived by a sister, Mrs. Milo R. Foley, of Denver, Colo.

Mr. Pickett was elected an Associate Member of the American Society of Civil Engineers on October 9, 1917.

WILLIAM THOMAS REED, Assoc. M. Am. Soc. C. E.[1]

Died April 28, 1935

William Thomas Reed was born at Lynn, Mass., on August 30, 1872, the son of Thomas P. and Esther (Richardson) Reed. He received his education in the public schools of Lynn, and was graduated with one of the earliest classes from the local English High School, in 1889, nearly at the head of the Class. He helped to organize the School Alumni Association and was elected the first President. His interest in the Alumni Association was great and steadily maintained during all the subsequent years until his death.

---

[1] Memoir prepared by Harry E. Sawtell, M. Am. Soc. C. E.

He was unable to attend a technical school or college, but gained a considerable knowledge of engineering principles by intensive home study and application. The work that led Mr. Reed into the field of structural design, and afterward into engineering contracting, was his first engagement in November, 1895, with the Norton Iron Company, at Everett, Mass., where he worked both in the structural shop and in the field. In the early part of 1897, he went into the Drafting Room of the Boston Steel and Iron Company, Boston, Mass., as a Draftsman, working on steel stairs as well as on structural design. Owing to his natural ability, hard study, and application, he rose rapidly in the Designing Room of this growing Company and filled, successively, the positions of Chief Designer, Chief Draftsman, and Engineer in Charge of Design. His work was so outstanding that he was transferred to the Estimating Department, and was soon placed in charge of that work as Contracting Engineer. While in that position he was responsible for the design of the steel structures of many important buildings in Boston, and in other parts of New England. About this time construction work in reinforced concrete was increasing rapidly and he concentrated on the application of the principles of mechanics to reinforced concrete structural design.

Early in 1904 Mr. Reed left the Boston Steel and Iron Company and, in May of that year, became associated with the Eastern Expanded Metal Company, of Boston, and, later, the Eastern Concrete Construction Company, a subsidiary, for which he designed many reinforced concrete buildings and supervised the construction of a number of them. Mr. Reed continued with this Company until March, 1910, when he with others formed the New England Concrete Construction Company, of Boston, of which he was the President, Treasurer, and Manager. This Company was organized for contracting, engineering, designing, and erecting structures of reinforced concrete, brick, steel, or timber. The Company specialized in industrial plant buildings, warehouses, and other similar structures.

In May, 1921, the Company was re-organized and named the William T. Reed Company, and Mr. Reed again became President, Treasurer, and Manager. Under his direction, the Company continued to perform the work of designing and constructing many important industrial buildings until his death on April 28, 1935. He had the honor of working on one of the first steel-frame buildings to be erected in the City of Boston, as well as one of the first reinforced concrete structures constructed in that vicinity. His activities are thus linked with the pioneer growth in these fields.

Mr. Reed was very successful in creating and maintaining a reputation for the highest character and honor in his work. Being satisfied with nothing short of the best, he was often spoken of as being too honest for a money maker. He always maintained that a reputation for doing good work and being fair to his clients and workmen was worth more to him than a fortune in money without them.

He succeeded in placing his contracting work on a high professional plane. His Company did work for literally hundreds of the best known firms in New England, and Mr. Reed took considerable pride in the fact that he seemed never to lose a client once he did his work, this being shown by the fact that of nineteen selected names of owners on his books, the average number of repeat orders was nine, and one company gave him at least twenty-three separate jobs, aggregating in cost approximately $1 000 000.

His religious principles were carried into his secular work, and he leaves many friends among the laborers of his Company, as well as business and professional associates, who regret his passing.

On October 8, 1902, Mr. Reed was married to Grace Edith Bickford, of Lynn, who passed away May 18, 1918. They had no issue, and Mr. Reed never married again. A brother, Frank C. Reed, survives him.

His interests were varied as shown by the following list of organizations of which he was a member: First Congregational Church, of Lynn; Sons of American Revolution; Massachusetts Charitable Mechanics Association; Lynn Historical Society; and Reade Society for Genealogical Research.

Mr. Reed was elected an Associate Member of the American Society of Civil Engineers on February 28, 1911.

HARRY ASHTON ROBERTS, Assoc. M. Am. Soc. C. E.[1]

Died April 6, 1935

Harry Ashton Roberts was born in Strawn, Ill., on April 2, 1876, the son of Edward H. and Eliza Roberts. At the age of twenty-six, he was graduated with honors from the University of Illinois, at Urbana, Ill., receiving the degree of Bachelor of Science in Civil Engineering. In 1916, the University of Illinois conferred upon him the degree of Civil Engineer. He was a member of Tau Beta Pi.

During vacation periods, between 1899 and 1901, Mr. Roberts was employed on various railroads as Rodman, Draftsman, and Transitman. In 1901, he was in charge of a party making townsite surveys for the United States Department of the Interior in Indian Territory. From 1902 to 1904 he was, successively, in the service of the Oregon Short Line Railroad Company, Delaware, Lackawanna and Western Railroad Company, and the Sante Fé System, his last assignment being in charge of a residency on the construction of the Newkirk-Pauls Valley Line, which involved heavy grading, masonry, and bridge work.

---

[1] Memoir prepared by Samuel Murray, M. Am. Soc. C. E.

In 1904, he re-entered the service of the Oregon Short Line Railroad Company, as Draftsman, shortly thereafter being promoted to be Assistant Engineer on Maintenance of Way, on the Montana Division, and in February, 1906, he was appointed Assistant Engineer on construction. The remainder of 1906 was a period of great activity for Mr. Roberts, the construction of yards, freight-houses, terminals, water stations, and various other railroad facilities at Nampa, Boise, Caldwell, and other points in Idaho, being carried out under his jurisdiction.

In November, 1906, he was promoted to the position of Division Engineer and Assistant Superintendent of the Oregon Short Line Railroad Company, with headquarters at Pocatello, Idaho, and although for the next eight years he was actively engaged with important maintenance and operating problems, Mr. Roberts found time for a deep interest in civic matters as a member of the Pocatello School Board, and a Director of the Young Men's Christian Association.

In September, 1914, he was called to the University of Kansas, at Lawrence, Kans., as Assistant Professor of Civil Engineering. In this position he spent probably the most pleasant days of his professional career, until America entered the World War and he joined the Service as a Captain in the Engineering Corps of the American Expeditionary Force. He was mustered out in February, 1919, with a record of conspicuous service overseas, returning to the University of Kansas in February, 1919. In the succeeding September he re-entered the service of the Oregon Short Line Railroad Company as Division Engineer, where he remained until 1920, when he was transferred to the Oregon-Washington Railroad and Navigation Company, a unit of the Union Pacific System, at Portland, Ore., as Engineer of Maintenance of Way. Here, he served until his death, which occurred unexpectedly at his country home at Aloha, Ore.

Harry Roberts was a competent and dependable engineer, and a fine example of American gentleman. He possessed high qualities of leadership, and inspired devoted loyalty from his subordinates. A strong adherence to principle was tempered with an unfailing sense of fairness and active sympathy for the "under dog." He had a host of friends who mourned his passing, among them many to whom he had endeared himself by his never failing willingness to help where help was needed.

In 1903, he was married to Henrietta Henderson, who, with his daughters, Henrietta M. Roberts and Mrs. George R. Barlow, and his sons, Donald H. and H. Kenneth, survives him. He is also survived by his sisters, Mrs. Harvey L. Beightol and Mrs. Miriam E. Brannum, and his brothers, Dr. A. J. Roberts and Dr. E. N. Roberts.

He was a member of the American Railway Engineering Association, the Society of American Military Engineers, the Reserve Officers' Association, and of the Congregational Church.

Mr. Roberts was elected an Associate Member of the American Society of Civil Engineers on April 4, 1904.

WILLIAM WHITE ROUSSEAU, Assoc. M. Am. Soc. C. E.[1]

Died September 28, 1935

William White Rousseau was born in Troy, N. Y., on April 18, 1873, the son of William White Rousseau, Sr., and Jeannette (Parker) Rousseau. He received his early education in the public schools of Troy and at the Troy Academy. He entered Rensselaer Polytechnic Institute in 1891, and was graduated in June, 1895, with the degree of Civil Engineer.

Following his graduation, Mr. Rousseau was employed in the Engineering Department of the Delaware and Hudson Railroad Company, at Albany, N. Y., until June, 1896. From June, 1896, to January, 1897, he was in charge of dike construction at Corning, N. Y., under the late Palmer Chamberlaine Ricketts, Hon. M. Am. Soc. C. E. From 1897 to the date of his death he was a member of the Faculty of Rensselaer Polytechnic Institute, holding, successively, the positions of Instructor, Assistant Professor, and Associate Professor of Surveying, Railroad Engineering, and Forestry. For the past fourteen years Professor Rousseau had been Faculty Adviser of Athletics, controlling the financial and eligibility conditions of athletics, maintaining cordial relations between the Faculty and the students under trying conditions, and gaining the love and esteem of both.

Professor Rousseau was Superintendent of Construction of the Troy Water-Works from February, 1907, to January, 1913. He was also a member of the firm of Breese, Rousseau, and Company, Real Estate and Insurance Agents. He was a member of the Rotary Club, of the Troy Chamber of Commerce, having served, at one time, as one of its Directors, and of various Masonic organizations. He was a member of the Rensselaer Society of Engineers, Sigma Xi, and Tau Beta Pi.

He was the Treasurer and Organist of the Church of the Holy Cross, at Troy, which is unique in having had until this year (1935), only two rectors and two organists from the time of its organization, Professor Rousseau succeeding his father as organist, their combined services covering a period of ninety-one years.

Professor Rousseau was married on June 5, 1901, to Frances Hardy, of Troy, who, with their two children, Parker H. and Ruth Rousseau, survives him.

His kindly nature and willingness to help all with whom he came in contact made for him a host of friends who mourn his passing. As a teacher, a citizen, and a Churchman, he gave himself to the service of his fellow men, and has doubtless received the reward: "Well Done, Thou Good and Faithful Servant, Enter Thou into the Joy of Thy Lord."

Professor Rousseau was elected an Associate Member of the American Society of Civil Engineers on December 1, 1908.

---

[1] Memoir prepared by E. R. Cary, M. Am. Soc. C. E.

WILLIAM DWIGHT SAMPLE, Assoc. M. Am. Soc. C. E.[1]

Died January 5, 1935

William Dwight Sample was born in Granville, Ohio, on October 13, 1881. He was the son of John H. and Virginia F. (Hughes) Sample. He was graduated from Denison (Ohio) University in the Class of 1902, and was a member of the Mu Chapter of Sigma Chi and a Phi Beta Kappa.

His entire life was spent in an engineering atmosphere, his father having been for many years an official in the Engineering Department of the Pennsylvania Railway Company. His mother was a sister of Lieutenant Hughes, U.S.N., who was in command of the U.S.S. *Petrel* at the Battle of Manila Bay.

After his graduation from Denison, Mr. Sample was employed in the Engineering Department of the Cleveland and Pittsburgh Division of the Pennsylvania Railroad and, later, he was engaged with the Southern Railway Company, in Alabama and Mississippi, on new railway location.

In 1907, together with several of his brother engineers, he was called to Brazil for the location and construction of the São Paulo-Rio Grande Railway, a subsidiary of the Brazil Railway System. The work consisted of location through a little known country south of the Rio Iguassú and down the Rio do Peixe, through Indian country, to the River Uruguay.

On the completion of this location in 1909, Mr. Sample left this Company to assist in the location of the Madeira-Mamoré Railway, in the Upper Amazon country, between Porto Velho and Guajará Mirim, which was then under way. He remained on this work until the location was finally finished to the end of the line at Guajará Mirim, on the Mamoré River, in 1910.

In 1910 and 1911, he was engaged in the construction of the Mexico North Western Railway in the State of Chihuahua as Resident Engineer and, later, as Assistant to the Chief Engineer. This period was during the first Mexican Revolution under Francisco Madeira and Pancho Villa, and it was due in great part to his efforts that the construction work on the railway could be carried on during this time.

In 1912, Mr. Sample returned to Brazil, and was connected with the location of the railways in the State of Rio Grande do Sul and, in 1913, he went to São Paulo, Brazil, in the capacity of Field Engineer with The São Paulo Tramway, Light, and Power Company, Limited, on the construction of the Sorocaba Power Plant.

When war was declared in 1914 he was among the first to volunteer for service and left São Paulo for England with a group of his English friends. On their arrival in London, Mr. Sample enlisted in the famous Rifle Brigade and served with this Regiment throughout the World War. He was in active service on the western front in France from early in 1915 until the spring of 1918 when he was badly wounded and sent to a hospital in England.

He received his discharge in 1919, and returned to the United States where he underwent several operations on his leg which had not healed properly and, in fact, left him lame for the remainder of his life. He was able, however, to return to his engineering work.

---

[1] Memoir prepared by Walter Charnley, M. Am. Soc. C. E.

He went back to Brazil with The São Paulo Tramway, Light, and Power Company, Limited, in 1920 as Field and Construction Engineer, and assisted in many hydro-electric developments, among others, the large Parahyba River Plant, at Ilha, State of Rio de Janeiro, and for the past ten years he had been connected with the great Serra Development, in the State of São Paulo.

During his long period of residence in Brazil Mr. Sample made a host of friends, and his passing is deeply felt by all who knew him.

His entire active life was spent in the field amid the hardships usually encountered in this class of work, especially in wild and unsettled country; but through it all he remained a keen active engineer, up to date in his profession and loved by his associates and friends in all walks of life for his kindliness, loyalty, and his ready helping hand to those in trouble.

He never married and was the last of his immediate family. The epitaph on his tombstone in São Paulo, Brazil, where he lies, reads:

"IN MEMORIAM
A SOLDIER AND ENGINEER"

Mr. Sample was elected an Associate Member of the American Society of Civil Engineers on December 1, 1908.

GORDON EARL SISSONS, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 31, 1935

Gordon Earl Sissons was born in Vina, Calif., on March 14, 1892. His parents were of French descent, and after finishing his earlier education, he attended The Polytechnique School of Engineering, in Paris, France, from which he was graduated in 1914 with the degree of Bachelor of Science in Civil Engineering.

Upon his return to California, Mr. Sissons secured a position with the Vina Ranch Company on a pumping and irrigation project. As Assistant to the Chief Engineer, he was responsible for surveying and mapping the territory involved, and for the design and construction of a pumping station and the various works connected with the irrigation of a tract of approximately 6 000 acres.

This assignment was completed at about the time of the outbreak of the war between France and Germany. Responding to the call of the French blood in his veins, Mr. Sissons enlisted with the Canadian Engineers, went overseas with the first contingent, as Lieutenant, and was among those subjected to the first gas attack of the war. He completed his war service in November, 1918, as Inspector and Testing Engineer with The Imperial Munitions Board of Canada.

---

[1] Memoir prepared by Timothy S. Williams, Assoc. M. Am. Soc. C. E.

From that time, Mr. Sissons' experience was wide and varied, and included the supervision of design and field work connected with the construction of hydraulic developments, paper mills, steam and hydro-electric power layouts, and foundations of all kinds, with many of the large engineering concerns of the United States and Canada. He also served with The New York and New Jersey Bridge and Tunnel Commission (later, the Port of New York Authority), on the Holland Tunnel, and was engaged on maintenance work in mechanical plants, etc.

During the construction of The Pennsylvania Railroad Terminal improvements, in Philadelphia, Pa., from 1928 to May, 1931, he acted as Chief of Design Squads of the force of The United Engineers and Constructors, engaged on the study and design of a large section of this work. The construction involved the use of open caisson foundation work, and heavy steel and concrete superstructures. Considerable study was necessary in developing methods by means of which the work could be executed without interfering unduly with train movements.

Since 1933 Mr. Sissons had held the position of Senior Engineer in charge of the Department of Health of the Borough of Richmond, New York, projecting, supervising, and in responsible charge of all Department activities in the Borough. His work received especial commendation from his superiors as being well and economically planned and executed, under most difficult conditions.

The gassing he received during the World War had continuously undermined his health, but he refused to heed the doctor's warning that he must have a period of complete rest or a collapse would result. His conscientious insistence on carrying on with his work 100% during the winter's cold hastened his end which he fought on his feet as long as strength permitted.

Mr. Sissons was a keen judge of men, and expected of those working with him their fullest co-operation (however, he never asked of them more than he would give himself). He had little patience with shirkers, but was always ready to help, in any possible way, the man who was giving of his best.

He will be remembered by his associates, not only as an able engineer, conscientious and painstaking to an unusual degree, but as one who dealt fairly and squarely alike with superiors and subordinates.

He was married on July 2, 1921, to Lillian Rickaby, of Windsor, Ont., Canada, and is survived by his widow and a son.

Mr. Sissons was elected an Associate Member of the American Society of Civil Engineers on October 14, 1930.

ALBERT ORANGE SMITH, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 30, 1934

Albert Orange Smith, the son of Charles Albert and Isabella (Dana) Smith, was born at West Hartford, Vt., on August 4, 1877. After his preparatory education, he entered the University of Vermont, at Burlington, Vt., from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1902.

---

[1] Memoir prepared by H. T. Tuthill, Esq., Westhampton Beach, N. Y.

Mr. Smith worked as a Rodman for the New York Central Railroad Company from May, 1897, to June, 1898, and as Transitman for the City Engineer of Barre, Vt., from June to September, 1898. From May, 1899, to September of the same year, he was Chief of Party for the Vermant Marble Company, and from July to September, 1900, he was employed as Transitman by the Rutland-Canadian Railroad Company. From June to September, 1901, Mr. Smith served as Draftsman for W. R. Wilcox, Architect. He was with the Lehigh Valley Railroad Company as a Draftsman from May, 1902, to February, 1903, after which, until October of that year, he was engaged as a Transitman for the Erie Railroad Company. From October, 1903, to May, 1905, he served as Transitman for the Ontario and Western Railroad Company.

It was in May, 1905, that Mr. Smith came to Suffolk County, New York, and began his work for C. P. Darling, Civil Engineer, at Huntington, Long Island.

In March, 1906, he decided to open an office for the private practice of engineering and contracting in Greenport, N. Y. Three years later, he was appointed County Superintendent of Highways by the Board of Supervisors of the County of Suffolk, with headquarters at Port Jefferson, N. Y., which position he held until 1914. In 1918, Mr. Smith was again named for that office and continued as Superintendent of Highways of the County of Suffolk until May 31, 1934, when he was retired.

His work in this position was quite varied and demanded a knowledge of all types of road and bridge construction, drainage conditions and their remedies, and the ability to approach people, in order to acquire rights of way for all State highways and county roads in the County.

The towns built their own concrete pavements from 1918 to 1930, under the direct supervision of local engineers, with the approval of plans, etc., by the County Superintendent. In 1930, a County Road System was inaugurated and, from that time, about 17 miles of reinforced concrete pavement was built each year. The plans and specifications for all this work were prepared under the direct supervision of Mr. Smith, and the contracts were let by him. His staff had increased to thirty-one in 1932, and Mr. Smith had established a very efficient organization.

Thirty-four bridges were built in Suffolk County under Mr. Smith's direct supervision. Plans and specifications were also prepared under his direction for the construction of two high-level highway suspension bridges. One of these bridges had a 700-ft main span and two 350-ft side spans. The other had a 1 000-ft main span, and two 600-ft side spans.

Mr. Smith had direct charge of the construction of the interlocking steel bulkheads, dredging, and rip-rapping, in Shinnecock Canal, an important connecting link in the waterways of Long Island, the total cost of the work amounting to approximately $200 000. He also prepared the specifications for an air map of Suffolk County, an area of 976 sq miles.

He had many friends, and his fair and honorable way of handling every situation won for him a fine reputation throughout Suffolk County. For more than twenty years he had served as Clerk of the Board of Education. He was Past Master of the Port Jefferson Lodge, F. and A. M.; former President of the Suffolk County Association of Highway Superintendents, which he had also served as Vice-President; and Vice-President of the Suffolk County Chapter of the New York Society of Professional Engineers. He was a member of the First Presbyterian Church, of Port Jefferson, N. Y.

Mr. Smith took an active interest in all civic affairs and was always working for the betterment of the community and for the country at large. His passing was a great loss to the community and to those who had the good fortune to be closely associated with him during his active career. The members of his staff feel most keenly the loss of his guiding spirit and his kindly interest in their welfare. He will always be remembered for his sterling qualities as an engineer and a gentleman.

He was married on October 30, 1906, to Susan Whiteman, of Burlington, Vt. Mrs. Smith died on January 29, 1933. He is survived by two daughters, Eleanor F. and Ruth C. Smith, and his mother Mrs. Isabella D. Smith, of Barre, Vt.

Mr. Smith was elected a Junior of the American Society of Civil Engineers on May 2, 1905, and an Associate Member on February 2, 1909.

EDWARD KING SMITH, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 8, 1935

Edward King Smith, the son of Thomas H. and Nellie (King) Smith, was born in Chicago, Ill., on July 31, 1891. His early life was spent in Beloit, Wis., where he attended Beloit College. His professional education was obtained at the University of Wisconsin, at Madison, Wis., from which he was graduated in 1914 with the degree of Civil Engineer.

Following his graduation Mr. Smith was appointed Instructor at the Summer Surveying Camp of the University of Wisconsin and placed in charge of hydrography and triangulation work. In the summer of 1914, he was appointed Assistant City Engineer of Beloit. In this capacity he had charge of all field work for major municipal improvements and, in addition, was engaged in the detailed design of storm sewers.

In July, 1917, upon the entrance of the United States in the World War, he entered the Army and was appointed Second Lieutenant in the Signal Corps. While on active service in France, he was placed in responsible charge of building camps, schools, hospitals, water supply structures, and repairing roads and buildings. He spent some time in the Signal Corps Photo Laboratory, in Paris, France, and took a keen interest in this phase of the work.

---

[1] Memoir prepared by W. F. Tempest, Esq., Chicago, Ill.

After his return to the United States, Mr. Smith again took up his duties as Assistant City Engineer of Beloit, and was in charge of plans and field work for special sewer construction and other improvements. He was responsible for the design of a new sanitary sewerage system for the City of Beloit, the estimated cost of which was $400 000. He was also active in the preparation of a local Building Code which he wrote in collaboration with the State Building Engineer.

In 1925, he was chosen to fill a vacancy as Assistant Manager of the Highways and Municipal Bureau of the Portland Cement Association, in Chicago. In this executive capacity Mr. Smith was active in engineering society work and prepared numerous articles for publication in technical journals based upon his field observations of projects in the United States and Canada. He took a special interest in airport improvement to which field he contributed valuable information.

In spite of a busy life, Mr. Smith was always unusually active in the organizations to which he belonged and held numerous offices. He served on many committees and to each contributed tirelessly of his time and energy.

He was a member of the American Society of Municipal Engineers, the Society of American Military Engineers, the National Reserve Officers' Association, and Captain, Engineers Reserve, U. S. Army. Mr. Smith was also a member of Advertising Men's Post No. 38, American Legion, and served on many important State and National Committees. He was a member of the Hamilton Club, of Chicago, and the Sons of the American Revolution. His fraternal affiliations included the Masonic Lodge, the Order of the Eastern Star, the Knights of Pythias, and the Benevolent and Protective Order of Elks.

His sudden death, while visiting his mother at Beloit, was a severe shock to his many friends to whom he was affectionately know as "E.K." He is survived by his widow, Arline M. Smith, and his daughter, Nancy Frazer.

Mr. Smith was elected a Junior of the American Society of Civil Engineers on November 4, 1914, and an Associate Member on September 10, 1923.

ASAHEL CLARK TOLL, Assoc. M. Am. Soc. C. E.[1]

DIED DECEMBER 22, 1934

Asahel Clark Toll, the son of Truman Mitchell and Harriet (Clark) Toll, was born in Baldwinsville, N. Y., on September 26, 1880, where he received his Grammar and High School education. After his graduation from High School, he entered Leland Stanford, Jr., University, at Palo Alto, Calif., for the course in Civil Engineering, from which he was graduated in 1906, with the degree of Bachelor of Arts.

---

[1] Memoir prepared by Manuel Font, M. Am. Soc. C. E.

After his graduation from college, Mr. Toll was employed for two years by the Bay Cities Water Company on surveys and preliminary studies of water supplies for San Francisco, Calif., and irrigation in the San Joaquin Valley. Subsequently, for two years, he was in the City Engineer's Office, in San Francisco, on preliminary studies for the Hetch Hetchy Water Supply and on the design of a high-pressure water system and supplementary cisterns for fire protection, as well as the design and installation of the main intercepting sewer for the city. During that time, he also worked privately for the Consulting Engineer to the City Attorney on an appraisal of the properties of the Spring Valley Water Company in connection with a suit for change in water rates.

Unfortunately, in 1911, due to impaired eyesight, Mr. Toll had, practically, to give up his professional activities, although he continued to engage in surveying and building, while devoting most of his time to fruit-growing in Puerto Rico where he had made his home.

Shortly before his death Mr. Toll had returned to the practice of his profession, and had been engaged by the Puerto Rican Emergency Relief Administration as District Engineer for Guayama. While in this position, through exposure to a tropical downpour, he developed pneumonia which caused his death.

Mr. Toll was a man of quiet manners, sedate, amiable, and friendly, and his death was felt by all those who knew him.

In 1912, he was married to Jane Bean, and is survived by his widow and two daughters, Harriet A. Toll and Jane B. Toll.

Mr. Toll was elected a Junior of the American Society of Civil Engineers on March 5, 1907, and an Associate Member on October 29, 1912. He was a prominent member of the Puerto Rican Section of the Society, having been its President during the year prior to his death.

JOSEPH INGHAM FRANCIS, Jun. Am. Soc. C. E.[1]

DIED AUGUST 22, 1934

Joseph Ingham Francis was born at Remsen, N. Y., on September 22, 1905, the son of Mr. and Mrs. George M. Francis. He was graduated from the local High School in 1923, and following some post-graduate work, entered Rensselaer Polytechnic Institute, at Troy, N. Y., choosing the four years' course in Civil Engineering.

After his graduation in 1928, Mr. Francis went with the Utica Gas and Electric Company as a Computer. The spring of 1929 found him a member of the Maintenance Survey Corps of the New York Central Railroad Company, at Weehawken, N. J., where he seemed to find the work he enjoyed most.

---

[1] Memoir prepared by C. E. Chase, Asst. Div. Engr., The N. Y. C. R. R., Weehawken, N. J.

It was a combination of field measurements on tracks and bridges, buildings, and docks, with farm drainage and topographical surveys, from which the data are taken into the office for compilation, design, and maintenance reconstruction.

Although he had not passed his thirtieth year, he was already a man of breadth and of foresight—serious-minded and conscientious to a marked degree. He seemed bent on leaving no stone unturned to acquire the studious habits of thought, observation, and performance which would mould his career into the form of the greatest constructive value to himself and to others.

Industrial upsets of 1930 and the following years threatening to engulf young men before they had started, seemed to make but a small dent in the determination of "Joe" Francis to face the cold facts and come through in spite of them. He reasoned that it was no fault of his, and he pushed on without the spur of the extra financial appreciation which previous generations of young graduates had expected and experienced. He planned ahead and worked for the day when the young man worth while would come into his own, and he did not relax in the effort as did many of his discouraged contemporaries. He never faltered, but carried well the burden of uncertainty. His faithfulness in the performance of the more important duties was matched only by his devotion to the demands of the minor projects.

In his life outside his profession, Joseph Francis had been very active. At every turn he had joined hands with others to help brighten their prospects and pave a smoother way. No wastrel of time or of opportunities to aid, he may well be assumed to have done his level best and succeeded. His memory is held in the highest esteem by those whose lives touched his.

Associates and co-workers testify to the vitality of their colleague, and to the extraordinary alertness of his mind, acquisitive and inquisitive in all the best senses of the words. Untiring energy, a buoyant spirit, and a cheerful smile were his trade symbols, added to a healthy personality and an honest effort to elevate others to his plane of thought—that was Joseph Francis. His early death seemed incompatible with the wholesomeness of his life.

In addition to his parents, he is survived by two sisters, several other near relatives, and a host of friends to mourn his passing.

Mr. Francis was elected a Junior of the American Society of Civil Engineers on October 26, 1931.

FRANCIS ALBERT LANDRIEU, Jun. Am. Soc. C. E.[1]

DIED AUGUST 9, 1935

Francis Albert Landrieu, the son of Victor Firmin and Cerintha C. (Mackey) Landrieu, was born at New Orleans, La., on April 10, 1904. He received his early education in St. Philip School and the Warren Easton High School, at New Orleans, and, in 1925, was graduated from Tulane Univversity, at New Orleans, with the degree of Bachelor of Engineering in Civil Engineering.

---

[1] Memoir prepared by W. T. Hogg, M. Am. Soc. C. E., and A. F. Jacobi, Assoc. M. Am. Soc. C. E.

Mr. Landrieu was employed from June, 1925, to November, 1928, as Draftsman for the Board of Commissioners of the Port of New Orleans. From November, 1928, to September, 1930, he was a Designing Draftsman in the Engineering Service Division of the United States Navy, at its Portsmouth (Va.) Yard, and from September, 1930 to February, 1931, he was again employed by the Board of Commissioners of the Port of New Orleans, as a Structural Designer.

From February, 1931, until his death in August, 1935, he was employed in the offices of the United States Engineers at New Orleans and at La Crosse, Wis. In the First New Orleans District, he served as Assistant Engineer in charge of bridge construction on the Intercoastal Canal from February, 1931, to October, 1933, when he was transferred to the St. Paul, Minn., District, where he was engaged as Assistant Engineer on lock and dam construction at Dam No. 8, on the Mississippi River below La Crosse, Wis. On August 1, 1935, just a few days prior to his death, Mr. Landrieu was promoted to the rank of Associate Engineer. His knowledge of harbor structures, his exceptional ability as a structural designer, and his conscientious devotion to his work, made his career as a structural engineer very promising, and he should have attained a prominent place in his chosen profession, had his life been spared.

He was married in 1926 to Ethel Ann Sinclair, of New Orleans, who was drowned with Mr. Landrieu when the approach span of the bridge across the Mississippi River, at La Crosse, collapsed after the end-post of the truss had been struck by a car in which Mr. and Mrs. Landrieu were passengers. They are survived by a son, Francis Albert, Jr., and a daughter, Charmigne Ann Landrieu.

His disposition and pleasing personality endeared him to all those with whom he came in contact, and his death is sincerely regretted by his many friends and associates.

Mr. Landrieu was elected a Junior of the American Society of Civil Engineers on October 1, 1926.

PHILIP LANAHAN WELKER, Jun. Am. Soc. C. E.[1]

DIED DECEMBER 16, 1935

Philip Lanahan Welker was born in Baltimore, Md., on June 23, 1905, the son of Philip A. and Gertrude (Lanahan) Welker. After his preparatory education, he entered Cornell University, at Ithaca, N. Y., from which he received the degree of Civil Engineer upon his graduation in 1928.

In June, 1929, Mr. Welker was appointed to an engineering position in the office of the District Engineer of the Corps of Engineers, United States

---

[1] Memoir prepared by William Bowie, M. Am. Soc. C. E.

Army, at New Orleans, La. He served with that organization until January, 1930, having been engaged on various classes of field work, notably as an Inspector on the Willow Grove Levee, the Lucy Goldmine Levee, and the Convent Levee, and as Inspector, Instrumentman, and Chief of Party on the Bonnet Carré Spillway, at Sellers, La.

Shortly after resigning from the office of the District Engineer at New Orleans, he became associated with the Sanford and Brooks Company, Engineers and Contractors, of Baltimore, Md., Norfolk, Va., and Charleston, S. C. He was engaged as a Field Engineer on a number of projects, including the Pennington Avenue Bridge, over Curtis Creek, at Baltimore, Canton Railroad Pier No. 11, for the Baltimore Mail Steamship Company, the Nanticoke River Bridge, at Vienna, Md., the plant of the Arundel-Brooks Concrete Corporation, on the Patapsco River, and the construction of the Bohemia River Bridge, in Maryland. In addition to his field work, Mr. Welker spent some time in the office of Sanford and Brooks on designs and estimates. He severed his connection with that firm on January 1, 1933.

From December, 1933, to March, 1934, he served as a Junior Civil Engineer on a Civil Works Administration project at the District of Columbia Penitentiary, at Lorton, Va., being engaged on the design of buildings, plumbing, heating fixtures, etc. In addition, he did the necessary field work, involving the layout and leveling, and also made maps showing the location of sewers, grades, etc.

On May 9, 1934, Mr. Welker became a member of the Division of Geodesy of the United States Coast and Geodetic Survey, and was engaged in making computations of the field observations secured in triangulation, leveling, and geodetic astronomy. For a brief period he served in the field as a Recorder and Observer on a triangulation party operating in the vicinity of the District of Columbia.

Because of his marked proficiency in the various classes of geodetic work involving field observations, mathematical computations, and adjustments of observations, he was one of the two engineers selected by the Director of the Coast and Geodetic Survey to carry on triangulation along the Guatemala-Honduras Boundary. The assignment of these two engineers was requested through the State Department by Sidney H. Birdseye, Chief Engineer on the Guatemala-Honduras Boundary Commission. After a furlough in January, 1935, from the Coast and Geodetic Survey, Mr. Welker proceeded to Guatemala, and reported for duty to Lieut. Joseph P. Lushene, the other engineer of the Coast and Geodetic Survey assigned to the Guatemala-Honduras triangulation.

Lieut. Lushene's report on the field operations carried on in Guatemala rated Mr. Welker very highly in professional ability, leadership, and personal qualities. The field work on the triangulation along this boundary involved the measurement of two base lines and the determination of the astronomical longitude and latitude at each of two of the triangulation stations near the ends of the arc.

Lieut. Lushene returned to the Washington, D. C., Office of the Coast and Geodetic Survey, but Mr. Welker was retained by the Boundary Commission to make all the computations and adjustments involved in the arc of triangulation.

He was engaged on this work until late in the summer of 1935, when a throat infection required treatment at a local hospital. The throat infection apparently subsided, or became less active, and it was believed that he was on the road to speedy recovery. However, within a short time, he had a relapse which so alarmed his wife who was with him and the attending physicians that he was placed aboard a steamer sailing for New Orleans. Upon arrival, he was taken immediately to the Touro Infirmary where he received the very best of medical attention. In spite of all that could be done, he passed away on December 16, 1935. His body was sent to Baltimore, for burial in Greenmount Cemetery.

Mr. Welker's untimely death was a great shock to his many friends and associates who considered him a young engineer of great promise, and who admired him for his many attractive personal qualities and high sense of honor. In spite of his having been engaged in Geodetic Surveying only a comparatively short time, he mastered some of the most intricate phases of it. It is noteworthy that he majored in Geodesy during his course at Cornell University. He failed to secure, upon graduation, an appointment to the field force of the Coast and Geodetic Survey, for which he had applied, because of a defect in his sight which required the use of glasses. Since much of the service of a field engineer of the Coast and Geodetic Survey must be given aboard surveying ships, practically perfect eyesight is required on the part of those receiving appointments.

Mr. Welker was a member of the Society of American Military Engineers and the Engineers Club of Baltimore.

He was married to Flora Mary, of New Orleans, in December, 1929, who survives him. He is also survived by his mother, Mrs. Gertrude Lanahan Welker.

Mr. Welker was elected a Junior of the American Society of Civil Engineers on May 12, 1930.

CHARLES GUY ELDREDGE, Affiliate, Am. Soc. C. E.[1]

Died November 9, 1933

Charles Guy Eldredge was born in Sabula, Iowa, on January 10, 1886, the son of Charles Guy Eldredge and Mary Elizabeth Eldredge. He was graduated from Cornell College, at Mt. Vernon, Iowa, in 1908, where he had specialized in inorganic research and water purification.

He began his professional career as Emergency Chemist with the Clinton Sugar Refining Company, of Clinton, Iowa, under Dr. A. P. Bryant, Chief Chemist. In 1909 and 1910, Mr. Eldredge served as Chemist of the Alturas

---

[1] Memoir prepared by John B. Hawley, M. Am. Soc. C. E.

Gold Mining Company, at Oakland, Calif., and in 1910 and 1911, he was Chemist in Charge of the Water Purification Plant, at South Pittsburgh, Pa. As Chemist in Charge of the Water Purification Plant, he served the City of Fort Worth, Tex., from 1912 to November, 1913. From November, 1913, to April 15, 1914, he was in the Canal Zone in charge of the Purification Plants for the Isthmian Canal Commission.

Returning to Fort Worth Mr. Eldredge again took up the duty of Chemist in Charge of the Water Purification Plant there, until 1918. During the World War, from January, 1918, to May, 1919, as First Lieutenant, Sanitary Corps, U. S. Army, he was in charge of several water purification plants of the American Expeditionary Force, at Base Section No. 1, in Western France. After his discharge from the Army he returned again to Fort Worth, where from November, 1919, to June, 1921, he served as Chief Chemist of the Chemical Department of Terrell's Laboratories. Mr. Eldredge then moved to Vacaville, Calif., where from 1921 to 1931 he devoted himself to horticulture and to chemical work for various public works concerns, and municipal plants.

Guy Eldredge, a modest, retiring, taciturn man, a true scientist, skilled to near perfection in the details of his chosen vocation, was respected by all who knew him, and warmly beloved by all his associates and intimates.

A pertinent anecdote will not be amiss: Sometime in the summer of 1918, after much correspondence and lavish cutting of "red tape", as to the "loan" of Scientist Guy Eldredge to the writer's "Section" (in order that he might take charge of the various filtration and sewage disposal plants in Brittany, or "Base Section Number One"), this writer and the famous war correspondent, Peter Clark MacFarlane, returning together from an inspection trip on water and sewer works in the "Section", were walking up the principal thoroughfare of St. Nazaire, when the writer incontinently left "Mac" and started on a keen, undignified (for a Field Officer) run, toward a tall, square-shouldered silhouette that appeared under a street light. When MacFarlane caught up, he found the writer tightly hugging the subject of this memoir. The distinguished correspondent, Lieutenant Eldredge, and the Field Officer in charge of Water Supply and Sewerage then dined together (and "Mac" got fond of Eldredge during the meal). "Mac" went to his hotel, and the Field Officer took Lieutenant Eldredge to his own camp quarters, not merely for the night, but "for the duration of the war", as Army parlance has it.

The intimate contact during that war period, cumulative of several years theretofore, fortifies the writer in paying this posthumous tribute to a good citizen, a devoted husband and kind father, a splendid scientist, an efficient operator of all public works entrusted to his care, and an Army officer without blemish on his record.

On April 19, 1914, Mr. Eldredge was married to Esther Sharpe, of Vacaville, Calif. The result of their ideal union is three children: Angie Beth, Charles, and Doris, who, with his widow, survive him.

Mr. Eldredge was elected an Affiliate of the American Society of Civil Engineers on June 3, 1915.

SAMUEL MAGEE GREEN, F. Am. Soc. C. E.[1]

DIED APRIL 25, 1936

Samuel Magee Green was born in Philadelphia, Pa., on August 9, 1851, the son of John and Mary (Pugh) Green. He received his education at Stephen Girard Institute (later, Girard College) at Philadelphia, having been a member of the Class of 1866.

In 1866 when he was 15 years of age, Mr. Green went to Milwaukee, Wis., where, in 1870, he became Manager of the railway equipment firm of Pierce and Whaling.

In 1872, Mr. Green entered the railroad contracting business with the late Stephen A. Harrison F. Am. Soc. C. E., under the firm name of Harrison and Green, with an office in Milwaukee. This firm constructed a large part of the lines of the Wisconsin Central, Northwestern, and "Soo" Railroads in Wisconsin and Minnesota. The firm also built and owned the first horse-car street railway in Milwaukee.

Mr. Green became greatly interested in gold, silver, and copper mining in the late Eighties and early Nineties, and with Mr. Otto Mears built and owned the Durango and Leadville Railroad, in Colorado. They also constructed the original Durango Smelters, at Durango, Colo., now owned by the American Smelting and Refining Company.

During this period, and until 1900, Mr. Green was actively engaged in the real estate business in Milwaukee. He was also interested in a Foundry and Furnace Company in that city.

In 1901, he again entered the railroad contracting business and built the Herrs Island Stock Yards, at Pittsburgh, Pa., for the joint use of the Pennsylvania Railroad Company and the Pittsburgh Provision and Packing Company. From 1904 to 1908, he constructed the extension of the Monongahela Railroad from Ache Junction to Brownsville, Pa., and jointly with the Crossan Construction Company, the extension of the same railroad from Brownsville to Rices Landing, Pa.

Immediately after the completion of this work, Mr. Green became a member of the firm of Green and Read. This firm constructed a street railway line for the Irwin Traction Company, at Irwin, Pa.

During 1908 and 1909, Mr. Green constructed a part of the Long Island Railroad, from Jamaica to Far Rockaway, Long Island, N. Y., and in 1910 and 1911, he built an extension of the Chicago, Milwaukee, and St. Paul Railroad, at Dedham, Iowa. This latter line was the last railroad contracting work that he undertook.

From 1911 until his retirement from active work in 1921, Mr. Green was engaged in the real estate business in Milwaukee.

He was married on April 25, 1872, to Harriet L. Harrison, of Milwaukee, and is survived by his widow and three sons, Harrison S., Gardiner D., and

---

[1] Memoir prepared by Raymond W. Green, Esq., Oconomowoc, Wis.

Raymond W., and two daughters, M. Emma, and Bessie L. Green. He died on their sixty-fourth wedding anniversary.

He was well known in Milwaukee and was one of three surviving life members of the Milwaukee Elks Club. He was a former Commodore of the Oconomowoc (Wis.) Yacht Club.

Mr. Green was elected a Fellow of the American Society of Civil Engineers on September 5, 1888.

HENRY CODDINGTON MEYER, F. Am. Soc. C. E.[1]

Died March 27, 1935

Major Henry Coddington Meyer, Civil War Veteran, Editor, and Pioneer in Sanitary Engineering, died at his home in Montclair, N. J., on March 27, 1935, after a short illness. He was 91 years old.

Henry Coddington Meyer, the son of Meyer Henry and Anne Maria (Price) Meyer, American citizens temporarily residing in Europe, was born in Hamburg, Germany, on April 14, 1844. His maternal grandfather, Eliphilet Price, was a Presbyterian clergyman who held a pastorate at Wappingers Falls, N. Y., while his father, a native of Denmark, was a merchant in New York City. He received his training in private schools at Montclair, N. J., and at Tarrytown and Yonkers, N. Y., and then entered the office of his uncle, T. B. Coddington, a manufacturer of New York City.

At the outbreak of the Civil War his parents would not allow him to enlist and he could not do so until he became eighteen years of age. In 1862, he enlisted in the Second New York Cavalry, known as the Harris Light, and served through most of the Civil War, emerging with the rank of Major and a wound from which he never entirely recovered.

During the war he served with his regiment through Pope's Campaign until after the Battle of Fredericksburg and, in 1863, received a saber wound at Brandy Station. In February, 1864, he was commissioned a Second Lieutenant in the Twenty-fourth New York Cavalry, and, later, was made a Captain, in the Wilderness Campaign. He saw service in the Battles of the Wilderness, Fredericksburg, Gettysburg, Spottsylvania, North Anna River, Cold Harbor, and the first assault on the works of Petersburg, Va., on June 17. It was during this engagement that he was badly wounded. After an assault on the enemy's works in which the Union forces were repulsed, it was reported to Captain Meyer that an officer of his Company had been shot. Captain Meyer went back over the battle-field in which corn had grown to the height of about a foot, to render assistance. He found the man desperately wounded and lying face down in the dirt. He turned him over, brushed the dirt from his mouth and nose, propped up his body on a corn hill, and left him. Captain Meyer was unable to carry the officer as he had been suffering from intermittent fever and was too weak to do so. As he was about to leave him and return to the Union breastworks, he was shot in the back, the bullet passing through his saber belt and up through his body to his shoulders. Captain Meyer crawled back to the Union lines under fire from the enemy. On reaching the breastworks, he was too weak to crawl over them and called out for help. Two soldiers jumped to the top of the breastworks, grabbed Captain Meyer by the arms and hauled him to a place of safety. As a result of his wound he spent eleven months in a hospital, and did not recover until some time after the war was over. Shortly after he was wounded Captain Meyer was brevetted Major and was subsequently discharged for disability.

---

[1] Memoir prepared by Henry C. Meyer, Jr., New York, N. Y.

For this deed, Major Meyer was awarded the Congressional Medal of Honor for "distinguished gallantry in action," the citation reading: "During an assault on the enemy's works, this officer rendered heroic assistance to a helpless brother officer in the face of a heavy fire, thereby saving his life, and in the performance of this gallant act sustained a severe wound."

After his recovery, Major Meyer returned to the office of his uncle, in New York City, then a leader in the New York Shot and Lead Company, manufacturers of shot and lead pipe. In 1868, he founded the Henry C. Meyer Company to deal in plumbing, and gas and steam fixtures, which later became the Meyer-Sniffen Company. In 1883, he gave up active connection with the concern, maintaining, however, his stock holdings and a position on the Directorate.

In 1877, Major Meyer and other members of his household suffered an attack of diphtheria. He subsequently traced the disease to the plumbing in his house, which had no vents for the escape of sewer gases. Becoming interested in the problem he devised a system of plumbing to remedy the defect. The next year, 1878, he founded *The Sanitary Engineer* which later became the *Engineering Record.* This was an authoritative publication in its field, and was designed specifically for the discussion of just such improvements for greater public health and comfort. One of its first projects was a competition for architects, in which plans for improving the type of tenement structures on the standard 25 by 100-ft lots were submitted. This contest led to a degree of public interest in the subject which resulted in the Tenement Act of 1879, a considerable improvement over the preceding regulations. This Act by the New York State Legislature restricted the area of the standard lot to be occupied by a building to 65% of the lot, instead of 90%, previously permitted. Major Meyer still stressed his first interest, that of improving plumbing and embodying these improvements in a series of regulations which would make them mandatory. His interest in this subject led to the Plumbing Laws of 1881, which, effective in New York State, were the first of the kind in the United States, and still serve as the basic structure on which such laws are drawn.

Major Meyer then turned to another important question of his day, the heating of railway cars by steam pipes from the locomotive. The railroad companies opposed him with the claim that it was impossible or impractical; he demonstrated that it could be done. In those days, railway cars were constructed of wood, and were heated by stoves. Some railway operators allowed their roads to deteriorate to the point where wrecks were frequent and disastrous. The wooden cars often were set on fire by overturned stoves, and the passengers died in the flames. Again, as in the instance of plumbing, New York State led the nation in legislation forbidding the use of stoves in cars, and Major Meyer was one of its principal advocates.

In 1884, Major Meyer published a book called "Water Waste Prevention." This work, and constant discussion of the necessity for water conservation, did much to minimize the prejudices met by water-works authorities along lines of eliminating waste.

The *Engineering Record* was under Major Meyer's supervisory Editorship for twenty-five years until, in 1903, it was sold to Mr. James H. McGraw. As the *Engineering News-Record,* it is still published by the McGraw-Hill Company.

Within a few years of his return from the Civil War, Major Meyer was married to Charlotte English Seaman. Mrs. Meyer died in 1915, and some time later, Major Meyer married her cousin, Mrs. Gertrude Seaman Merrill, Mrs. Meyer and two sons, Henry Coddington Meyer, Jr., and Francis Thurber Meyer, survive him.

He was a member of the Century and Union League Clubs, of New York City, and the Military Order of the Loyal Legion.

Major Meyer was elected a Fellow of the American Society of Civil Engineers on October 22, 1885.

"Analysis of Multiple Arches." Alexander Hrennikoff. 388. Discussion: L. E. Grinter, N. M. Newmark, T. Y. Lin, A. H. Finlay, A. W. Fischer, and A. A. Eremin. 406.

"Weights of Metal in Steel Trusses." J. A. L. Waddell. 1. Discussion: Arthur M. Shaw, Joseph G. Shryock, Albert F. Reichmann, Robert W. Abbett, George C. Diehl, F. G. Jonah, Clarence D. Foight, A. H. Fuller, William E. Wilbur, W. N. Downey, J. R. Grant, Theron M. Ripley, T. Kennard Thomson, H. H. Allen, and John Venable Hanna. 12.

CANALS.

"Proposed Improvement of the Cape Cod Canal." E. C. Harwood. 1440. Discussion: C. S. Jarvis, and George R. Rich. 1476.

CEMENT.

"Stabilizing Constructed Masonry Dams by Means of Cement Injections." D. W. Cole. (With Discussion.) 714.

COLUMNS.

"Rational Design of Steel Columns." D. H. Young. 422. Discussion: William R. Osgood, Alfred S. Niles, J. F. Baker, K. L. DeBlois, Marvin A. Gray, R. G. Sturm and Marshall Holt, F. E. Turneaure, N. J. Durant, E. C. Hartmann, Edward Godfrey, and L. T. Wyly. 452.

CONTRACTORS' PLANT.

"Stabilizing Constructed Masonry Dams by Means of Cement Injections." D. W. Cole. (With Discussion.) 714.

CORROSION AND PROTECTION OF METALS

"Frictional Resistance in Artificially Roughened Pipes." Victor L. Streeter. (With Discussion.) 681.

"Underground Corrosion." K. H. Logan. 811. Discussion: Thomas F. Wolfe, John R. Baylis, E. P. Fetherstonhaugh, John F. Skinner, and F. N. Speller. 826.

COSTS OF WORK.

Cost estimates of improving Cape Cod Canal. 1454.

Cost of Springwells Filtration Plant, Detroit, Mich. 379.

Costs of stabilizing constructed masonry dams. 719.

DAMS.

"Analysis of Thick Arch Dams, Including Abutment Yield." Philip Cravitz. 501. Discussion: I. M. Nelidov, and A. Floris. 514.

Building check dams in California. 1347.

"Photo-Elastic Determination of Shrinkage Stresses." Howard G. Smits. (With Discussion.) 927.

"Stabilizing Constructed Masonry Dams by Means of Cement Injections." D. W. Cole. 714. Discussion: Oren Reed, F. F. Fergusson, Joseph Wright, Charles W. Comstock, V. L. Minear, and James B. Hays. 752.

"The Stress Function and Photo-Elasticity Applied to Dams." John H. A. Brahtz. 1240. Discussion: I. K. Silverman, Fred L. Plummer, Arshag G. Solakian, Lars R. Jorgensen, Elmer O. Bergman, and D. P. Krynine. 1278.

DRAINAGE.

"Flood and Erosion Control Problems and Their Solution." E. Courtlandt Eaton. (With Discussion.) 1302.

"Relation Between Rainfall and Run-Off from Small Urban Areas." W. W. Horner and F. L. Flynt. (With Discussion.) 140.

EARTH PRESSURES.

"Distribution of Stresses Under a Foundation." A. E. Cummings. (With Discussion.) 1072.

ECONOMICS.

"Weights of Metal in Steel Trusses." J. A. L. Waddell. (With Discussion.) 1.

ELECTRIC POWER PLANTS.

See **POWER PLANTS.**

ENGINEERS AND ENGINEERING.

"The Engineer and His Code": Address at the Annual Convention, Portland, Oregon, July 15, 1936. Daniel W. Mead. 1483.

EROSION.

"Flood and Erosion Control Problems and Their Solution." E. Courtlandt Eaton. (With Discussion.) 1302.

ETHICS.

"The Engineer and His Code": Address at the Annual Convention, Portland, Oregon, July 15, 1936. Daniel W. Mead. 1483.

EXCAVATION.

Excavation methods used in improving Cape Cod Canal. 1461.

FILTRATION.

"The Springwells Filtration Plant, Detroit, Michigan." Eugene A. Hardin. 344. Discussion: F. H. Stephenson, and Robert Spurr Weston. 383.

FLOODS.

"Flood and Erosion Control Problems and Their Solution." E. Courtlandt Eaton. 1302. Discussion: Arthur G. Pickett, R. W. Davenport, C. S. Jarvis, Harry F. Blaney, W. P. Rowe, J. B. Lippincott, E. I. Kotok and C. J. Kraebel, and Donald M. Baker 1331.

"Flood-Stage Records of the River Nile." C. S. Jarvis. 1012. Discussion: Halbert P. Gillette, R. W. Davenport, H. E. Hurst, Thomas H. Means, J. W. Beardsley, J. C. Stevens, Jesse W. Shuman, and Kamel Osman Ghaleb. 1031.

FLUMES.

"Adaptation of Venturi Flumes to Flow Measurements in Conduits." Harold K. Palmer and Fred D. Bowlus. 1195. Discussion: N. F. Hopkins, Hunter Rouse, F. V. A. E. Engel, J. S. Stevens, and Filippo Arredi. 1217.

FOUNDATIONS.

"Analysis of Thick Arch Dams, Including Abutment Yield." Philip Cravitz. (With Discussion.) 501.

"Distribution of Stresses Under a Foundation." A. E. Cummings. 1072. Discussion: Clement C. Williams, D. P. Krynine, L. C. Wilcoxen, Marshall G. Findley, M. A. Biot, Jacob Feld, George Paaswell, G. S. Salter, W. S. Housel, N. M. Newmark, A. A. Eremin, and A. Casagrande. 1084.

"The Stress Function and Photo-Elasticity Applied to Dams." John H. A. Brahtz. (With Discussion.) 1240.

FRICTION.

"Frictional Resistance in Artificially Roughened Pipes." Victor L. Streeter. (With Discussion.) 681.

GEOLOGY.

"The Silt Problem." J. C. Stevens. (With Discussion.) 207.

GRAPHICAL CHARTS.

"Analysis of Thick Arch Dams, Including Abutment Yield." Philip Cravitz. (With Discussion.) 501.

GROUTING.

"Stabilizing Constructed Masonry Dams by Means of Cement Injections." D. W. Cole. (With Discussion.) 714.

HYDRAULIC JUMP.

"The Hydraulic Jump in Terms of Dynamic Similarity." Boris A. Bakhmeteff and Arthur E. Matzke. 630. Discussion: Hunter Rouse, Sherman M. Woodward, Robert E. Kennedy, L. Standish Hall, Morrough P. O'Brien, F. V. A. E. Engel, Baldwin M. Woods, J. C. Stevens, Nolan Page, Andrei I. Ivanchenko, F. T. Mavis and Andreas Luksch, and I. M. Nelidov. 630.

HYDRAULIC LABORATORIES.

"Hydraulic Laboratory Results and Their Verification in Nature." Herbert D. Vogel. 597. Discussion: W. F. Heavey, Chilton A. Wright, Paul S. Reinecke, Morrough P. O'Brien, John A. Jameson, Jr., J. C. Stevens, Paul W. Thompson, and Samuel Shulits. 614.

HYDRAULICS.

AUTHOR INDEX

ABBETT, ROBERT W.
Weights of metal in steel trusses. 14.

ALFORD, WILLIAM VALORUS.
Memoir of. 1511.

ALISON, THOMAS HENRY.
Memoir of. 1513.

ALLEN, CHARLES KYES.
Memoir of. 1515.

ALLEN, H. H.
Weights of metal in steel trusses. 27.

ALLEN, JAMES PIERSON.
Memoir of. 1517.

ARMITAGE, GEORGE WASHINGTON.
Memoir of. 1675.

ARREDI, FILIPPO.
Venturi flumes and flow measurements. 1231.

ASHWORTH, FRANK KARR.
Memoir of. 1676.

ATTERBURY, WILLIAM WALLACE.
Memoir of. 1518.

ATWATER, ALMON BYRON.
Memoir of. 1524.

BAKER, DONALD M.
Flood and erosion control problems. 1356.

BAKER, J. F.
Elastic properties of riveted connections. 569.
Rational design of steel columns. 455.

BAKHMETEFF, BORIS A.
"The Hydraulic Jump in Terms of Dynamic Similarity." 630.

BASSETT, HERBERT HOWARD.
Memoir of. 1526.

BAYLIS, JOHN R.
Underground corrosion. 828.

BEARDSLEY, J. W.
Flood-stage records of the River Nile. 1045.

BEATTY, JOHN M.
The shear-area method. 988.

BERGMAN, ELMER O.
Stress functions and photo-elasticity and dams. 1287.

BERNARD, MERRILL M.
Rainfall and run-off from urban areas. 186.

BEYER, ALBIN H.
The shear-area method. 984.

BIOT, M. A.
Distribution of stresses under a foundation. 1097.

BIRKELAND, H. W.
The shear-area method. 995.

BISSCHOP, PHILIP R. R.
The silt problem. 271.

BLACK, ROGER DERBY.
Memoir of. 1528.

BLANEY, HARRY F.
Flood and erosion control problems. 1337.
The silt problem. 265.

BONNER, FRANK E.
The silt problem. 261.

BOWLUS, FRED D.
"Adaptation of Venturi Flumes to Flow Measurements in Conduits." 1195.

BRADLEY, J. N.
Tunnel and penstock tests. 1428.

BRAHTZ, J. H. A.

Photo-elastic determination of stresses. 936.

"The Stress Function and Photo-Elasticity Applied to Dams." 1240.

BRINKER, RUSSELL C.

Relation of analysis to structural design. 1380.

BROWN, THERON McCABE.

Memoir of. 1678

BURCH, ALBERT NELSON.

Memoir of. 1532.

BUTLER, GEORGE.

Memoir of. 1680.

CARPENTER, SAMUEL T.

The shear-area method. 966.

CARUTHERS, WILLIAM STODDERT.

Memoir of. 1533.

CASAGRANDE, A.

Distribution of stresses under a foundation. 1119.

CHILDS, JAMES ALANSON.

Memoir of. 1535.

CHURCH, EARL F.

Adjustment of a level net. 853.

CLARKE, ERNEST WILDER.

Memoir of. 1537.

COLE, D. W.

"Stabilizing Constructed Masonry Dams by Means of Cement Injections." 714.

COLEMAN, LEVI OSCAR.

Memoir of. 1681.

COMPTON, HORACE B.

"The Shear-Area Method." 945.

COMPTON, RUEL KEITH.

Memoir of. 1538.

COMSTOCK, CHARLES W.
Stabilizing constructed masonry dams. 756.

CONNELL, HENRY LEO.
Memoir of. 1684.

CORNELIUS, ERNEST HARRY.
Memoir of. 1686.

COWLES, ROBERT FULTON.
Memoir of. 1540.

CRANE, FRANCIS ELIHU.
Memoir of. 1542.

CRAVITZ, PHILIP.
"Analysis of Thick Arch Dams, Including Abutment Yield." 501.

CROSBY, W. W.
Bituminous paving compositions. 1155.

CROSS, HARDY.
"The Relation of Analysis to Structural Design." 1363.

CUMMINGS, A. E.
"Distribution of Stresses Under a Foundation." 1072.

CUSHING, JOHN FRANCIS.
Memoir of. 1543.

DAVENPORT, R. W.
Flood and erosion control problems. 1333.
Flood-stage records of the River Nile. 1033.

DAVIS, ROBERT BENJAMIN.
Memoir of. 1546.

De BLOIS, K. L.
Rational design of steel columns. 460.

DELL, GEORGE H.
"The Adjustment of a Level Net." 834.

DIEHL, GEORGE C.
Weights of metal in steel trusses. 15.

DOHRENWEND, CLAYTON O.
"The Shear-Area Method." 945.

DONHAM, BENJAMIN CURTIS.
Memoir of. 1551.

DOWNEY, W. N.
Weights of metal in steel trusses. 21.

DRUMMOND, GARRETT B.
Analysis of continuous structures. 115.
The shear-area method. 1001.

DURANT, N. J.
Rational design of steel columns. 473.

EATON, E. COURTLANDT.
"Flood and Erosion Control Problems and Their Solution." 1302.

EHASZ, F. L.
Structural beams in torsion. 918.

ELDREDGE, CHARLES GUY.
Memoir of. 1716.

ELLIOTT, GEORGE ALEXANDER MILLER.
Memoir of. 1553.

ENGEL, F. V. A. E.
The hydraulic jump in terms of dynamic similarity. 657.
